1895 MODEL OF CALDERWOOD ARCH DAM.
By A. V. Karpov and R. L. Templin 185

Discussion:
By A. W. Simonds 220
Lars R. Jorgensen 224
A. C. Janni 227
P. Wilhelm Werner 231
Eldred D. Smith 235
Elmer O. Bergman 240
E. Probst 244
A. V. Karpov and R. L. Templin 247

1896 FORMATION OF FLOC BY FERRIC COAGULENTS.
By Edward Bartow, A. P. Black, and Walter E. Sansbury 263

Discussion:
By Edward S. Hopkins 277
W. D. Hatfield 278
L. B. Miller 279
Linn H. Enslow 279
C. J. Brockman 282

1897 MODIFYING THE PHYSIOGRAPHICAL BALANCE BY CONSERVATION METHODS.
By A. L. Sonderegger 284

Discussion:
By H. H. Chapman 305
E. B. Debler 306
Frank E. Bonner 307
C. S. Jarvis 315
W. P. Rowe 317
J. C. Stevens 324
Gerard H. Matthes 326
J. B. Lippincott 328
Rhodes E. Rule 335
A. L. Sonderegger 337

1898 AN APPROACH TO DETERMINATE STREAM FLOW.
By Merrill M. Bernard 347

Discussion:
By C. S. Jarvis 363
LeRoy K. Sherman 365
W. W. Horner 368
C. H. Eiffert 370
Charles S. Bennett 371
R. L. Gregory and C. E. Arnold 372
Gordon R. Williams 383
W. G. Hoyt, L. L. Harrold, and F. F. Snyder 384
Merrill M. Bernard 389

1899 DISCHARGE FORMULA AND TABLES FOR SHARP-CRESTED SUPPRESSED WEIRS.
By C. G. Cline, Esq 396

Discussion:
By Jasper O. Draffin 414
W. Bruce McMillan 415
C. G. Cline 422

No. Page

1900 LABORATORY TESTS OF MULTIPLE-SPAN REINFORCED CONCRETE ARCH BRIDGES.

By **Wilbur M. Wilson** 424

Discussion :

By C. B. McCullough 455

Carroll L. Mann, Jr 461

M. Hirschthal 465

Wilbur M. Wilson 467

1901 RENEWAL OF MITER-GATE BEARINGS, PANAMA CANAL.

By **Clinton Morse** 471

Discussion :

By E. S. Randolph 496

Clinton Morse 496

1902 WATER-POWER DEVELOPMENT OF THE ST. LAWRENCE RIVER.

By **Daniel W. Mead** 498

Discussion :

By T. H. Hogg 517

Theron M. Ripley 529

W. S. Lee 531

Frank E. Bonner 532

Rufus W. Putnam 539

James W. Rickey 540

Walter M. Smith 541

J. W. Beardsley 545

L. F. Harza 547

Adolph J. Ackerman 551

Daniel W. Mead 552

1903 LOSS OF HEAD IN ACTIVATED SLUDGE AERATION CHANNELS.

By **Darwin Wadsworth Townsend** 558

Discussion :

By H. L. Thackwell 567

Henry R. King 573

M. H. Klegerman 575

Darwin Wadsworth Townsend 578

1904 WILLIOT EQUATIONS FOR STATICALLY INDETERMINATE STRUCTURES IN COMBINATION WITH MOMENT EQUATIONS IN TERMS OF ANGULAR DISPLACEMENTS.

By **Charles A. Ellis** 580

Discussion :

By Ralph A. Tudor 599

Leon S. Moisseiff 601

A. A. Eremin 604

Charles A. Ellis 605

1905 RAINFALL STUDIES FOR NEW YORK, N. Y.

By **S. D. Bleich** 609

SOME SOIL PRESSURE TESTS

By H. de B. Parsons[1], M. Am. Soc. C. E.

With Discussion by Messrs. J. C. Meem, Eugene E. Halmos, L. C. Wilcoxen, O. K. Froehlich, H. L. Thackwell, Jacob Feld, T. Farrance Davey, D. P. Krynine, Charles Terzaghi, R. L. Vaughn, M. Hirschthal, and H. de B. Parsons.

Synopsis

This research is a sequel to a previous paper entitled "Hydrostatic Uplift in Pervious Soils".[2] Measurements were made of the horizontal pressures on a stationary bulkhead, resulting from bank sand and bank gravel. The fills were 7 ft deep, and alternately dry, fully saturated with water, and drained. The results indicated that the horizontal pressures for a pervious soil are more dependent on the angle of internal friction than on the angle of repose. At the beginning of irrigation, the pressures became less until the hydraulic pressure, due to the rising water, began to increase more than the relatively diminishing pressures from the soil.

General

This research was made to verify the horizontal pressure due to a fill completely saturated with water. Such conditions may occur behind retaining walls and dams. Writers of textbooks have assumed that the horizontal pressure equalled the hydraulic pressure plus the soil pressure when using the weight of soil in water and not in air. These tests on sand and fine gravel indicated that the value of ϕ should be that of the angle of internal friction and not the angle of repose. The tests also developed a novel and interesting phenomenon, namely, at the beginning of irrigation the horizontal pressures (due to the fill and to the water near the bottom) first

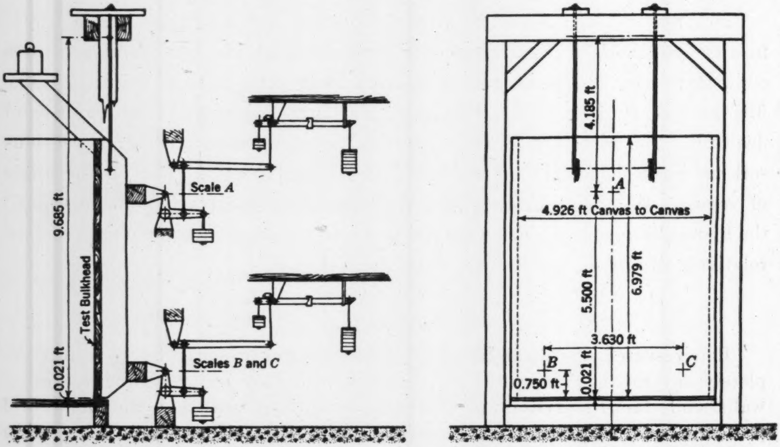
[2] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1317.

decreased and then began to increase as the hydraulic pressure from the rising water increased. This change of pressure will be mentioned more fully later.

The testing apparatus used in this investigation is described in detail at the end of this paper. The front end of the testing apparatus was closed by a suspended bulkhead, sealed at the edges with painted canvas (see Fig. 1). This bulkhead was supported by steel rods and links, and was carefully balanced to hang vertically after the scales were attached. When in position, the lower edge was $\frac{1}{4}$ in. above the floor of the apparatus. The area exposed to the fill was 4.926 ft wide by 6.979 ft high. Three scales, *A, B,* and *C,* of the lever and movable-weight type, with knife-edges and ball-bearings, were attached to its outside face. Each scale could weigh 3 000 lb, or a total of 9 000 lb for the set. The scales were located so that each might take practically the same loading when the apparatus was full. The end levers had a freedom of movement at their tips of $\frac{1}{2}$ in, and the measuring leverage was 125 to 1. In consequence, movement of the bulkhead was restricted to 0.004 in. Therefore, the bulkhead can be considered as stationary at all loadings.

Fig. 1 illustrates the face of the bulkhead exposed to the pressure of the fill, and also gives a side view with the scales attached. The crosses on the face (Points *A, B,* and *C,* Fig. 1 (*b*)) mark the centers of the scale attachments. The dimensions are in feet, as determined from the finished bulkhead. The canvas, sealing the edges, is not shown, but will be described later. The sum of the three scale readings gave the horizontal pressure, and the center of the resultant pressure was determined from the individual scale readings. The calculations, by moments and levers, to find the centers of pressure were



(*a*) SECTION AT TEST BULKHEAD SHOWING SCALE ARRANGEMENT

(*b*) VIEW OF TEST BULKHEAD SHOWING LOCATION OF SCALES

FIG. 1.—TESTING BULKHEAD, SHOWING SECTION AND FACE

made always from the links, while the distances from the centers to the bottom of the bulkhead were found by subtraction.

The apparatus was standardized by filling it with water. A series of tests were made with water at various depths on the bulkhead, and the calculated results at each depth (Column (1)) are given in Column (3) and the averaged results by the scales in Column (5), of Table 1. The theoretical hydraulic pressures, using weight of water at 62.22 lb, on the area of bulkhead found by multiplying the actual depth by a width of 4.926 ft, were approximately 5.1% greater than the sums of the scale pressures, Column (5); that is, 5.1% of the water pressure was required to overcome the stiffness of the bulkhead and the influence of the canvas sealing its edges. It was also found that the actual location of the center of pressure fell somewhat below the theoretical, indicating a reduction in the head acting on the bulkhead. To compensate for the reduced pressure and to harmonize the discrepancy in the location of the center of pressure, it was assumed that the water acted on an "effective" area 5.1% less than its total area exposed to the water. As both the width and height had to be diminished, this assumption results in a slight error which, however, was thought permissible.

By inspection, the effective areas had an approximate width of 4.75 ft, and effective depths of 0.073 ft less than the actual ones. These reductions in dimensions would not have remained constant for shallower depths of water, but that is immaterial as only the actual depth (6.979 ft), was used in the soil tests.

TABLE 1.—STANDARDIZING TESTS; WATER PRESSURES—CALCULATED AND BY SCALES

HEAD OF WATER ON BULKHEAD, IN FEET		Theoretical water pressure, in pounds	PRESSURE ON BULKHEAD, IN POUNDS		CENTER OF RESULTANT PRESSURE ABOVE BOTTOM OF BULKHEAD, IN FEET	
Actual (1)	Effective (2)	(3)	Reduced from theoretical (4)	Average by scales (5)	Calculated (6)	Average by scales (7)
3.979	3.906	2 390	2 268	2 272	1.302	1.321
4.979	4.906	3 784	3 590	3 575	1.635	1.656
5.979	5.906	5 469	5 190	5 155	1.968	1.978
6.979	6.906	7 460	7 079	7 080	2.302	2.300

In Table 1, the effective heads of water, given in Column (2), were determined by deducting 0.073 ft from the actual head in Column (1). The figures in Column (4) represent the water pressures on the effective areas, while those in Column (5) were obtained from the averaged scale readings. The figures in Column (6) are one-third of those in Column (2), while the figures in Column (7) are the averaged results of calculating the centers of resultant pressures from the scale readings. A comparison of the figures in Column (4) with those in Column (5) and, also, of the figures in Column (6) with those in Column (7), show the agreement between the working of the scales and the calculations based on the effective area of the bulkhead.

To get the true pressure of the fill in any test, the sum of the pressures as recorded by the scales should be increased in the ratio of 100 to 94.9. This "corrected pressure" should be divided by 4.926 ft, the width of the bulkhead from canvas to canvas, to get the "corrected pressure" per foot width, as mentioned later.

The horizontal pressures recorded are for dry, saturated, and drained fills, and all had a depth of 7 ft, which, with the $\frac{1}{4}$-in. clearance under the bulkhead, made the 6.979-ft depth on the bulkhead. While the scales recorded the pressures due to the dry and drained (wet) fills, those for the saturated fills were the sum of the full hydrostatic pressure plus the pressure due to the irrigated soil.[2] The recorded pressures do not include frost action, as freezing creates another set of conditions and likewise of pressure.

Many of the calculations were made with the slide-rule. When made numerically, long decimals were shortened. Soil tests, such as those described in this paper, will not repeat with strict accuracy, and only a close approximation was essential.

MATERIALS TESTED

The soils tested were bank sand and bank gravel. Three samples of each were passed through a set of Tyler sieves, and Fig. 2 shows the mechanical analyses in graphic form. It will be noted that the bank gravel contained a

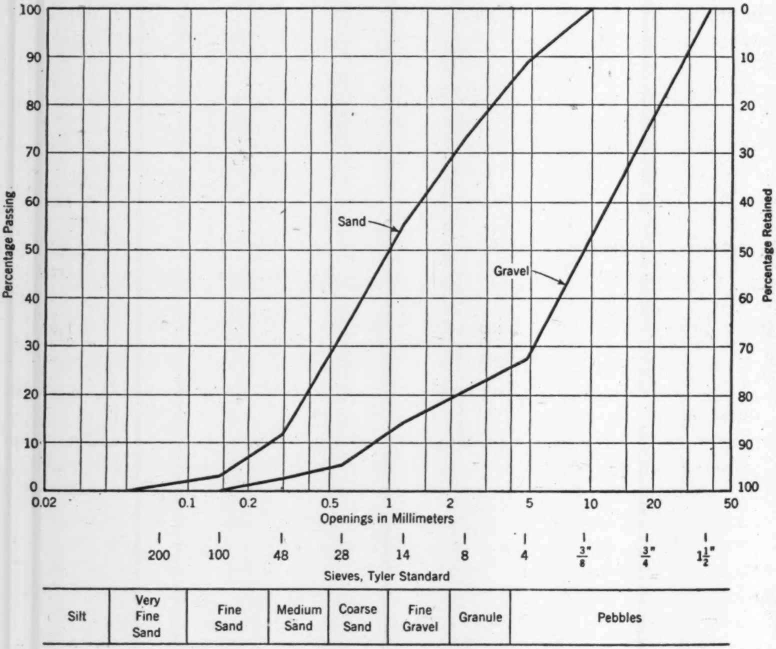


FIG. 2.—MECHANICAL ANALYSES

considerable proportion of small particles. Samples were taken of the bank sand as received, and its loss of weight (moisture) was determined by drying at 5.45 per cent. With the gravel, the loss was about 5.5 per cent. All the tests herein recorded as "dry" really contained these percentages of moisture.

Careful tests were made to find the weights and other characteristics of the sand and gravel, which are given in Table 2.

The samples were "rodded" according to the rules of the American Society for Testing Materials, Specifications C–29–27. The samples were rammed by a 20-lb bar, dropped 6 in. The bottom of the bar had an area of 6 sq in., in order to conform with the "rammed" material in the pressure tests, in which the material was placed in 1-ft layers and compacted with a 50-lb tamp with a fall of 6 in., each layer being rammed twice. The tamp was always used with the flat of the base parallel to the slope; that is, the handle was at a right angle to the surface of the slope.

TABLE 2.—General Data for Materials Tested

Description	Sand	Gravel
Weight of loose material, in pounds per cubic foot	101.5	115
Weight of rodded material, in pounds per cubic foot	111	122
Weight of rammed material, in pounds per cubic foot	112.5	122
Weight in water, in pounds per cubic foot	67.75	74.5
Specific gravity	2.59	2.60
Percentages of voids on rodded material	30.48	23.55
Weight of water, in pounds per cubic foot, at average of temperatures used	62.22	

The low percentage of voids in the gravel was due undoubtedly to the fact that the gravel was well graded, the spaces between the larger particles being filled with the finer material.

Pressure Tests

Seven series of tests were made, with seven tests in each series, or forty-nine in all. In each series, the soil was put into the testing apparatus, without surcharge, its surface being always level and 7 ft above the bottom of the apparatus. It was then alternately irrigated and drained. The water was allowed to enter the apparatus in the open space behind the cross-partition; it rose at an approximate rate of 1 ft in 5 min, and this space was kept full until the water became flush with the surface of the soil. Records of the scale pressures were made before water was admitted, and afterward at intervals of from 3 to 5 min, until the soils were fully saturated and the scale readings became constant. The apparatus was then drained at the approximate rate of 6 in. in 5 min until 2 ft was drawn off, after which the rate was increased to 2 ft in 5 min, as measured in the open space. As before, the scale readings were taken at intervals of from 3 to 5 min, and continued until the readings became constant. This procedure was repeated for three irrigations and two drainings. At the end of the last irrigation, the apparatus remained full of soil and water for 18 hr, or longer, and then was allowed to drain for 12 hr. The water did not rise and fall at the bulkhead at the aforementioned rates, because it was admitted to, and drained from, the space behind the plank partition (see Fig. 4), and had to leak through the partition and seep through the soil (which required time) before it could rise and fall at the bulkhead. The time for a full irrigation was about 2 hr, and for a drainage about 1 hr and 15 min. There was also an interval of several hours between some of the drainages and the next irrigations, but these intervals had no appreciable effect on the results as the scale pressures were similar to those of tests between which there were no intervals.

In the first series, the sand was shoveled loose into the apparatus, without any effort to compact it. When the first irrigation was completed the sand had settled 4 in. of its original 7-ft depth, or nearly 5 per cent. As this settlement altered comparisons with the results of the other six series, in which the soils were compacted, only a few results of loose, dry sand are reported, thus:

Depth of sand on bulkhead, in feet................	6.979
Load on Scale *A*, in pounds......................	760
Loads on Scales *B* and *C*, in pounds.............	1 751
Total load on all scales, in pounds................	2 511
Corrected total load, in pounds per foot of width...	536
Center of pressure above bottom of bulkhead, in feet.	2.187
Theoretical center at one-third of effective depth, in feet	2.302
$\tan^2 (45° - \frac{1}{2} \phi)$	0.218
Angle ϕ	40°

Shoveling the sand into the testing apparatus probably increased its weight per cubic foot in the lower portions and thus brought the center of pressure below the theoretical one-third of effective depth.

* Values in parentheses are pressures due to the soil: that is, total pressures less the hydraulic pressure.

In each of the other six series of tests, the procedure was identical with the foregoing except that the apparatus was filled with the soil in 1-ft layers and each layer was compacted until the 7-ft depth was completed. After the last drainage, a final reading of the scales was taken at the end of 12 hr, and the series was ended.

These series were designated by numbers from 2 to 7, inclusive, and were compacted in the various ways described in Column (2), Table 3. In each series the compacting was done by the 50-lb tamp, as already described. The depth of the soil at the bulkhead was always 6.979 ft, and the effective head was 6.906 ft, as determined from the standardizing tests with water.

The measured pressures (Table 3) are those of the scales after the readings had become constant and showed that the repeated irrigations and drainages destroyed the effects from compacting. The 12-in. layers were too thick for any enduring effect under irrigations and drainages, and the results when the layers sloped either from or toward the bulkhead did not show any appreciably distinct characteristics from those when the layers were horizontal. The compacting, however, did consolidate the soils, as shrinkage, on application of water, was practically nil.

From an inspection of the results in Table 4, it will be seen that the horizontal pressure from the sand or gravel when dry (that is, as received from the bank and containing somewhat more than 5% of moisture), was 523 lb and 456 lb, respectively, per foot of width, but only 131 lb (1 641 − 1 510) and 196 lb (1 706 − 1 510) when fully irrigated; that is, saturated with water. These latter pressures are the differences between the saturated soil pressures and the water pressure only.

‡ An allowance of 5.1% was made for stiffness of bulkhead and influence of canvas at edges.

As the apparatus stood long enough for the water to saturate fully the mass (by rising from the bottom to the top), the water acted on the bulkhead both through the voids and by transmitting pressure through the soil particles. Therefore, the excess pressure recorded by the scales over that due to water only, was the pressure from the weight of the soil. Applying the

Rankine or Coulomb theory, for a fill without surcharge, the angles between the horizontal and the planes of internal friction for the dry soils and for the fully saturated soils varied. The angles always were smallest for the drained soils, intermediate for the dry soils, and largest for the saturated soils. It will be remembered that the intensity of the horizontal pressure varies inversely with the angle of internal friction.

The figures in Item No. 5, Table 4, were determined from the equation, horizontal pressure $= \frac{1}{2}\, w\, h^2 \tan^2 (45^\circ - \frac{1}{2}\, \phi)$, in which the pressures are given in Item No. 4, the values of w in Table 2, and h taken as the effective heads. In the drained conditions, water remained in the interstices between the particles, although drained for 12 hr, and made the soils heavier, which would increase the horizontal pressures. For the drained conditions, an allowance for increase in weight was made by assuming that one-half the voids were full of water; that is, for the drained sand the weight was taken at 120.4 lb per cu ft, and for the gravel at 129.3 lb. An error in this assumption will not cause a serious change in the results quoted. It was not necessary to be too exact, as soils are not homogeneous, but differ throughout their mass. The computed angles of internal friction, Item No. 6, Table 4, correspond to the tangents in Item No. 5. It is difficult to duplicate the exact conditions of a large test mass of a soil in a much smaller sample, but an effort to do so was made which gave the angles "by experiment," as mentioned in Item No. 6. This was done by putting the compacted soils in two boxes and measuring the force to pull one over the other, allowances being made for the weight of the upper box and for the friction between the boxes. This method gave the tangents corresponding to the angles quoted. The soils were tested both dry and saturated.

During drainage the velocity of the water between the particles must have been appreciable. It would seem that the retreating water removed some support from the particles, which it maintained while the mass was saturated in a quiescent state. On the next irrigation, the apparent support of the particles by the water was restored.

The recorded scale pressures developed an interesting phenomenon as irrigation of the soil progressed, which the writer believes to be novel, and reported for the first time. After an initial reading of soil pressure was made, and the admission of water commenced, the combined pressure decreased until the water rose about 1 ft, or somewhat less, in the soil. Then, as water continued to rise in the soil, the pressure increased and continued to increase until complete saturation had taken place, with water standing at the level of the top of the fill. This phenomenon was repeated in most of the irrigation tests, and Table 5 gives the scale records for two of the tests.

The height of soil on the bulkhead was constant at 6.979 ft, while the depth of water was variable, rising from 0 ft at the initial pressure record to the top of the soil at the last record. It is not clear why this fall of pressure at the beginning of irrigation should occur. As a possible explanation the following suggestion is offered: Below the water level, the soil weight would be lighter (due to its weight in water), while above the water level, the soil would retain its dry weight. This would reduce the horizontal pressure due to the soil. As the irrigation-water level rose, the increase in hydrostatic pressure would be greater than this reduction of soil pressure. Furthermore, introduction of the water increased the internal angle of friction of the soil, resulting in a decrease of the volume of the soil wedge causing the horizontal pressure. This reduction in pressure from the soil would be relatively greater when the water levels were low and the hydrostatic pressure was small.

When drainage commenced, the pressure fell until about 2 ft of water remained in the soil, and, thereafter, it decreased very slowly until the final drained reading was recorded. A hypothetical calculation of the pressures, as drainage progressed, indicated that the regimen of decrease in pressure would be similar to that for rise in pressure due to irrigation; that is, the pressure would decrease below and then increase to the final drained pressure. The hypothetical calculation was based on the assumption that, at any intermediate stage of the water level, the horizontal pressure was the sum of the

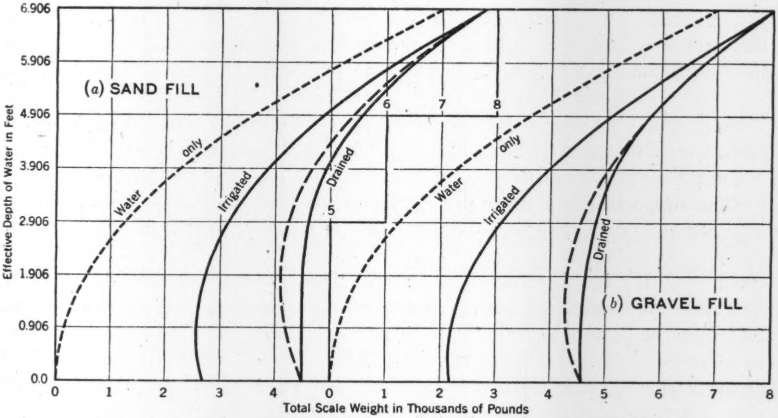

FIG. 3.—TYPICAL PRESSURE CURVES AT VARIABLE DEPTHS OF WATER

pressure due to the dry fill above the water level, of the pressure due to the fill below the water level, and of the hydrostatic pressure. It was realized that the value of $\tan^2 (45° - \frac{1}{2} \phi)$ did not remain constant as the water rose, and a compromise was made by plotting the values for dry and saturated conditions, with water depths as ordinates, and joining the points by a straight line. Then, values for each foot of depth of water could be determined. Probably the change in values of the tangents did not vary as this linear assumption, but the interpolations were approximate.

The pressures for Series 6 with sand and for Series 7 with gravel are illustrated in Fig. 3, on which curves of pressure due to water only have been drawn. The broken lines for the drainage curves are computed values. The horizontal distance between the water curve and either of the remaining curves, measures the pressure from the soil. It will be noted that the difference between the water curve and the irrigation curve steadily decreases as the water rises. In other words, the part of the total pressure due to the soil becomes less and less as irrigation progresses until, at full saturation, the pressure due to the soil is only a small percentage of that due to water alone. Furthermore, it is only a small portion of that due to the soil without any water (initial pressure).

DESCRIPTION OF APPARATUS

The testing apparatus, Fig. 4, was constructed of 2-in. dressed yellow pine planks, grooved and fitted with splines for water-tightness. It was stiffened by 6 by 4-in. uprights at the sides and sleepers across the bottom and by steel tie-rods across the top. The box stood on a level concrete floor, and its interior width was tapered to reduce any arching of the soils. It was lined with building paper, and the front end was the free bulkhead shown in Fig. 1, suspended by two steel rods, linked into shorter rods having washers and nuts, that were supported by cross-pieces. The cross-pieces, in turn, were supported by braced posts. There was opportunity in the supporting arrangement to adjust the bulkhead to the front end of the testing box.

The supporting rods were practically in the plane of the center of gravity. The three scales were attached and supported, as shown in Fig. 1. To balance the bulkhead in a truly vertical position, counterweights attached to the top of the bulkhead were provided. The openings at the edges of the bulkhead were closed by canvas tacked to the sides and bottom, then miter-folded at the bottom corners, and tacked to the bulkhead. The canvas was in two layers and painted to prevent leakage. When the apparatus was empty and ready for testing, the scales were balanced at zero readings, and were very sensitive to pressure on the bulkhead. The rear end of the box was arranged to open for the easier removal of the soils between each series of tests. The box was designed long enough for a more extended research, but such additional work was not undertaken. To reduce the quantity of soil handled, a loose plank partition was placed 7 ft back from the bulkhead as shown in Fig. 4. This was far enough so as not to interfere with the planes of rupture of the soils. Water for irrigation was admitted to the empty space in the rear of this partition, and it flowed through the open joints and the soil to the bulkhead. There was also a valve for drainage.

FIG. 4.—TESTING APPARATUS

SUMMARY

1.—There are many variables in soil problems, and only by the agreement of a number of researches can actual facts become established, which is the excuse for publishing this work.

2.—It may be said that "arching" affected the results of these tests. Arching might have occurred in the "dry" tests, but the repeated irrigations and drainages which followed gave such uniform results that arching did not appear to be a factor.

3.—The results of these tests approximate the Rankine and the Coulomb theory for soils without surcharge, provided ϕ is the angle of internal friction and not the angle of repose. Field observations of unsupported banks, in which the soil had some moisture content, show a surface of rupture that is not a true plane, but is nearly vertical at the surface and becomes more horizontal near the bottom. Such observations confirm the test results, namely, that the wedge causing the pressure is smaller than in theory, which uses the angle of repose.

4.—These tests indicated that the center of pressure, on repeated irrigations and drainages, approximated the theoretical $\frac{1}{3}h$, except for the drained gravel where the center was considerably higher than the theoretical (see Table 4). It is not apparent why the point of resultant pressure was high for the gravel, especially in the drained state. It is conceivable that the plane of rupture in this coarser material was a warped or curved surface, which reduced the section of the wedge from the theoretical triangular shape and placed its center of gravity above that of the triangle. The wet condition after drainage may have increased the cohesion of the gravel particles and thus produced a smaller wedge by a curved rupture plane.

5.—When the soil was fully irrigated, the pressure consisted of the hydrostatic pressure plus a pressure due to the soil. The portion of the pressure which was due to the soil was less than ~~that~~ which would have been expected when using the angle of internal friction as deduced from the dry material (that is, containing about 5% moisture), and making an allowance for the reduced weight of the material; that is, the ratio of its weight in water to its weight in air. It may be that under saturated conditions, the plane of rupture is curved, rather than flat, as explained herein under Summary Item 4.

6.—Under fully irrigated conditions it would seem from Table 4 that the pressure due to the sand was 131 lb (total pressure, 1 641 lb, less hydraulic pressure, 1 510 lb). This soil pressure was about 25% of the dry soil pressure, namely, 523 lb. In the same way, for the gravel, the total pressure was 1 706 lb less the hydraulic pressure, 1 510 lb, leaving 196 lb for the gravel portion of the total. This latter value is about 43% of the dry gravel pressure of 456 lb. It will be noted that these soil-pressure percentages are much less than the percentages of the weight of the sand or gravel in water to their weight in air, which were about 61 in both cases.

7.—Under drained conditions, the horizontal pressures of the soils were high and the computed angles of internal friction were low, when compared to the results for dry and saturated conditions. This was probably due to the increased weight of the water retained in the interstices, and also to a possible hydrostatic pressure resulting from the "head" corresponding to the water thus held by the particles. Ordinarily, wet soils are stiffer than dry soils due to cohesion between the particles, but these drained soils possibly retained more water than necessary for maximum cohesive effect.

8.—The scale pressures as given in the horizontal lines of Table 5, were taken at similar intervals, and, therefore, the sequence of decrease and subsequent increase of pressures is comparable for both the sand and gravel tests. Probably the gravel, being the coarser, allowed the water to seep through its mass faster than through the sand and rise more quickly on the bulkhead. Thus, the lowest pressure for the gravel occurred at the first interval, after the initial, while for the sand the decrease continued until the fourth interval.

ACKNOWLEDGMENTS

The writer acknowledges his thanks to the Trustees of Rensselaer Polytechnic Institute, Troy, N. Y., for partial financial assistance, and to Palmer C. Ricketts, Hon. M. Am. Soc. C. E., for space for the apparatus. He is indebted, furthermore, to T. R. Lawson, M. Am. Soc. C. E., and Professor Edward J. Kilcawley, for determining the weights of the soils; to Lieut. Hunt V. Martin, C. E., U. S. N., a Post-Graduate Student at the Institute, for the manipulation of the tests; and to Eugene E. Halmos, M. Am. Soc. C. E., for assistance in the analytical work.

DISCUSSION

J. C. MEEM,[3] M. AM. SOC. C. E. (by letter).—It is not an agreeable task which has been self-assigned to the writer—that of criticizing adversely this carefully and painstakingly prepared paper. There is one criticism, however, which is fundamental in its application to a soil pressure test of this scale. Due to the normal lateral pressure of soil, the results of any tests must be misleading if not valueless unless they are made on a scale sufficiently large to preclude the possibility of lateral arching, either vertical or horizontal. This applies even with greater force to kiln-dried sand which, in the writer's judgment, is the only material in which such tests should be made and final results of value computed.

The fallacy of expecting results of value from apparatus having a face of even 5 ft in width can be shown by making the following simple test or experiment. A box of 1-ft cube is constructed without top or bottom. A bottom plate, slightly larger in area than that of the box (say, 14 by 14 in.), carrying four 15-in. bolts, one near each corner, forms the loose unattached bottom. The box is filled level full with kiln-dried sand and a top plate about 10 by 10 in. in area, with bolt holes, forms the top. The bottom plate is brought to bear firmly against the bottom edges of the box by tightening the washer bearing nuts at the top. As these nuts are tightened, the sand in the box is firmly compacted; but instead of transmitting this pressure to the bottom, it is transmitted laterally, and friction is developed between the sand and the sides.

It will be seen that the development of this friction can readily be made sufficient to carry the sub-arch sand bearing on the bottom, at which time the box can be lifted as a whole and carried about without danger of collapse. If the inside faces of the box are not too smooth, the friction, of course, will be developed more readily.

It is necessarily true that if this can be done with a 1-ft cube, it can be done with a 5-ft cube; except that it is relatively more difficult to transmit by hand the pressure necessary to develop the required friction to support the 1 000-lb load on the bottom of a 5-ft cube than to support the 8-lb load on the 1-ft cube. Under natural conditions this is developed by increased friction and cohesion due to moisture and to increase of depth sufficient to provide relatively larger frictional area.

If it can be shown, therefore, that lateral pressure on a 5-ft cube may be fully developed even in kiln-dried sand, the results of tests made in a box with only a 5-ft opening must necessarily be misleading and without definite value. This is true not only with kiln-dried sand, but with moist sand, since it can be readily shown that one side of a 5-ft cube of ordinary moist or moulding sand may be cut vertically without developing any side pressure whatever.

---

[3] Cons. Engr., Brooklyn, N. Y.

For a long time the writer has advocated and proposed the making of soil tests on a scale sufficiently large to obviate the possibility of erroneous results from lateral arching or other causes. The tests or examinations, as suggested, are hereinafter noted.

FIG. 5.—DETAILS OF SAND BIN FOR MEASURING LATERAL EARTH PRESSURES.

Test 1.—Determination of Force and Value of Lateral Earth Pressure.—In order that this determination may be definite and convincing, it must be made on a scale at least approximately as large as that shown, otherwise the cohesiveness of soil particles, as well as the lateral arching properties of the soil will make the tests of little or no value.

Fig. 5 shows an apparatus consisting of a bin 20 ft high, 40 ft wide, and 40 ft long, net inside dimensions, in a pit or in the open, and braced and tied across so as to leave it internally clear and free of all tie-bolts. The face of the bin is made of four louvers, each 5 by 40 ft, and backed by two 24-in., 70-lb beams to insure stability and stiffness. These beams are faced and connected so that the top one of each pair slides on a horizontal arm in order that no pressure is exerted on the one next below it or on the bottom itself. Eight hydraulic pressure gauges or dynamometers are used to measure the pressure that is transmitted directly to these gauges. In order to overcome friction and to insure exact data, the pressure on all gauges is raised equally to, say, 10 lb (or as noted), by means of eight weights. Each of these weights, acting through and over a pulley, is attached outwardly to each end of a louver. It is thus seen that any pressure from the soil will be transmitted directly through each louver to the gauge.

A light roof or cover should be provided to insure the maintenance of dryness, particularly for the kiln-dried sand with which the bin is first filled. As soon as the bin is filled, and while it is being filled, the gauges are read to note the varying and continuing pressures. As soon as this test has been repeated to insure against errors, the bin is left level full with dry sand and the readings are noted. Uniformly spaced and properly located superimposed loads are then erected on the top of the sand and the readings of the various gauges noted as the loads are increased. The bin is then emptied and filled with normally dry sand and finally emptied and filled with normally dry sand and gravel, and the various readings are noted.

It is essential that this test be made with superimposed louvers sliding on arms in contact with, but independent of, each other, backed by heavy beams to insure against distortion and having friction balanced by independently acting weights.

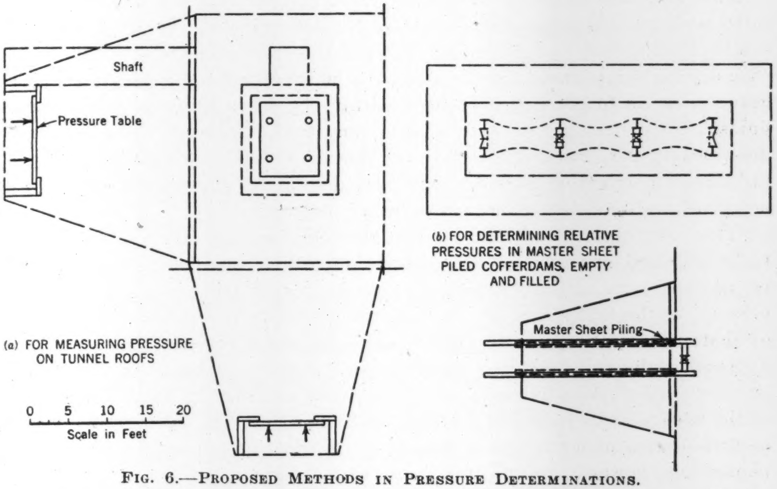
Test 2.—The next test is to determine the arching value of soil in its relation to pressure on a tunnel roof at varying depths. A pit about 15 by 20 ft at the bottom, is excavated to a depth of 20 ft, with sides as steep as the ground will stand. A heavy box platform about 15 by 15 ft by 4 ft high, opening into a braced shaft at one side of the pit (see Fig. 6 (*b*)), has a 10 by 10-ft opening in the top and is arranged with a false bottom below and inside the top. It is supported by four hydraulic jacks with gauges. The bin is then filled with kiln-dried sand and the increased pressure on the gauges is noted as the depth of sand is increased, or until no further increase of pressure is observed.

If or when this point or height is reached, superimposed loads are added and increases of pressure (if any) are noted. This test may be repeated with moist or normally dry sand or gravel, but it is believed that the best results will be noted with the kiln-dried sand.

Test 3.—A large pit, say, 30 by 50 ft at the top (see Fig. 6(*b*)) and perhaps 20 by 40 ft, at the bottom, and about 20 ft deep, is dug in firm nonporous soil. A coffer-dam of the master sheet-pile type is then driven into the bottom soil with the master-piling penetrating about 5 ft and the sheet-piling just into or below the bottom. The master piles are then braced at the top with adjustable bracing.

Fill the pit outside the coffer-dam with sand, then flood it to above the level of the sand. Replace the bracing with bracing carrying pressure gauges and note the pressure. Then gradually pump the water from inside the coffer-dam and note the increase of pressure (if any) due to the lowering of the water. This test should be of incalculable value to those who contemplate building coffer-dams.

It is believed that the tremendous importance of the results from such tests would lead the author to consider the possibility of making them with co-ordination between such facilities as he may have at his command. It is in effect simply bringing his own tests out of the danger zone of a scale too small to be of value.



(a) FOR MEASURING PRESSURE ON TUNNEL ROOFS

(b) FOR DETERMINING RELATIVE PRESSURES IN MASTER SHEET PILED COFFERDAMS, EMPTY AND FILLED

FIG. 6.—PROPOSED METHODS IN PRESSURE DETERMINATIONS.

Concerning the question of the use of the term, angle of repose, the author finds some objection because the plane of repose or rupture for normally dry or moist soils is found usually to have a curved instead of a rectilinear cross-section. The angle of repose is that angle between the normal slope of the soil after the soil above the plane of repose has slid away, and the vertical. If the line measuring this angle is curved instead of rectilinear, the angle of repose may be taken as the mean of the sum of all the angles between the tangents and the vertical.

It is certain that the only pressure possible in a retaining wall from sandy soil must come from that volume of soil sliding or tending to slide, and the measure of its cross-sectional area is that between the plane of repose and the vertical.

EUGENE E. HALMOS,[4] M. AM. SOC. C. E. (by letter).—A large amount of work was done in gathering data for this paper, both in the laboratory and in the office, and the writer wishes to pay his compliments to Mr. Parsons' ingenuity for having been able to condense the voluminous information collected into such a short paper. All the essential findings of the tests and the author's analytical studies have been included in a manner which can be easily digested by the reader.

---

[4] Res. Engr., Parsons, Klapp, Brinckerhoff & Douglas, Sutherland Project, North Platte, Nebr.

Tests to determine the pressure of earth on retaining walls have been in progress for nearly a century, the purpose of such tests being, first, to develop formulas for the design of retaining walls, and, later, when the theory of earth pressure was more fully developed, to determine the value of the constants entering into such formulas. Most of the previous tests were conducted with dry materials and, in many cases, the materials were selected to be truly granular so as to come more closely within the scope of cohesionless semi-fluids. The writer has no knowledge of any tests conducted along the lines described by Mr. Parsons and believes that these are the first in which the influence of irrigation and drainage was determined throughout the entire height of a fill consisting of "run-of-bank" material.

The writer agrees with Mr. Parsons that considerably more data will have to be collected and studied before certain peculiar characteristics disclosed by the tests can be fully explained. Such a peculiarity is the fall of the pressure at the first stages of the irrigation; another is the material decrease of that part of the pressure attributed to the earth alone as the irrigation approaches the full height of the fill. This latter may be due to "arching" or "bin action" transferring part of the weight of the fill to the side walls of the apparatus by means of friction. It is not clear why such action should be accentuated under irrigated condition. Neglect of either or both of these phenomena, however, results in a conservative design.

The most interesting and the most important practical disclosure is that described in Conclusion (7) which states the fact that after full drainage the residual pressure was found to be much greater than that of the originally dry earth. This should have an appreciable bearing on the assumptions underlying the safe design of retaining walls in which the supported bank has no positive surface drainage and, therefore, it is conceivable that after heavy rains the earth fill may be in the same condition of wet consistency as that of the tested fill after drainage was completed.

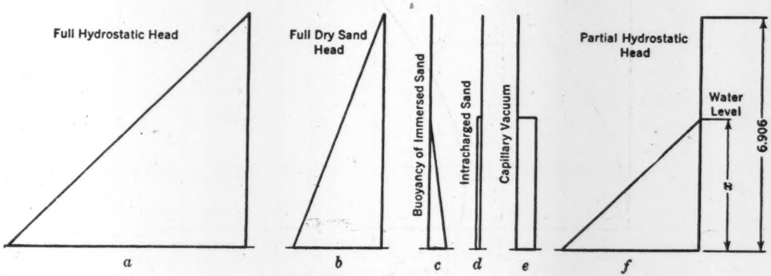
Retaining walls are designed usually on the assumption that as long as weep-holes, about 3 in. in diameter and about 25 ft apart, are placed in the lower part of the wall, the earth pressure during and after rains will remain the same as that estimated for the dry condition of the back-fill. A substantial proportion of retaining wall failures have occurred after heavy storms, indicating that more knowledge is needed on the pressure exerted by a back-fill alternately wetted and drained. Mr. Parson's experiments show that this pressure is about twice the assumed thrust, when the draining is from a fully saturated state.

Further tests should be made, simulating the effect of heavy and extended rain, with weep-holes inserted in the bottom of the test wall, or with sub-drains at the back of the wall, in order to determine how much additional pressure should be assumed in the design to compensate for the wet consistency of the back-fill resulting from any expected rate of rainfall.

It may be argued that the test results referred to in Conclusion (7) are brought forth by the "passive" resistance of the fill which prevents the bulkhead from moving toward the fill when the outward pressure is diminished. The writer believes that the effect of this resistance should be negligible, considering the extremely small movements of the bulkhead. However, if the tests are repeated, it is suggested that measurements be made to determine the vertical component of the earth pressure and the magnitude of the elastic deformation of both the bulkhead and the side walls of the apparatus.

L. C. Wilcoxen,[5] Assoc. M. Am. Soc. C. E. (by letter).—The total pressure of sand on a bulkhead is reduced when the lower 1-ft stratum is immersed. This is a paradox that the author demonstrates positively. In view of the fact that he does not give a satisfactory explanation of the cause, the writer will relate a simple test that gives the clue to the nature of the phenomenon. An analysis based thereon follows: A glass jar was partitioned vertically and on one side a dry mortar sand was rammed level with the top. Water was then poured slowly into the open side. It was found that the water in the sand rose and remained the full 6 in. above the level on the open side. The difference in levels was due to the capillary action of the sand. This is the cue to a physical action that takes place when sand behind a bulkhead is immersed.

Consider the case of a hypothetical bulkhead, 1 ft wide and 6.903 ft high, backed by a sand weighing 112.5 lb per cu ft, having a void ratio of 30.48% (solid ratio, 69.52%), and a horizontal reaction when dry of 21.88 lb per sq ft per ft of depth; that is, the ratio of the horizontal to vertical reaction is 0.194. The reaction diagram of this sand is shown (Fig. 7 (*b*)) in comparison with a similar one for water of the same depth (Fig. 7 (*a*)).



Horizontal Reactions on the Bulkhead

Fig. 7.

If the water level is raised to any height on the bulkhead, capillary action will cause it to rise, say, 6 in. higher in the sand behind. Several results accrue from the introduction of the water: First, there is the buoyancy of the immersed sand with its proportionate reduction of the horizontal reaction; second, the sand is intracharged at the surface of the water, by the weight of water suspended by capillary action (this proportionally increases the horizontal reaction of the sand on the bulkhead); third, downward from the level of the water in the sand, the capillary action induces a vacuum pressure equal to the height of water supported by it; and, fourth, from the same level downward the hydrostatic head is effective.

---

[5] Asst. Civ. Engr., City Engr.'s Office, Detroit, Mich.

Assuming a capillary head of 6 in. and the weight of water as 62.22, the quantitative results will be as follows: First, the buoyancy of the immersed sand will be (0.6952 × 62.22 =) 43.25 lb per cu ft, and the resulting reduction in the horizontal reaction will be (43.25 × 0.194 =) 8.39 lb per sq ft per ft of depth (Fig. 7 (*c*)); second, the intracharge due to the 6 in. of water suspended at its surface in the sand, will be (0.5 × 62.22 =) 31.11 lb per sq ft, resulting in an increased horizontal sand reaction of (31.11 × 0.194 =) 6.03 lb per sq ft (Fig. 7 (*d*)); third, the vacuum pressure due to capillary action will be (0.5 × 62.22 =) 31.11 lb per sq ft (Fig. 7 (*e*)); and, fourth, the hydrostatic head will be 62.22 lb per sq ft of depth (Fig. 7 (*f*)).

From this it may be shown that the total horizontal reactions, in pounds, will be: $536 - 25.08x + 26.92x^2$, when x is the height of the water surface in the sand. This indicates that as the lower stratum of sand is immersed, the total pressure is decreased, the minimum pressure occurring when $x = 0.44$. At this point the decreased pressure is 5.8 lb. The computed pressure curves of water only and the irrigated sand for the author's bulkhead are shown (Fig. 8). They check closely the experimental results of Fig. 3. At the full head, the author observes a difference between the total reactions of water and irrigated sand of (7 691 − 7 080 =) 611 lb, whereas the writer's computed difference from the equation is (8 041 − 7 309 =) 732 lb.

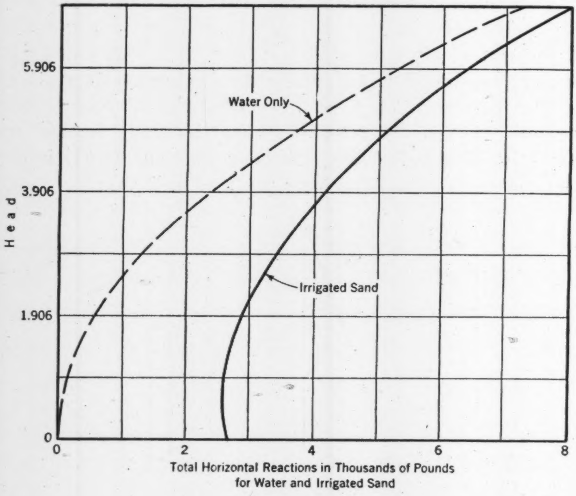


Fig. 8.

The author is to be complimented for the accuracy of his tests, which have brought to light so interesting a phenomenon.

Dr. ING. O. K. FROEHLICH[6] (by letter).—When attempting to interpret qualitatively and, as far as possible, quantitatively, the results of soil pressure tests, dealt with in Mr. Parson's valuable paper, one must keep in mind that:

(1) The well-known, existing, so-called "classical" theories on earth pressures relate to a two-dimensional problem, such as an infinitely long retaining wall.

(2) The earth pressure problem of a sand or gravel fill, contained in the apparatus illustrated in Fig. 1, is three-dimensional.

(3) The bulkhead and side walls of the apparatus in Fig. 1 were not absolutely rigid, but were flexible to some extent, and the deflections were not measured.

(4) The deflections, caused by water only (no soil), did not influence the distribution of water pressures.

(5) The "dry" fills were not placed regularly in thin layers in the apparatus, but were shoveled in, so that the equilibrium of the lower portion probably was affected by dynamic influences.

(6) The measured values of the weight of material (loose and rodded) per cubic foot are only approximate average figures.

(7) The vertical wall friction was not measured.

(8) The difference between the quantity of water used for irrigation and the quantity that drained, was not measured.

Consequently, it seems to be advisable to avoid exaggerated mathematical rigidity in interpreting the most important results of these earth-pressure tests. First, consider the simple case of an infinitely long vertical retaining wall with a height, h, and supporting a horizontal, cohesionless back-fill, weighing w units per unit of volume. Let ϕ be the angle of internal friction, and ϕ', the angle of friction between the wall and the fill. According to the general wedge theory, the horizontal component, H_a, of the active lateral earth pressure (on the assumption that $\phi = 40°$ and $\phi' = 37° 30'$) amounts to:

$$H_a = 0.207 \left(\tfrac{1}{2}\, w\, h^2\right) \cos \phi' = 0.164 \left(\tfrac{1}{2}\, w\, h^2\right) \qquad (1)$$

Leaving the inclination, ϕ', of the total earth pressure unchanged, the horizontal component, H_p, of the passive earth pressure is:

$$H_p = 1.11 \left(\tfrac{1}{2}\, w\, h^2\right) \cos \phi' = 0.880 \left(\tfrac{1}{2}\, w\, h^2\right) \qquad (2)$$

Active and passive pressures are created by slight wall movements away from, and toward, the fill, respectively. Between these values, H_a and H_p, there is a "neutral" earth pressure,[7] H_i, which corresponds to the motionless, or rigid, wall and amounts to:

$$H_i = 0.5 \left(\tfrac{1}{2}\, w\, h^2\right) \qquad (3)$$

---

[6] The Hague, The Netherlands.

[7] "Drukverdeeling in Bouwgrond," *De Ingenieur*, 1932, No. 16; 1933, No. 25.

The ratios between active and "neutral" and between passive and "neutral" pressure, according to Equations (1), (2), and (3), are, respectively:

$$\frac{H_a}{H_i} = 0.328 \qquad (4)$$

and,

$$\frac{H_p}{H_i} = 1.76 \qquad (5)$$

Assume that these ratios also hold true for the three-dimensional problem of the bin, having flexible side walls. At present, this assumption can only be checked empirically, as the three-dimensional general wedge theory has not yet been developed.

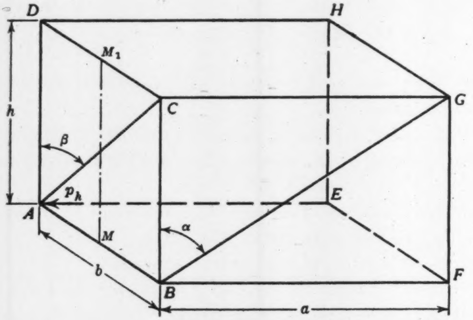

FIG. 9.—COMPUTATION OF "NEUTRAL" EARTH PRESSURE

The theory of the three-dimensional "neutral" earth pressure problem[8] enables one to determine the lateral pressure, exerted by the granular fill of a rectangular bin having a section of 7.0 by 5.0 ft, and a height of 7.0 ft, if the side walls and bottom of this bin are practically rigid.

The horizontal pressure, p_h, per unit of area at Point A of the side wall, $b \times h$, is approximately given by the following expression (see Fig. 9):

$$p_h = \frac{w\,b}{2\,\pi}\left\{ \log\left(\cot\frac{\beta}{2}\tan\frac{\alpha}{2}\right) + \cos\alpha \right\}\cot\phi' \qquad (6)$$

By applying Equation (6) to the points of the lines, $A\ D$ and $M\ M_1$, Fig. 9, at depths of 1, 2, 3, ..., 7 ft, under the surface, $C\ D\ H\ G$, of the fill in the bin, the unit pressures, p_h, in Table 6, are obtained by multiplying each value by $\frac{w\,b}{2\,\pi}\cot\phi'$. The averages in Table 6 are obtained, as follows (at a depth of 1 ft. for example: $0.199 + \frac{2}{3}(0.390 - 0.199) = 0.327$.

---

[8] "Drukverdeeling in silo's * * *", *Polytechnisch Weekblad,* 1933, Nos. 38–39.

Using the values, $w = 101.5$ lb per cu ft for sand; $b = 5$ ft; and $\phi' = 37° 30'$; the total thrust is:

$$\frac{101.5 \times 5}{2\,\pi} \cot 37° 30' \; \frac{(2 \times 6.641 - 1.372) \times 1 \times 5}{2} = 3\,130 \text{ lb}$$

If an allowance of 5.1% is made for the influence of the canvas at the edges, etc., $H_t = 3\,130 - 160 = 2\,970$ lb. From Table 4, the total scale pressure on the bulkhead for dry sand was 2 453 lb; that is, 17.4% less than the "neutral" earth pressure. This reduction is due to the inevitable movement of the bulkhead of (maximum) 0.004 in. = 0.1 mm.

TABLE 6.—"NEUTRAL" UNIT PRESSURES, p_h, ON BULKHEAD

Depth, in feet	Side line, *A D*	Center line, $M\ M_1$	Average
1	0,199	0,390	0.327

7	0.960	1.578	1.372
Total	....	....	6.641

As regards the magnitude of the pressures on irrigations and drainages, the writer offers the following explanation: The water pressure on the side walls of the apparatus, which is approximately three times as great as the earth thrust, produces wall deflections—however small these may be — and allows the fill to follow an "active" tendency. When the water is drained away, the deflections are restored and the four side walls of the bin exert a passive pressure on the fill.

To develop this idea, one must keep in mind: First, that the unit weight of the sand immersed in water was 61% of the weight in air; and, second, that the principle of superposition of pressures must remain valid in the present case.

According to Equation (4), the sand pressure against the bulkhead, if the sand is saturated, must be:

$H_a = 0.328 \times 0.61 \times 2\,970$.......... = 594 lb
Water pressure according to Table 4.......... = 7 080 lb

Total.................. = 7 674 lb

Table 4 gives 7 691 lb as the average result. After drainage the sand pressure against the bulkhead is passive, and Equation (5) yields: $H_p = 1.76 \times 2\,970 = 5\,230$ lb. Table 4 gives 5 052 lb as the average result.

These figures would confirm the previously mentioned opinion, that slight deflections of the side walls took place during irrigation and were restored during drainage. In an absolutely rigid apparatus the following total pressures might be expected: Dry, 2 970 lb; saturated, 0.61 × 2 970 + 7 080 = 8 890 lb; and, drained, 2 970 lb.

H. L. Thackwell,[9] Assoc. M. Am. Soc. C. E. (by letter).—Due to the paucity of reliable information on a subject that deals with the forces exerted on non-homogeneous materials, such as earth, sands, clays, and gravels, and a combination of all such materials under various conditions of saturation, the average practicing engineer has resorted either to personal judgment, or to "rule-of-thumb" methods, for assigning the forces assumed to act against walls, the sides of tanks, and bins. This excellent paper describing soils tested under saturated and drained conditions, with measured lateral pressures, is a valuable addition to a subject in which many engineers have been groping for a method of rational analysis.

If the conditions of loading, and the physical properties of such non-homogeneous, granular, and plastic materials, could be ascertained accurately, it would be possible to develop a correct theory for the particular case under consideration. Correct theory is only possible when based on inductive reasoning (from the particular to the general); the particulars must be studied by experiment, and such experiments must be based on conditions that are likely to be encountered in practice. The classical theories of Rankine and Coulomb have served very well in the design of walls back-filled with dry materials of uniform nature. With these formulas, ϕ is the angle of repose, although Boussinesq has pointed out that the angle of internal friction would be more applicable.

In the frequent case of a wall to be designed with a vertical back and with the requirement that it retain a level bank of earth, the customary formula is:

$$P = \frac{w}{2} h^2 \tan^2 \left(45^\circ - \frac{\phi}{2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

If this formula is correct in theory, it is necessary, in order to use it properly, to assign the correct values for w and ϕ, which are the only unknowns. If the conditions of back-filling are known in advance, it would be possible, by experiment, to obtain the weight of the material, or combination of materials, to be used in the fill, and also the angle, ϕ, which should be the angle of internal friction.

In practice, it is seldom that the engineer who is entrusted with the problem of designing simple concrete retaining walls, will have the time or the money to make the necessary experiments for determining the correct values of the aforementioned variables. For example, consider that an engineer has been retained to design, and supervise the construction of, a sewage disposal plant for a city of 5 000 population. The usual procedure is to select a suitable site for the plant, and then to make a topographic map of it, including a few borings for soil and sub-surface drainage conditions. This map, with the borings for a guide, then becomes the field for office locations of all tanks, walls, etc., that will be incorporated in the design. The designing engineer, after a few trial layouts, will finally select the exact positions for the various buried tanks and the retaining walls for filter enclosures. It is impractical to expect that the engineer entrusted with the design of a small project, and receiving only a 5% fee for engineering work, will make a sufficient number of tests of the filling material and of the angles of internal friction, which will occur at various positions behind the structures, in order to obtain accurate values that will eliminate the unknowns of the equation.

---

[9] Cons. and Const. Engr., Longview, Tex.

Moreover, the conditions after back-filling are subject to change, due to a rise in the ground-water table, rises and falls in temperature, freezing of the surface layers, or to the peculiar properties of certain (black land) clays which, on drying out, shrink away from the surface of structures.

The usual methods of back-filling around tank walls and filter retaining walls, are to dump the previously excavated material, reserved for that purpose, into the excavation and puddle it with water. Under these conditions the materials have become more or less mixed in the process of excavating and removal for storage, which storage pile is later used for back-fill and probably removed some distance from the locality where it was excavated.

With all these conditions in mind, and with "post" reflections on completed walls, the writer, against engineering approval, has been guilty of using the unscientific method of "equivalent fluid pressure" for approximating earth thrusts on minor walls and structures. With the "equivalent fluid method," of course, considerable is left to the judgment of the engineer. Table 7 is offered in an attempt to justify the "fluid method" of approximate thrusts, using Rankine's formula for the bouyant earth pressures under complete saturation, and considering the water pressure added to the lateral earth pressures, ϕ being the angle of internal friction of the material. The head used is 6.979 ft as in the soil test apparatus of the paper, the angle, ϕ, being 58° for the lightest material and increasing 1° for each 10 lb of weight, until a maximum of 63° is reached for a weight of 120 lb of dry material. The specific gravity was assumed as 2.60, and the weight of water taken as 62.22 lb per cu ft.

It can be seen from Table 7 that, in a fully saturated soil, the resultant combined lateral pressures of earth and water are practically the same for all possible weights of soil. It is quite logical then to assume that an equivalent fluid pressure may be adopted, which will give the same results as the more

TABLE 7.—EFFECT OF VARIOUS WEIGHTS OF SATURATED SOILS ON LATERAL PRESSURES, USING RANKINE'S FORMULA WITH A VARIABLE VALUE OF ϕ.

refined and exact method, provided the angle of internal friction has only slight variations with different weights of soil, which are likely to become incorporated in the fill.

In this case of full saturation the equivalent fluid would have a weight of 66 lb per cu ft, and with a drained condition would have a weight of 44.2 lb per cu ft, this latter pressure being obtained by using the corrected total pressure of 1 077 lb as shown in Column (6), Table 4. The writer has been using a value of 40 lb for drained conditions, and 70 lb for a full fluid condition of back-fill, for East Texas sands and clays.

The phenomenon illustrated in Fig. 3 of decreasing pressures as the water rises up to the 1-ft mark, may be due to air binding. Water rising under a sand filter would have the effect of compressing air in the voids of the sand, and until this compressed air reached a pressure sufficient to overcome the frictional resistance of the sand grains it would not be released Under the condition of partial air compression, some uplift would occur which would be reflected in the lateral pressures as measured.

The writer agrees with the author in his "Summary" of conclusions, and is grateful for this valuable addition to the meager information on this subject, now at the disposal of practicing engineers.

JACOB FELD,[10] M. AM. SOC. C. E. (by letter).—The description of tests to determine the lateral pressure of sand and gravel with various degrees of saturation, as offered by Mr. Parsons, is clear and complete. To permit comparison with the paper and with other tests, the present remarks are divided into discussion of the apparatus, results, and conclusions.

Apparatus.—It is unfortunate that the apparatus was not equipped with provision for measuring the vertical components. Since the pressure of the water on the vertical test wall is horizontal, the effect of the soil in water at varying heights would have been more striking. The calibration of the apparatus with water cannot be questioned. It was found that the effective width of the wall for water was 4.75 ft, and it is assumed that the same applies for the soils. Such assumption cannot be accepted without further proof, especially because of the converging sides of the bin. Such convergence has no effect on water pressure, but must have a decreasing effect on soil pressure. The volume of the wedge of rupture (actual or fictitious) is reduced. The pressures on the end vertical strips of the test wall are very much less than those on the inner strips. A further test can give some valuable data; namely, to add soil to a bin full of water and determine the increase in pressure under these conditions. In this type of test, the variation in the vertical component would give important information.

Results.—The material used is described as a bank sand and gravel. The effect of water on this material is striking. When water was added, complete saturation could not occur immediately. A time interval must pass before the entrapped air is expelled. During this period the pressure decreased—the amount of decrease being less for gravel than for sand. In spite of a smaller percentage of voids, the individual interstices in the gravel were larger than in the sand, and the air could leave faster. Without complete saturation and a continuous film of water, hydrostatic pressure could not be recorded. Apparently, additional moisture content under partial saturation decreased the pressure because of an increase in the coefficient of internal resistance of the material.

---

[10] Cons. Engr., New York, N. Y.

Experiments reported by the writer[11] on sand containing from 5 to 9% moisture indicated a uniform relationship between the coefficient of internal resistance and lateral pressure. From the amount of shrinkage of loose fill (see "Pressure Tests"), the sand used in these tests could hold a considerable percentage of water. In the compacted state, as a result of flooding or ramming, the coefficient of resistance will be greater than in the loose state.

For the loose sand, the author reports a value of 40° for the angle of internal resistance, or a coefficient of 0.839. An increase of this coefficient by less than 10% to 1.00, or 45°, would mean a decrease in lateral pressure of 22½% (theoretically).

The low values for the position of the resultant pressure are caused partly by the shape of the bin, eliminating larger parts of the wedge of rupture in the upper levels than in the lower levels.

Conclusions.—The most important conclusion is that, the belief of many "practical" engineers notwithstanding, a lateral pressure greater than the hydrostatic pressure of water can occur.

The "arching" effect was entirely disproved by the tests at the University of Cincinnati[11] where identical results were obtained with rigid and free side walls. The discussion of theoretical and practical reasons for the elimination of the angle of repose from any consideration is also included in the paper reporting these tests.[11]

The point of application of the resultant pressure for consolidated fills should be above the one-third point because consolidation is equivalent to surcharge. The effects of saturation and drainage must cause internal re-adjustments in the fill—more so in sand than in gravel, with greater variation in results from theoretical values for sand than for gravel.

T. FARRANCE DAVEY,[12] ASSOC. M. AM. SOC. C. E. (by letter).—As the author states it is only by the agreement of a number of researches that actual facts become established. In like manner, it is only by the observed results of failures (which, by their implications, are likely to be obscured), that full-scale results can be established. This is the writer's justification for introducing a record of several failures that have a bearing on Mr. Parsons' paper.

Fig. 10 refers to two sections of a dry, rubble, masonry retaining wall, about 10 ft high, built of old red sandstone and supporting a fill of old, decomposed red sandstone. The failures occurred when the material had been wetted by rain. The decomposed material had a somewhat clayey coating as had also some of the sandstone in the wall itself. The immediate cause of the failure was the superimposed moving loads, the compacting of the fill due to live load, and the vibration of this load.

[13] "Reinforced Concrete Construction," by George A. Hool, Vol. II, Second Edition, p. 433.

Fig. 10 (*c*), Fig. 10(*d*), and Fig. 11 show the wall in another section after it had bulged to complete failure. The conditions seem to correspond somewhat to what Mr. Parsons describes as a "drained" condition. In this instance, the surface of rupture was along a straight slope of maximum pressure (see Fig. 10(*c*)), although (due to the concentrated loads that caused the failure) the actual mass displaced was somewhat conical. This is contrary to Mr. Parsons' observation as to unsupported banks, probably because of a lack of cohesion between the large pieces of rock. The finer material behind the wall conformed with the author's observations and failed along a plane nearly perpendicular at the surface.

FIG. 12.

With reference to Conclusion 6 of Mr. Parsons' "Summary" the failure of the seal of an interlocked wood sheet-pile coffer-dam near Long Beach, Calif., in 1928, is of interest. Because sand of "quick" behavior had been found at near-by points, the coffer-dam (Fig. 12) was excavated by jetting and pumping with the entire site flooded. Bearing piles were driven first and were followed down to their required depths by a "dolly." When the coffer-dam had been excavated, but while it was still flooded, a number of piles had to be driven where they had previously been omitted. The result was that the seal at the bottom was broken and the sand, mixed with water, became quite liquid, and invaded the excavated site. From the final levels (which can be assumed to have been obtained while the material was effectively liquid, due to pile-driving), a simple calculation can be made of the pressure exerted vertically by a liquid sand.

Treating the inside and outside of the coffer-dam as the legs of a manometer and using X as the unit weight (pounds per cubic foot) of the fluid sand (see Fig. 12): $40\,X = 34\,X + 14 \times 62$, or, $X = 145$ lb. Possibly, the decrease in pressure on first irrigating, as reported by Mr. Parsons, was due to the sand falling toward the center of the mass during irrigation as it compacts 5% of its depth (see under the heading, "Pressure Tests"), and thus falling away from the wall.

D. P. KRYNINE,[14] M. AM. SOC. C. E. (by letter).—Notwithstanding the existence of a long series of experiments on earth pressure against retaining walls, this paper represents an able addition to the technical literature in this field. The value of Mr. Parsons' experiments is indisputable.

Behavior of Soil in Containers.—To the eight conclusions offered, the writer would like to add one more, namely: These experiments clearly show that present knowledge as to the behavior of soil in containers is extremely limited; and until a sound theory of such behavior is developed, quantitative results of smaller soil tests can be extended to larger structures only with great care.

In order to clarify this idea, it is necessary to realize that a soil mass in an experimental box possesses six faces, each of which may be considered as the surface. Hence, surface phenomena may develop on six faces, while a soil mass in practice possesses one face, or two faces, but seldom more. For instance, the soil mass under a building is to be considered as possessing one face only—the soil surface under the foundation.

The problem of how a plate acts on a soil mass in which there is only one horizontal face, is still not definitely solved, although it has become evident that the soil condition in this case depends largely on both the size and the rigidity of the acting plate. Hence, it may be realized how complicated the stress distribution is, in a box with five or six plates acting on the same soil mass. It is quite logical to believe that if, in the case of a single plate, the stress condition depends on the size and the rigidity of the acting plate, the same is true in the case of five or six plates acting simultaneously or, in other words, in the case of an experimental box.

---

[14] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

Experiments show that when a plate acts on the horizontal surface of a soil mass, a disturbed zone may develop under that plate.[15] An immediate conclusion follows that a disturbed zone exists at the bottom of each experimental box filled with earth, since the bottom reaction is quite similar to a force transmitted by a plate. Perhaps disturbed zones close to the walls and the bottom of an experimental box are responsible—at least partly—for the obscure phenomenon of sand arching.

The interesting fact that there is a decrease of horizontal pressures at the beginning of irrigation, as discovered by the author, can be explained by surface phenomena as stated subsequently; but before passing to that phase of the discussion, the writer wishes to emphasize that even in a full-sized earth-pressure test in a box the influence of the walls may be so considerable as to disturb the entire picture of stress distribution. Smaller samples sometimes furnish more reliable results than larger ones as, for instance, in the case of the well-known Terzaghi compression device, in which samples should be as thin as possible.

Until a theory as to the behavior of the soil in containers is advanced, experimental apparatus should be adjusted by trial. For instance, the loose-board partition of the box in Fig. 4 should have been placed at variable distances from the bulkhead, and the scale readings compared. The correct distance would then be determined by the stabilization of the reading at subsequent movements of the partition. The width of the wall is to be determined in a similar way. It would be interesting to know how the length and the width of the experimental box (Fig. 4) were actually determined by the author.

Decrease of Horizontal Pressures at the Beginning of Irrigation.—This noteworthy fact discovered by the author is explained in the paper as the result of: (*a*) A decrease in the weight of the soil below the water level, while above the soil, the dry weight is retained; and (*b*) a reduction of the angle of internal friction in the submerged section. The angle of internal friction of sand changes only slightly under water; and the apparent loss of weight in water cannot influence the walls of the container since, in the points of contact with those walls, the mass "sand and water" develops its full weight.

The phenomenon may be explained by the action of the surface tension of the capillary water. In the beginning of irrigation, capillary water rises rapidly, preceding the gravitational water. This contributes to the partial contraction of the sand mass, connected with its partial removal from the walls and consequent decrease of pressure. In order to demonstrate this, the writer made the following experiments using small portions of dry soil powder placed in crucibles. The crucible shown in Fig. 13 is simply a porcelain container with some small perforations in the bottom. The price of a crucible is negligible and the experiments are so simple that they can easily be checked by one who does not even possess laboratory training. A little round piece of filter or blotting paper should be placed on the bottom of the crucible in order to prevent fine soil particles from dropping through.

[15] "Some Shear Phenomena in a Loaded Soil Mass," by D. P. Krynine, M. Am. Soc. C. E., *Civil Engineering,* Vol. 3, No. 10, October, 1933, p. 574 *et seq.*

Experiment 1.—The crucible was filled with dry fine New Haven sand (6.5% remaining on Sieve No. 100) and placed in water about $\frac{1}{4}$ in. deep. Even before the visible capillary moisture reached the top, a clearly defined fissure, $\frac{1}{50}$ in. wide, appeared between the soil mass and the walls of the crucible. The sand column was standing by itself and did not exert any lateral pressure on the walls of the crucible. This lasted $2\frac{1}{2}$ min, after which an excess of capillary moisture softened the soil column, and the fissure disappeared.

FIG. 14.

Experiment 2.—Experiment 1 was repeated with the difference that when the fissure appeared, the crucible was removed from the water hastily so that no excess of capillary moisture was permitted to enter the soil mass. A fissure, $\frac{1}{50}$ in. wide, was clearly visible for 1 hr thereafter.

Experiment 3.—The crucible was filled with dry clay powder containing about 24% of particles smaller than 0.005 mm, with a plasticity index of about 15. A fissure, $\frac{1}{30}$ in. wide, was observed prior to the appearance of the visible capillary moisture at the top. The crucible was left in water throughout the entire experiment, and the fissure did not close for 1 hr thereafter.

Experiment 4.—The crucible was filled with Ottawa sand. No fissure could be distinguished on its moist surface owing to the coarse texture of the tested material. The crucible was removed from the water and slightly tapped with a finger. The sand mass then separated from the walls and the excess of water dropped through the bottom of the crucible. Vertical settlements of the soil mass were observed in each of the four experiments.

Basing his conclusions on these experiments, the writer believes that when the box in Fig. 4 was being filled with water, the capillary moisture was rising rapidly above the water level, thus binding the particles as described. This caused a certain decrease of pressure (A). As the water level rose, the pressure increased to a variable amount (B), due to the weight of the water. When the water level was low, Pressure A was greater than Pressure B, and the total pressure on the retaining wall decreased; but quite soon the contrary occurred $(B > A)$, and the factor, A, lost its influence on the general shape of the pressure curve, although it ceased to exist only when the water level came close to the top of the experimental box. The experimental sand contained about 10%, and the gravel about 3%, of fine particles, and these were primarily responsible for the partial rigid binding of the entire soil mass.

As another proof of his belief, the writer wishes to describe a field observation made by him in the summer of 1933, in Cornwall, Conn. A wooden box, 4 ft by 4 ft by 2 ft 6 in., was partly filled with loam soil for certain measuring purposes. A heavy rain obliged him to postpone the work and to leave the filled box outside. The rain lasted an hour or more. The water drained through the soil mass, and some moisture adhered to the particles. An examination of the box 15 hr after the rain, disclosed that the particular soil had become rubber-like and obviously exerted no lateral pressure on the walls of the box. Fig. 14(*a*) represents the deformation of the soil mass in question under the weight of a man standing on it.

Pressure of the Drained Material.—In the drained condition water remained in the interstices for 12 hr, and the author assumed that, after this period of time, one-half the voids were still full of water. According to Mr. Parsons an error in this assumption will not cause a serious change in the results. This may be quite true when moisture distribution is more or less uniform throughout the soil mass. The writer believes, however, that the actual moisture content was insignificant close to the top and, on the contrary, that it was considerable close to the bottom of the experimental box. Several investigations along this line have been made by soil physicists. Mr. F. H. King,[16] for instance, filled several galvanized-iron cylinders, 8 ft high and 5 in. in diameter, with sand, made water percolate through the sand for 190 hr, and then kept the cylinders for 2½ yr under conditions of no surface evaporation and no addition of water. Moisture content was obtained by cutting the tubes down in 3-in. sections and removing and drying the sand at 110° C until constant weight was reached as this is usually done in laboratories.

Table 8 represents some of Mr. King's data.[17] A similar moisture distribution would perhaps mean that another method of computing the angle of internal friction for the drained material is required.

Coulomb and Rankine Formulas.—The author should be highly commended for definitely identifying both the Coulomb and the Rankine formulas. Actually, the Rankine ratio, u, between the principal stresses for the case of a horizontal ground surface, $\left(u = \frac{1 - \sin \phi}{1 + \sin \phi}\right)$, may be reduced easily to the expression:

$$u = \tan^2\left(45^\circ - \frac{\phi}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which, ϕ is the angle of friction. Furthermore, for a ground surface that slopes at an angle, i, with the horizon:

$$u = \frac{\cos i - \sqrt{\cos^2 i - \cos^2 \phi}}{\cos i + \sqrt{\cos^2 i - \cos^2 \phi}} \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Introduce an auxiliary angle, j, which would satisfy the condition:

$$\cos j = \frac{\cos \phi}{\cos i} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

and divide both the nominator and the denominator of Equation (9) by $\cos i$. Then:

$$u = \frac{1 - \sin j}{1 + \sin j} = \tan^2\left(45^\circ - \frac{j}{2}\right) \ldots\ldots\ldots\ldots (11)$$

It should be noted, however, that the Coulomb and the Rankine formulas can be applied to the so-called "one-phase soil systems" only, such as dry cohesionless sand. They do not yield accurate results when cohesion acts in addition to friction. The angles given by the author in Table 4 are rather "angles of internal resistance."[18]

Shape of the Wedge Behind a Retaining Wall.—Apparently, Mr. Parsons admits that the theoretical wedge behind a retaining wall is bounded by a true plane. The writer understands that the existence of such a true plane was merely an assumption on the part of Coulomb, and that exact computations reveal that the wedge in question is slightly curved, even in the case of quite cohesionless sand. Such computations were made, for instance, by H.

---

[18] "Lateral Earth Pressure," by Jacob Feld, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1448 *et seq.*

Reissner[19] and Th. v. Kármán.[20] Complicated mathematics (omitted herein) led the latter investigator to the conclusion illustrated in Fig. 14(*b*) (for $\phi = 30°$). Obviously, such a small difference may be neglected. Besides these strictly exact solutions, there are many approximate theories of curved shearing surfaces in dry sand, without mentioning those dealing with cohesive soils. Careful experiments were made by F. Takabeya,[21] who used dry sand for this purpose and obtained shearing surfaces behind a retaining wall that were true planes, perhaps slightly curved at the bottom. Professor Takabeya also made very interesting experiments using moist sand.

CHARLES TERZAGHI,[22] M. AM. SOC. C. E. (by letter).—The essential results of Mr. Parsons' tests are assembled in Table 4, the most important being the values of $\tan^2 (45 - \frac{1}{2}\phi)$ and of ϕ (Items Nos. 5 and 6, Table 4). The values of $\tan^2 (45 - \frac{1}{2}\phi)$ are also known as "lateral pressure coefficients," because they are equal to the ratio between the measured horizontal component, H, of the lateral pressure of the back-fill and the lateral pressure exerted by a liquid, the unit weight of which, s, is equal to that of the back-fill. For a saturated back-fill the value, H, is equal to the difference between the measured lateral pressure and the full water pressure, and the unit weight, s, is equal to the unit weight of the dry back-fill reduced by the full hydrostatic uplift. In the following discussion, $\tan^2 (45 - \frac{1}{2}\phi)$ will be denoted by k.

At first, Items Nos. 5 and 6, Table 4, are startling because they indicate that the lateral pressure of the drained back-fill was more than twice as great as that exerted by the dry fill; yet, in the light of previous experience, they are exactly what one should expect to obtain from experiments performed with Mr. Parsons' apparatus.

In 1920, in his first paper on earth-pressure tests,[23] the writer called attention to the fact that the value of the lateral pressure coefficient, k, depends not only on the value of the coefficient of internal friction but, also, to a very important extent, on the distance, l, through which the wall is allowed to yield during the test. In 1929, the writer had an opportunity to verify his conclusions on a large scale, by means of the earth-pressure apparatus at the Massachusetts Institute of Technology, in Cambridge, Mass.[24] This apparatus was constructed so that the model retaining wall can be considered perfectly rigid, and its movements are measured by means of Ames dials with direct readings of 0.0001 in. Results of tests on this apparatus have been published elsewhere.[25] Fig. 15 represents a brief abstract of all those test results obtained with dry sand, which have a direct bearing on the topic of the discussion. The abscissas indicate the average distance through which the wall yielded (actual distance, in millimeters, and distance expressed as a fraction of the depth, *h,* of the back-fill), and the ordinates, the hydrostatic-pressure ratio, *k,* of the earth pressure. The solid line corresponds to an outward movement of the wall and the dotted line to a subsequent movement of the wall toward the fill. During this second part of the process, a movement of the wall through an average distance of 0.5 mm was sufficient to increase the value of *k* from 0.12 to 0.30!

[25] *Engineering News-Record*, February 1, 1934, p. 136, particularly Figs. 2 and 6.

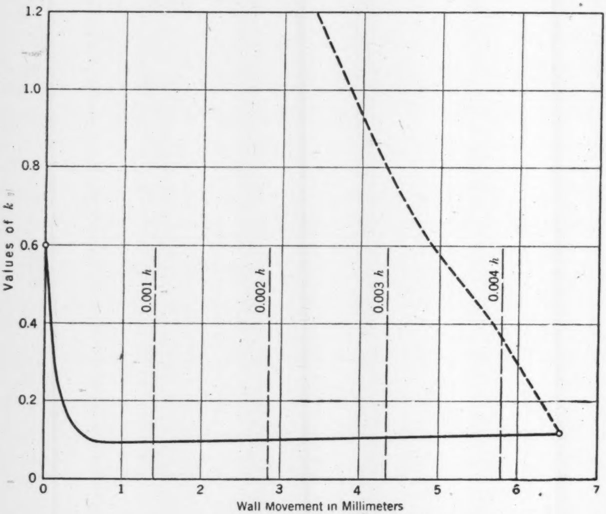

FIG. 15.

Fig. 16 represents the result of a test during which the back-fill of the wall was alternately saturated and drained. The depth of the back-fill was equal to 7.0 ft. The light solid lines show the relation between *k* and *l* for the drained condition and the light broken lines for the saturated condition. The heavy vertical lines represent the change in the value of *k* while the wall remained stationary. Thus, for instance, at Condition *d,* Fig. 16 (*a*), the value of *k* was 0.133 and the angle of wall friction, δ, was 30° 10′. Eighteen hours later (see Point *e,* Fig. 16 (*a*)), the value, *k,* had increased to 0.184, and the angle, δ, had decreased to 22°, while the wall had not changed its position. When the water was admitted into the fill, *k* assumed a still greater value of 0.225 (Point *f,* Fig. 16 (*a*)), which, during the following 21 hr increased to 0.254 (Point *g*). Subsequent drainage caused an insignificant increase of the value of *k* from 0.254 to 0.258.

Fig. 16 shows that the process of saturation invariably caused a slight increase in the value of *k,* while according to Mr. Parsons' Table 4 saturation of the back-fill caused an important decrease of *k.* On the other hand, drainage at Point *g*, Fig. 16, had no influence on the value of *k*, while the back-fill drainage in Mr. Parsons' tests caused *k* to rise to almost four times its original value.

Knowing the facts represented by Fig. 16,[26] there can be no doubt as to the cause of the facts revealed in Table 4 (Items Nos. 5 and 6). The tests by Mr. Parsons and by the writer were made with practically identical materials, the writer's sand being intermediate between the sand and gravel used by Mr. Parsons (effective size, 0.54 mm). For the test plotted in Fig. 16, the depth of the back-fill was the same as in Mr. Parsons' test; and yet the results of the writer's tests were normal in every respect, while those of Mr. Parsons exhibited the striking anomalies previously mentioned. Therefore, the cause of these anomalies must be in the arrangement of Mr. Parsons' testing apparatus. When comparing the two devices the following differences are noted: The writer's model retaining wall was made of a 5-in. reinforced concrete lining, stiffened by extra heavy 24-in. I-beams. It weighed 13 tons, while the bulkhead described by Mr. Parsons consisted of 2-in. planks, bearing against a framework of wooden stiffeners and could certainly be lifted by two men. Furthermore, the width of Mr. Parsons' bin was only 5 ft as against a width of 14 ft for the writer's bin.

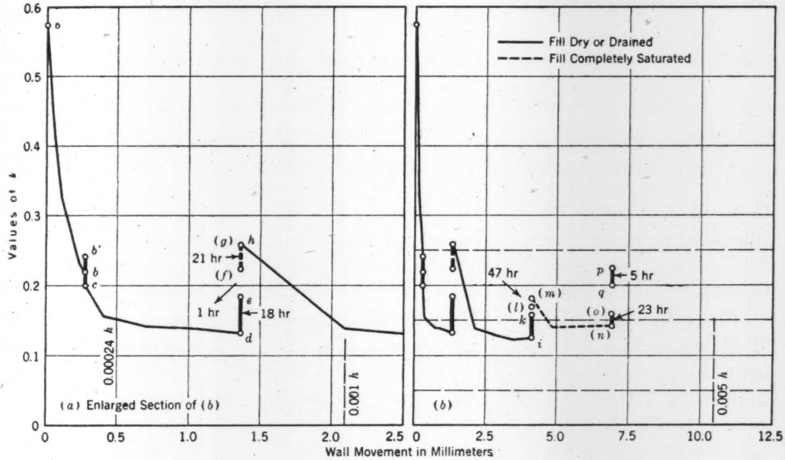

FIG. 16.

Hence, Mr. Parsons' bulkhead was very flexible if compared with the writer's model retaining wall. The relatively small width of Mr. Parsons' bin still further helped to increase the effect of the deflections of the wall on the value of the lateral pressure coefficient, *k*, because in a narrow bin a slight lateral expansion of the fill not only mobilizes the internal friction of the fill, but also the friction between the fill and the wall. Considering, in addition, the facts represented in Fig. 16, it is easy to visualize the causes of Mr. Parsons' startling results.

---

[26] See, also, *Engineering News-Record*, February 1, 1934, p. 136.

Let H ($= 2\,453$ lb) be the horizontal pressure exerted by the dry sand back-fill; H_1 ($= 7\,691$ lb), the horizontal pressure of the saturated sand back-fill, with water pressure included; H_2 ($= 5\,052$ lb), the horizontal pressure of the drained sand back-fill; x, the average deflection of the bulkhead under the influence of the horizontal force, H; and, $x_1 = x \frac{H_1}{H}$ and $x_2 = x \frac{H_2}{H}$, the average deflections of the bulkhead under the influence of a lateral pressure, H_1 and H_2, respectively.

The values, x, x_1, and x_2, are supposed to represent the deflections of the bulkhead with reference to the plane through the points of support, *A, B,* and *C,* in Mr. Parsons' Fig. 1 (*b*). Therefore, it is proper to assume that the values, x, increase in simple proportion with the intensity of the lateral pressure. For a quantitative study of the phenomena it would also be necessary to consider, in addition, the movements of the points of support.

Since H_1 is greater than H, saturation caused an increase of the deflection of the wall and a corresponding decrease of k. On the other hand, due to H_2 being smaller than H_1, drainage caused the bulkhead to press back again toward the fill, which produced a substantial increase of the value of k. The curves in Fig. 17 are the values of $k = \tan^2 (45 - \frac{1}{2}\,\phi)$ from Table 4 plotted against the deflections, x, of the wall.

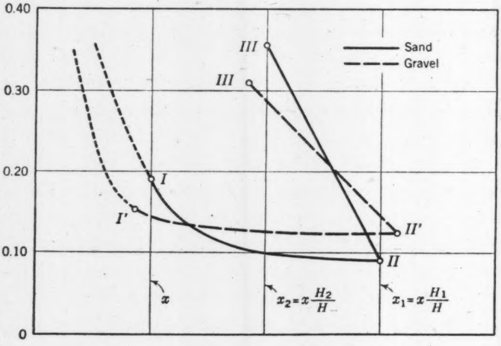

FIG. 17.

Knowing the importance of the effect of wall movements, the writer insisted on providing the aforementioned apparatus with a practically rigid wall, in spite of the expense involved. The braces and stiffeners of this wall were computed in such a way as to make certain that their deflections would have practically no effect on the intensity of the lateral pressure. The computation was based on the results of previous experiments. Unfortunately, Mr. Parson's paper does not contain the exact dimensions and the spacing of the bulkhead stiffeners required for determining the values of x in Fig. 17. For obtaining reliable data concerning this subject the writer suggests that the movements of Mr. Parsons' bulkhead be measured by means of Ames dials and that the deflections of its various structural members under the influence of water pressure, and, if possible, of the lateral pressure of a dry sand-fill, be determined likewise. A rough estimate based on the results of measuring the dimensions of the members of Mr. Parsons' retaining wall as contained in his diagrams, indicates a good agreement between the results of his tests and those of the Massachusetts Institute of Technology represented by Figs. 15 and 16.

Mr. Parsons' test arrangement for measuring the coefficient of internal friction must have been somewhat inadequate, since he obtained coefficients of internal friction of 64° 40′ and 58° 0′ against 48° 40′ and 48° 0′ for the dry materials. The latest American and European friction tests with first-class apparatus have demonstrated conclusively that the angle of internal friction for saturated sands it either equal to, or a trifle smaller than, the angle for the dry material.

The tests by Mr. Parsons have taught engineers that a repeated in-and-out movement of the wall leads to a kind of reversible state, in which the lateral earth pressure corresponding to the extreme positions of the wall becomes practically independent of the number of repetitions. This finding represents a valuable contribution to present knowledge of earth pressure.

R. L. VAUGHN,[27] M. AM. SOC. C. E. (by letter).—One important distinction made in this paper is that ϕ is the angle of internal friction, not necessarily the angle of repose. Other writers have recognized this fact in recent years, but it is one which should be emphasized. The well-known formula for horizontal earth pressure, $P = \frac{1}{2} w h^2 \tan^2 (45° - \frac{1}{2} \phi)$, was evolved long ago. The derivation was for an ideal granular material presenting no other internal resistance than that due to friction. For such a material it could be demonstrated that the angle of internal friction was equal to the angle of repose.

At a somewhat later date the proposition was demonstrated that when such an ideal material was submerged the same formula for horizontal earth pressure would apply, providing that, in such case, w be taken as the weight of material when submerged, in addition to which there would be full hydrostatic pressure corresponding to the given head of water. The present series of experiments marks the first attempt, of which the writer has any knowledge, to verify the last conclusion. The question is of importance in connection with the design of bulkheads and quay walls to retain submerged fills.

The author refers to ϕ as the angle of internal friction. Exception might be taken to this definition, and it is suggested that a better term would be "angle of internal resistance." It would be difficult to conceive of any manner in which the internal friction in compacted sand could be markedly increased when the sand was saturated, and it is evident that some property other than friction is brought into play by the inundation. This additional property is generally referred to as "cohesion," and it is supposed to be due to capillary action of the water in the small passages between the grains of sand. If this is the true explanation, then one might expect to find a much greater increase in internal resistance when sand was saturated than when gravel was saturated, because the water passages in the latter are much larger. The results of the author's tests tend to confirm this explanation.

---

[27] Cons. Engr., San Francisco, Calif.

If it is granted that the angle of resistance is due to a combination of friction and cohesion, it follows at once that the value of ϕ will vary with the depth of material, and the mathematics of the investigation become quite complicated. In addition, there is no experimental proof, as far as the writer knows, that either the friction or the cohesion remains constant with a varying water pressure. For instance, if the bank of sand 7 ft high, the pressure of which was measured by the author, had been resting against the base of a dam 200 ft high, the results might have been far different. It scarcely seems likely that such would have been the case, but the contrary has never been proved.

While in no wise wishing to disparage the author's results, which are valuable and interesting, the writer desires to point out that the tests are on a bank of sand only 7 ft high. They show a most marked change in the coefficient of internal resistance, for sand, upon inundation. This may be caused by the development of additional internal resistance due to capillary action. The numerical value of such capillary resistance, presumably, is limited. If this is true, its effect upon the coefficient of internal resistance would decrease as the total of such internal resistance, due to all causes, increased; that is, the additional resistance due to cohesion in the test case caused a change of 100% in the coefficient of internal resistance; but if this same amount of cohesion had been introduced into a bank of sand 100 ft high in which the true internal friction was many times as great, then upon inundation the change in the coefficient of resistance might have been relatively insignificant.

Actual experimental proof is urgently needed as to whether this relative change in the value of tan ϕ upon inundation holds good for high banks of soil, or whether as the depth becomes greater the importance of the observed effect decreases. Of even greater importance is the need for exhaustive experiments regarding the behavior of the cohesion in finer grained soils, such as silts and clays, under heavy pressures.

These questions are anything but academic. There is at present in prospect a resumption of hydraulic mining in California. Existing laws make mandatory the construction of dams to retain the débris from such operations, in order to avoid the silting up of the main rivers. There is a wide divergence of opinion among engineers as to the basis upon which such dams should be designed. One school claims that the pressure against such dams will actually be less than that due to a full head of water. Another group of engineers, in a position of some authority, insists that such dams shall be designed to withstand a pressure due to a liquid having a weight of 160 lb. per cu ft. In many cases, if not all, the decision as to whether or not mining shall be resumed will depend upon the cost of the necessary débris dam. Some of these dams may be considerably higher than 100 ft. No actual information concerning earth pressures, whether or not of saturated material, involving heights even approaching these, is known.

Direct measurements of ϕ by the method described in the paper, or by any other method, are difficult to make with any degree of accuracy. The fact that in this instance such direct measurements gave higher results than those derived from the observed pressures suggests the possibility that cohesion was present in the material when the direct measurements were taken. The effect of such cohesion would be to increase the value of tan ϕ for light loadings. Had the upper box in the measuring apparatus been weighted to give the average unit pressure that existed in the bin, the agreement between observed and derived values might have been closer.

It does not seem logical to suppose that the loss in total pressure upon partial inundation could be due to loss of weight in the submerged material, as the author suggests. It is true that when submerged the material loses weight, and that, if the value of ϕ were constant at all times, the pressure from the submerged earth would be less than that from the same earth when not submerged. However, the water of submergence exerts an additional pressure and, upon the principle that action and reaction must be equal, it would be impossible for the water, through its buoyant action, to take away more pressure than it itself added through its presence.

It is suggested that a more plausible explanation of this unexpected phenomenon may be found in the varying value of ϕ. The total pressure against the bulkhead may be regarded as made up of four parts: (*a*) The pressure of the dry earth, above the line of submergence, against that part of the bulkhead with which it comes in contact; (*b*) the pressure of the submerged earth, due to its own weight only, against that part of the bulkhead with which it comes in contact; (*c*) the pressure of the water against the submerged part of the bulkhead; and (*d*) the pressure against the submerged part of the bulkhead, exerted through the submerged earth, due to the load or surcharge upon that earth, caused by the dry earth above. The weight of this surcharge would not be the weight of the earth above, but would be that weight decreased by the amount of the friction of such earth against the face of the bulkhead, and the distribution of this imaginary surcharge would vary with the distance from the bulkhead. In computing Part (*a*) w and ϕ for dry sand would be used; for Part (*b*) the corresponding values for the inundated condition would be used; while for Part (*d*) the amount of the surcharge and its distribution would require further investigation and the value of ϕ for the submerged condition would be used. To put the idea in other words: When some of the material is submerged that portion loses weight, and there is a consequent loss in pressure. Furthermore, since ϕ is increased, the pressure due to the weight is further decreased; and, again, the weight of the unsubmerged earth above causes an additional pressure to be transmitted to the bulkhead through the submerged earth; but if the value of ϕ is increased, then the pressure so transmitted will be decreased. On the other hand, the water of submergence itself exerts a pressure against the bulkhead. Until some considerable depth of submergence is reached, the sum of the three losses may exceed the gain due to the presence of the water.

The suggestion that ϕ may show a marked and hitherto unsuspected increase on submersion, at least in the case of sands, is most interesting. If this result should be confirmed by further experiments and for greater depths, it might help to explain several observed facts which have not been accounted for in a completely satisfactory manner. Hydraulic dredge operators have long known that an otherwise deficient bulkhead could be relieved by pumping an embankment against it before completing the remainder of the fill. Just why this should be so, particularly where the material was a permeable one, such as a sand, has not been entirely clear, since before the fill could be completed the water level must be raised to the top, apparently giving a full hydrostatic head against the bulkhead in any event. The most common idea has been that the embankment first deposited had time to settle, consolidate, and develop cohesion. Undoubtedly, these factors had some effect, but the explanation has never been completely satisfactory to the writer and he has been inclined to suspect that leakage through the bulkhead, together with the well-known loss of head experienced by water flowing through earth, materially reduced the hydraulic head effective against the bulkhead. In other words, after the bulkhead had been protected by some width of earth the cracks and leaks in it served the same purpose as the weep-holes that every one knows should be placed in all retaining walls. The author's results indicate that, particularly in the case of fills which were partly submerged, an unexpectedly high value for ϕ might furnish a partial explanation. However, such a consideration could not explain how some bulkheads which evidently could not withstand a full water head alone, not to mention an additional load due to earth, could retain a dredger fill, and the writer still thinks that loss of head due to leakage is an important factor. It would be interesting to run another set of tests with the author's apparatus, leaving a number of small leaks in the bulkhead.

Most bulkhead design is an empirical affair at best. Some modern types of steel sheet-pile bulkhead are practically water-tight. If a steel bulkhead were designed so that each part of it were mechanically equal in strength to the corresponding part of some wooden bulkhead which experience had shown to be adequate, the designer might get into trouble because there was no leakage to relieve the water pressure.

Bulkheads depend on the passive resistance of the earth outside their toe for stability. Through a process of reasoning similar to that by which the pressure formula was derived, it can be shown that this resistance (sometimes called "passive pressure") is equal to: $R = \frac{1}{2}\, w\, h^2 \tan^2 (45° + \frac{1}{2}\, \phi)$. Both these formulas are not even approximately true for cases in which cohesion plays an important part, unless the pressure is measured first and then ϕ is computed to suit; in other words, if the answer is known, the formula can be "patched up." Any values of ϕ obtained by taking published "angles of repose," or by measurement of surfaces of repose, or by direct measurement of the same material under different conditions of moisture content and unit pressure, will give seriously erroneous results when substituted in either of these formulas, if cohesion is present at any time.

A number of reliable European experimental investigators have reported that the passive resistance was at least twice that given by the formula, for any sand or gravel having an angle of repose not flatter than two horizontal to one vertical. No one has ever proved that there was any inherent relation between the angle of repose and the angle of internal resistance (which governs pressures), except in some ideal case that probably never would be encountered in Nature. Furthermore, there was nothing in the accepted theory to account for this added resistance. It has seemed dangerous to rely upon such a factor in preparing a design, at least until some explanation was advanced which would indicate that the effect would be present invariably. The writer has been inclined to believe that the effect was reliable, and was due to friction on the face of the bulkhead, which would tend to increase the effective weight of the material that furnishes the passive resistance. However, in some cases at least, the effect could be explained through unsuspected variations in the value of ϕ which the author's tests indicate may be more common than might be supposed.

Comment is made in the paper concerning the slope assumed in Nature by banks of the material tested. This is by no means a rare phenomenon. It is a matter of every-day occurrence in the dredging business, in which case the sides of channels generally assume some kind of a curve, concave upward, and the upper part of the curve may approach the vertical. Such slopes bear scant resemblance to the natural side slopes not flatter than (say) two to one frequently mentioned in the specifications, and shown by straight inclined lines on the cross-sections. There have been many arguments about side slopes between dredging contractors and engineers. These curved slopes are doubtless due to the effect of cohesion or some similar property; theoretically a true granular, cohesionless material should assume a straight slope, but few materials ever do so under water.

M. HIRSCHTHAL,[28] M. AM. SOC. C. E. (by letter).—The difficulties encountered when making earth-pressure tests to obtain results that simulate actual conditions in the field are suggested in this paper describing Mr. Parsons' painstaking tests. For example, there is an utter lack of test data as a basis for studying the action or variation of earth pressure with increasing heights of fill and for different types of surcharge on such fills.

From the standpoint of the railroad engineer this particular problem is of great importance since a wide variation of conditions is encountered in railroad embankments. Observations on structures built in connection with such embankments have shown ample evidence of varying angles of repose in the same material for varying heights of embankment. Furthermore, examination of earlier structures built on the Delaware, Lackawanna and Western Railroad clearly indicates a flattening of the slopes with increase in heights of embankment such that the slopes in Table 9 have been adopted for use in the design of retaining walls of various heights, and in the determination of the dimensions of structures supporting such embankment.

---

[28] Concrete Engr., D. L. & W. R. R., Hoboken, N. J.

TABLE 9.—DESIGN DATA FOR EARTH PRESSURES

Height, in feet	$\tan^2 \frac{1}{2}(90 - \phi)$	Angle of repose	Slope
Up to 20........	0.286	33° 41′	1.0 on 1.5
20 to 30........	0.300	32° 33′	1.0 on 1.57
30 to 40........	0.315	31° 24′	1.0 on 1.64
More than 40....	0.333	30° 00′	1.0 on 1.732

It was found that even with this flattening of slope the fill would "slop" over the wing-walls, or over the parapets of supporting arch barrels, so that present practice is to make provision for a slope of 1.0 on 1.7 for all embankments between 20 ft and 40 ft, increasing the allowance for heights greater than 40 ft.

These results are bound up with the effect of sloping surcharge. The effects of both uniform and sloping surcharge have not been sufficiently analyzed and determined. It is quite certain that a surcharge of both types produces a change in the angle of "internal friction" as well as in the angle of repose of the underlying material in the course of the compaction of this material.

Mr. Parsons calls attention to the fact that the Rankine or Coulomb theory, for a fill without surcharge, yielded varying results for the angles between the horizontal and the planes of internal friction for dry soils and fully saturated soils. As far back as 1912 the writer emphasized[29] the inconsistency of results obtained by the application of either the Rankine or the Coulomb theory of earth pressures to uniform, as compared with sloping, surcharge for certain conditions.

The only reliable results obtainable as a guide for future design are to be sought (and found) through the installation of pressure-cells in actual construction, so as to register the pressure of the filling material against the retaining walls and abutments for the various conditions, including that of a surcharge that may obtain at a definite site and the resulting soil pressure on the foundations.

Engineers entrusted with such design and construction are earnestly urged to induce their clients to install these cells, in order to obtain the very valuable resulting information as a guide for subsequent design.

The question of weight of material, of course, is an interesting and important one in connection with the pressures against the structure, and no doubt the various degrees of saturation modify the results. There is an anomalous condition, however, produced by saturation, inasmuch as complete saturation may produce pressures apparently greater than hydrostatic pressures due to the greater apparent weight of the filling material than that of water; whereas the water produces an upward pressure causing buoyancy and a reduction in the weight of the filling material. This compensating effect of buoyancy would naturally reduce the resulting horizontal pressure and under certain conditions, possibly, bring it within the range of the pressure exerted by the dry material. These results will be greatly modified, of course, by the grading of the filling material.

---

[29] *Engineering News*, April 25, 1912, p. 799.

The weight of the filling material is of secondary importance in the design of retaining structures since it also plays the part of aiding the stability of the structure by means of the vertical component of the resultant pressure where the design involves a base or footing projecting into the fill, a batter in the direction of the fill, or a sloping surcharge.

Retaining walls never fail in shear through any section, and infrequently by sliding on the base. Most failures are due to excess of pressures at the toe (or abutment) resulting in possible overturning. A slight difference in the location of the resultant at the base will produce a marked difference in the maximum soil pressure at the toe, and this difference in the location of the resultant is traceable to the assumption of the angle of "internal friction" (or angle of repose) of the filling material in its action causing the overturning moment due to the horizontal thrust.

The question of internal friction is another puzzling one when it is considered that the filling material may be a uniform sand, each granule being an independent little mass more or less globular; or, it may be a rock fill laid in layers, with dirt filling the voids.

All these points indicate the need of further research on this important subject of earth or soil pressures—including foundation pressures, which are really passive resistance of the soil to superimposed pressures.

H. DE B. PARSONS,[30] M. AM. SOC. C. E. (by letter).—This research was made to study the horizontal pressure of a back-fill against a bulkhead or retaining wall. The numerical values apparently reflected a movement of the bulkhead. The results demonstrated (1) that there was a reduction in pressure at early stages of irrigation; (2) that the repetitions of irrigation and drainage cause no permanent change in the pressures; and (3) that there is a difference between internal friction and internal resistance of soil grains under wetted conditions. The second result is akin to a quay wall against which a tide rises and falls.

While compiling the test results, the writer conceived the theory that atmospheric pressure may have caused the reduction of the soil pressure when the soil was saturated. This theory will be elaborated more fully hereafter.

In Mr. Meem's box of 1-ft cube, the forces set up by tightening the bolts do not correspond with the pressures discussed in the paper. Mr. Meem evidently refers to "arching" as affecting the horizontal pressures of the tests. The repeated tests gave uniform results, and had arching existed to any marked extent, the results would have shown greater variation. Mr. Meem's idea of an apparatus having a wide width would help to avoid doubt as to arching, although increasing the expense of a test. The writer did consider a testing apparatus having water or oil rams for measuring the pressures, but he abandoned the rams because they were not as delicate as the scales for recording small differences in pressures.

---

[30] Prof. Emeritus, Rensselaer Polytechnic Inst., Troy, N. Y.; Cons. Engr., New York, N. Y. Mr. Parsons died on January 26, 1935.

Mr. Meem is correct in stating that the plane of rupture is curved, but he is in error in describing the angle of repose as between the vertical and the plane of repose. It is the angle between the horizontal and the plane of repose; and the planes of repose and of rupture are not identical.

Mr. Halmos was familiar with the manuscript of the paper, and concurred with the writer that minute possible movement of the bulkhead would not materially affect the results. Neither he nor the writer knew, at that time, the results of the experiments conducted at the Massachusetts Institute of Technology,[31] and no doubt Mr. Halmos would modify his opinion, in the light of these experiments, which showed that a slight movement of a bulkhead, or wall, decreased the active pressure.

Mr. Wilcoxen's analysis of the reduction in the pressure of the bulkhead, when the lower strata of the back-fill were immersed, is interesting; and his idea of capillarity may account for some soil phenomena. The writer believes that the irrigating water entered too fast for active capillary action to occur. Capillary water rises above gravity water by creeping between the particles due to some attractive force. Voids, left by the upward-moving capillary water, would be re-filled by water, and this water movement would be resisted by its surface tension and by friction of the water moving over the surfaces of the soil particles. This is a slow process, and capillarity requires time.

The unit weight of the sand in the test bin averaged more nearly the rodded weight of 111 lb than the rammed weight of 112.5 lb, as used by Mr. Wilcoxen. As the effective height of 6.906 ft was used, he should also have used the effective width of 4.75 ft instead of the full width of 4.926 ft from canvas to canvas.

It is of interest that Mr. Wilcoxen has referred to vacua as affecting the pressures in a mass of soil, and that Professor Terzaghi, in analyzing the Massachusetts experiments,[32] has also referred to vacua in his "suction-head", as both these ideas are analogous to the writer's vacuum theory,[33] which conceives a change due to atmospheric pressure in a soil under certain conditions, as will be mentioned more fully elsewhere.

Dr. Froehlich's eight premises are not open to argument, except that the weight of the soils as recorded were close average values rather than approximate. The "'rodded" weights, in Table 2, were considered to be closer to the average actual unit weights of the compacted materials in the testing bin, than the "rammed" unit weights, and the former were used by the writer. Dr. Froehlich considered that the bulkhead and bin walls were not rigid, and that movements, both outward and inward, took place during the tests. The side walls were strongly braced by waling-pieces and outside diagonal braces; they were always wet after the standardizing tests with water; and they had an outward thrust against them from the compacted fills, and this thrust was not removed by drainages although it was reduced. The bulkhead had a theoretical movement of 0.004 in. (0.1 mm) due to the scale attachments; and, if it did deflect, the actual movement is not known. During the tests, the writer assumed that there was no side-wall movement, and that the possible movement of the bulkhead was too minute to affect the horizontal thrusts of the back-fill materially. However, he must admit that some movement did take place and regrets that it was not actually measured. This change of opinion is due to the experiments made at the Massachusetts Institute of Technology.[31] In his discussion Professor Terzaghi has made a direct comparison with his Massachusetts experiments, and has shown the similarity between both sets of tests. The ratios found by the Massachusetts experiments are not numerically applicable to soils that differ from the cohesionless, coarse sand used in those experiments, but they do indicate the tendency.

---

[31] "Large Retaining Wall Tests", by Charles Terzaghi, M. Am. Soc. C. E., *Engineering News-Record*, February 1, and 22, 1934; March 8 and 29, 1934; and April 19, 1934.

[32] *Engineering News-Record*, March 19, 1934, p. 404.

[33] "Vacuum in Soil Mechanics", by H. de B. Parsons, M. Am. Soc. C. E., *Civil Engineering*, December, 1933, p. 690.

Dr. Froehlich believes it probable that the "passive" resistance on drainage accounts for the high values of the horizontal pressures as reported in the paper. When the water was drained, the full hydraulic pressure was released, and the bulkhead might have moved inward, causing the soil to resist being pushed back along its plane of rupture. This reverse action is known as the passive resistance, in contra to the active pressure of the soil wedge forcing the bulkhead outward.

Mr. Thackwell advocates using an "equivalent fluid pressure" method to find the approximate horizontal thrust of a soil wedge on a wall. Usually, this fluid method is based upon the assumption that the material acts like a liquid having a unit weight equal to that of the material, and that the result should be multiplied by a factor determined by experience. For fills without surcharge, this factor is the value of $\tan^2 (45^\circ - \frac{1}{2} \phi)$, and it varies between dry, saturated, and drained conditions. In the Massachusetts experiments, Professor Terzaghi used an hydrostatic pressure ratio, namely, the horizontal component of the soil pressure divided by the horizontal pressure that would be exerted by a liquid the unit weight of which is equal to the unit weight of the back-fill. In other words, the expected soil pressure would equal "$k \times$ liquid pressure". These experiments showed how k varied for slight movements of the wall. It is possible that a series of values may be established in the future for the tangent-square, or k, corresponding to varying weights of soils, arranged according to their characteristics, uniformity, dryness, saturation, and wetness (drained), to help obtain results sufficiently accurate for ordinary purposes.

Mr. Thackwell used a depth of 6.979 ft when computing his Table 7. It would have been more consistent to have used the effective head of 6.906 ft, as he used the water pressure at the effective head in the next to the last column of his table.

The writer does not believe that air binding caused the decreasing pressures during the beginning of the irrigations. He thinks it was due to the loss of weight (buoyancy) of the submerged soil and to the increase in the angle of internal resistance of that portion of the soil which was submerged. As the irrigating water rose in the back-fill the hydrostatic pressure increased sufficiently to offset this loss.

Mr. Feld's objection to the converging sides of the bin as causing a decrease of the pressure of the soils on the bulkhead, especially at the sides, is more theoretical than actual. The writer feels that the slope given to the sides materially reduced arching effects, as shown by the consistent results of the repeating tests, and that the benefits from the slope outweighed the disadvantages.

The slope of one side was 0.5 ft in 16 ft, or 0.031 ft per ft of length. The canvas nailed to one side was 0.037 ft in thickness; therefore, the slope of one side did not narrow the back-fill as much as the canvas thickness in the first 1.2 ft as measured on the surface of the fill back from the bulkhead. As a plane of rupture slopes from the surface toward the bulkhead, the narrowing of the back-fill by the contraction of the sides was progressively decreasing from the surface downward. Furthermore, an actual plane of rupture, in a soil having cohesion, is a curved surface concave to the bulkhead; it is not a true plane, and the distance from the bulkhead to the place where a curved rupture plane cuts the surface of a back-fill is less than the distance where the theoretical true plane of rupture would cut the surface. Furthermore, the layer of sand along the side walls, equal to the canvas thickness, helped to give more accurate results than if the bulkhead had been the full width from side wall to side wall. In other words, the layer of sand along the bottom (the $\frac{1}{4}$ in. below the bottom edge of the bulkhead) and the layers of sand along the sides bounded the wedge causing the pressures by soil and not by the bottom and the sides of the bin.

The writer believes the low values (for sand especially) for the position of resultant pressure were not caused by the shape of the bin, but by a movement of the bulkhead, the effect of which was not anticipated when the apparatus was designed.

Regarding loss of pressure at early stages of irrigation, the writer agrees with Mr. Feld in his statement that "additional moisture content under partial saturation decreased the pressure because of an increase in the coefficient of internal resistance of the material".

Mr. Davey's descriptions of actual failures are most interesting. Masonry is not homogeneous, and a stone wall is not of equal strength throughout its length. A break in a retaining wall would only approximate the theoretical slip of a fill or bank. The illustrations, however, are quite representative of the active forces.

Mr. Davey suggests that possibly the decrease in pressure on first irrigating was due to the compression of the soils, thus permitting them to fall away from the bulkhead. This suggestion is not the writer's idea. The soils were in compacted states, and settlement was not noticed. If any settlement did occur, it was minute. The 5% settlement, to which Mr. Davey refers, was with loose, not compacted, sand.

The writer accepts Professor Krynine's additional conclusion that quantitative results of the "behavior of soil in containers" can be extended to large actual structures only with great care. When accurate test results are correctly interpreted, the conclusions do present knowledge for the design of engineering structures. If the mathematical analysis is correctly applied, using approximately correct data, theoretical and actual results will be close enough to be covered by the usual factor of safety. The rear partition in the bin was too far back from the rupture plane to have had any influence on the pressures on the bulkhead, and the $\frac{1}{4}$-in. layer of soil below the lower edge of the bulkhead helped to remove the "bottom face" and tended to make the tests resemble natural conditions.

The experimental box was made to the dimensions as marked (Fig. 4), which were checked by a tape. The sides were held securely to the dimensions by the tie-rods across the top and by the bottom flooring. Each foot of depth above the bottom was marked on the sides. As the bulkhead was suspended $\frac{1}{4}$ in. above the bottom, the full depth of fill (as measured on the bulkhead) was 6.979 ft. In their discussions, both Dr. Froehlich and Professor Terzaghi state that there was deflection or movement. Measurements were not made to determine deflection of the sides. The bulkhead had a possible movement of 0.004 in. (0.1 mm) due to the scale attachments, and if it did deflect, such additional movement was not measured.

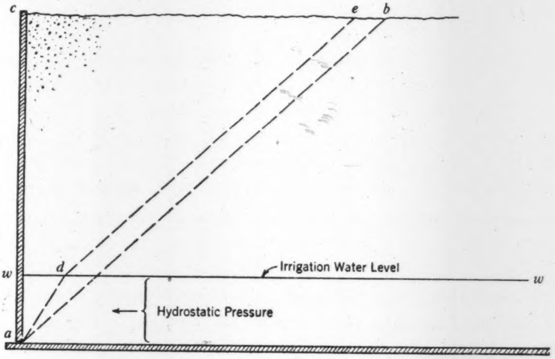

FIG. 18.

Professor Krynine's idea that surface tension of the capillary water causes the decrease of horizontal pressure at the beginning of irrigation is similar to that of Mr. Wilcoxen, mentioned previously. The tests showed that the angle of internal resistance increased when the soils were irrigated, and Fig. 18 illustrates the writer's idea of the loss of pressure at early stages of irrigation. Assuming for the sake of simplicity that the critical planes are true planes, let *ab* be the plane of rupture of the dry material; *abc,* the wedge causing pressure on the bulkhead; and let *ww* represent the level of the irrigation water at an early stage. The angle of internal resistance of the wetted material, *aw,* increased so that the critical plane of this material would be *ad,* while that of the dryer material above would be *de.* The wedge causing pressure would be *adec* smaller than the original wedge. In addition, the weight of the material in the wedge, *adw,* would be its weight in water. The bulkhead pressure would be increased by the hydrostatic pressure having a head, *aw.* As the irrigation water level rises the total pressure will increase faster than the reduction of pressure due to the soil. This reduction in pressure due to the "soil only" is shown in the horizontal distances, Fig. 3, between the curves marked "Water only" and "Irrigated". The writer has advanced the theory that the angle of internal resistance of an irrigated compacted soil is greater than its angle of internal friction, due to the action of atmospheric pressure.[33]

In the drained material, Professor Krynine believes that the water remaining was not uniformly distributed, but that the water content was more concentrated near the bottom. This is true if the material stands long enough in a drained state. The writer's assumption was made to avoid complication.

Professor Krynine is correct in stating that the calculated angles in Table 4 are angles of internal resistance, rather than of internal friction.

The writer believes that the wedge behind a retaining wall is bounded by a curved rupture plane. He has referred to a true plane only for the sake of more easily studying the pressure phenomena. In Nature, curvature of a rupture plane probably varies according to the amount of cohesion in a soil. A true plane can be conceived for simplicity as one which is an average of the curved surface.

Professor Terzaghi's discussion is of interest because he has explained many phenomena which were puzzling. The experimental apparatus at the Massachusetts Institute of Technology[31] was capable of great refinement, since it had means of measuring, closely, the movement of the wall. Professor Terzaghi's experimental wall weighed 13 tons, while the writer's bulkhead weighed about 800 lb, exclusive of the supporting rods.

The ¼-in. layer of soil below the bulkhead was arranged in order that the lower strata of soil would rest on soil and not on the floor of the bin. The effect of this layer on the results certainly tended toward accuracy.

A comparison with the results of the experiments at the Massachusetts Institute of Technology has been made by Professor Terzaghi and shows a general agreement. The Massachusetts experiments were made with artificially dried, cohesionless sand, having an effective size of 0.54 mm, and an uniformity coefficient of 1.70; while the soils in the writer's tests contained about 5½% of moisture, were not cohesionless, had effective sizes of 0.25 mm for sand, and of 0.57 mm for gravel, and had uniformity coefficients of 5.8 for sand and of 21.0 for gravel.

In the Massachusetts experiments, the value of k (horizontal pressure as measured divided by the horizontal pressure of a liquid the unit weight of which is equal to the unit weight of the back-fill) became smaller as the movable wall yielded outward. The bulkhead of the writer's apparatus vibrated while the back-fill was being placed and compacted. To protect the scale bearings and knife-edges, the scale lever arms were wedged. When the bin was filled, these wedges were withdrawn, so that the scales could operate. The movement of the bulkhead was limited to 0.004 in. (or 0.1 mm) which is equivalent to 0.00005 h (in which, h = depth of fill). At the time of testing, it seemed to the writer that this movement was too small to affect the results, but, in the light of Professor Terzaghi's experiments which were made to record the effect of a movable wall, it is probable that a movement of the bulkhead did cause a reduction in the horizontal pressures and in the values of k. The movements were so slight that slips and settlements were not noticed on the soil surface in the bin.

The writer's values for k are 0.22 for loose sand, 0.20 for compacted sand, and 0.16 for compacted gravel. These values are computed from the "corrected" results given for loose sand, and for compacted sand and gravel in Column (4), Table 4, using the rodded weights. The Massachusetts experiments recorded $k = 0.36$ for its loose sand, with an outward tilting movement of the wall of 0.00005 h; and for its compacted sand, with the wall yielding outward and parallel to its original position these experiments recorded values of $k = 0.31$ at 0.00005 h; $k = 0.21$ at 0.0001 h; and $k = 0.18$ at 0.00015 h. As the bulkhead described in the paper was hung from links above (Fig. 1), any movement resembled the Massachusetts Test No. 2, in which the wall yielded parallel to its original position.

In the Massachusetts experiments, the centers of pressure were higher than in the writer's tests, but this may have resulted from the fact that the writer's bulkhead moved outward more at the bottom than at the top, whereas the wall of the Massachusetts experiments moved in the reverse direction (see Tests Nos. 1 and 3)[34], or equally at top and bottom (see Test No. 2).

According to Professor Terzaghi,[34] the horizontal pressure ratios, k, depend on the intensity of the frictional stresses that act within the wedges, and the greater these stresses the smaller is the corresponding value for k. This is the same conclusion that the writer's tests illustrated, and the effect of atmospheric pressure may offer a possible explanation, especially for wet soils, as will be explained hereafter.

Six Goldbeck cells were used by the writer, but were not mentioned in the paper, because they did not "make and break" contact sharply so as to give results sufficiently accurate for his research. As Professor Terzaghi used Goldbeck cells in the Massachusetts experiments[35], it would increase general knowledge to record the writer's experience.

The cells were in pairs, three on approximately the center line of the bulkhead and three on one side wall 15 in. back from the bulkhead. The upper pair were 2 ft below the surface of the back-fill, the middle pair, 3 ft 6 in., and the bottom pair, 6 ft. Each cell was set in a mortise and the space around it was tightly packed, making the face of the cell flush with the inner surface of the bin. The air and electric connections entered from the outside, and the pressures were recorded in inches of mercury. The cells were calibrated during the standardizing tests with water, and corrections found for each. It is possible that the corrections for water did not hold true for sand, and, also, as the cells stood vertically, the sand pressures recorded might not have been the true horizontal pressures, but diagonal pressures of an unknown degree.

[35] *Loc. cit.*, February 22, 1934, p. 262.

The pressures, in inches of mercury, as averaged from the records of four dry tests, ten irrigated tests, and eight drained tests of compacted sand, are given in Table 10. The pressures for "sand only" under saturated conditions were found by subtracting from the cell readings for saturated sand the readings for water under the same head as the depth of back-fill. Table 10 gives the readings for the cells on the bulkhead, and on the side wall, as mentioned. The average pressures are plotted in Fig. 19, and the pressure curves drawn. These curves reflect any movement of the writer's bulkhead which may have made the pressures on the bulkhead cells generally lower than those on the side-wall cells (see Table 10).

TABLE 10.—PRESSURE, IN INCHES OF MERCURY, DETERMINED BY GOLDBECK CELLS.

DESCRIPTION OF SAND	DRY			SATURATED SAND ONLY			DRAINED		
Cells	Bulk-head	Side wall	Average	Bulk-head	Side wall	Average	Bulk-head	Side wall	Average
Upper........	1.24	1.33	1.285	0.94	0.88	0.910	1.42	1.31	1.365
Middle.......	1.45	1.86	1.655	0.72	0.88	0.800	1.51	2.66	2.085
Bottom......	2.25	2.45	2.350	0.63	0.70	0.665	2.76	3.17	2.915

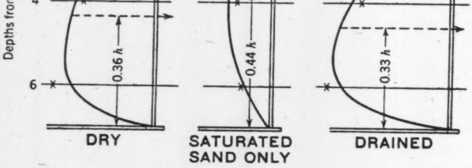

FIG. 19.—PRESSURES AS RECORDED BY GOLDBECK CELLS.

The writer recognized, before reading Mr. Vaughn's discussion, that there seems to be a difference between "internal friction" and "internal resistance", and has used the latter expression in his closure. There seems to be more than "friction" between the grains of a compacted and saturated fill before slipping can occur on a critical plane. Under conditions of a compacted fill that is saturated (not super-saturated) the voids are filled with water, and the writer's theory[33] is that the partial vacua created when the grains tend to, or do, move apart on a plane of rupture cause a portion of the atmospheric pressure to resist movements and to hold the grains from separating. The water in the voids cannot expand (like a gas) when the grains try to move away from their neighbors. However, time and the surface tension of the water may affect the results. Atmospheric pressure is similar to hydrostatic pressure, and acts through the grains of the soil where they are in intimate contact, and also on the water in the interstices between the grains. In consequence, a critical plane, to cause slipping, would have to be steeper for a saturated soil than for the same soil in dry condition; that is, the angle, ϕ, commonly called the "angle of internal resistance", would be greater for saturated than for dry conditions.

To illustrate, let MF (Fig. 20(*a*)), represent a part of a plane of rupture for a dry soil. Draw the vertical, MG, to denote the weight of the soil above M, and GF normal to the plane. Then, MF would be the shear or internal friction, just causing rupture. If the same soil is saturated and partial vacua tend to form at M when the grains above the plane of rupture try to move, a portion of the atmospheric pressure would act along MA, and MX would be its vertical component. Then, lay off XW to denote the weight above M, of the soil in water; and draw the normal, WF_1. The new shear, MF_1, would be less than that required for rupture. If the plane of rupture is made steeper (see MF_1, Fig. 20(*b*)), and MA represents the same unit value for air pressure as before, MX, its new vertical component, and XW, the weight of soil in water as before, the value of MF_1, or shear, will be equal to or greater than MF in Fig. 20(*a*), and rupture will occur. The line, HF_1, represents the horizontal pressure, and will be smaller under

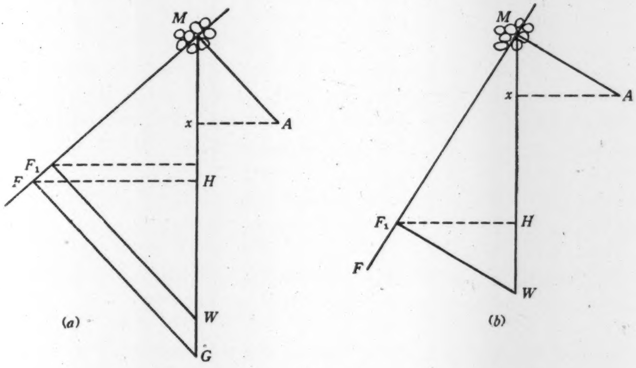

FIG. 20.

saturated conditions than *HF* under dry conditions in Fig. 20(*a*), which is the result shown by the tests.

The writer has given values to these lines from his test records, and it would appear that the air pressure under saturated conditions which would just cause rupture in Fig. 20 (*b*), would be less than one-quarter of an atmosphere.

From an inspection of Fig. 20, it is seen that, near the surface of a back-fill, the weight, *MG,* is small and the plane of rupture must be steep to cause slipping. Farther down in the fill the weight, *MG,* is greater, and the plane can be less steep to create an equal shearing force. This may explain why banks cave on curved surfaces, and why surfaces of rupture for soils are curved and not true planes.

With a saturated back-fill or deposit, against the lower part of the back of a dam which is submerged by the water in the reservoir (the voids being full of water with the grains in a compacted state and not forced apart by super-saturation), it would seem that the same conditions apply as described for a saturated back-fill, the surface of which is exposed to atmospheric pressure. The wedge of the submerged back-fill exerting pressure on the dam would be bounded by its plane of rupture. The total pressure would act with full effect through the mass and would tend to prevent the grains from separating on a normal plane of rupture causing an increase in the size of the voids. Therefore, the plane of rupture would have to be steeper before gravity could separate the grains and slip could occur. If the mass of the fill is super-saturated—that is, if the grains are separated by super-saturation—it is conceivable that the water would act as a lubricant and diminish the angle of internal resistance.

It would seem that atmospheric pressure has a more important part in many soil phenomena than has been recognized heretofore, and its action is more than a relation to capillarity. The tests show that drainages removed the "vacua" support, while subsequent irrigations restored it. The repetitions of loss and recovery of support were very consistent in the tests.

Referring to Mr. Vaughn's discussion of the reduction in horizontal pressure during the first stages of irrigation, the writer mentioned in his paper that the phenomenon was probably caused by the loss of weight of that part of the back-fill which was submerged and to a change in the angle, ϕ, due to the irrigation water. An increase in the angle of resistance would reduce the pressure from the irrigated portion of the fill, both by reduced weight of soil and size of wedge, and would also reduce the size of the wedge of the dry part above. At early stages of irrigation, these reductions might be less than the additional hydrostatic pressure, as explained in connection with Fig. 18.

Mr. Hirschthal mentioned soil-pressure cells, and the writer's results of pressures recorded by the cells used in his research are mentioned herein. In further explanation of Mr. Hirschthal's reference to internal friction, the writer calls attention to the effect of the movement of the bulkhead holding the back-fill, and to the atmsopheric pressure acting internally in the soil mass, thus increasing "internal friction" to "internal resistance". Both these subjects have been discussed herein.

WATER-BEARING MEMBERS OF ARTICULATED BUTTRESS DAMS

By Hakan D. Birke,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. R. A. Sutherland, P. Wilhelm Werner, Charles P. Williams, Paul Baumann, A. Floris, and Hakan D. Birke.

Synopsis

This paper presents a scientific method of determining mathematically, the most economical proportions of the water-bearing members of the articulated type of buttress dam.

Introduction

Wide buttress spacings combined with massive masonry sections are improvements in buttress dam design that have accompanied the recent trend toward the use of dams of great height. Greater safety and economy have been attained through these improvements, and through the more scientific methods of design that have been developed at the same time. At first, the use of a wide buttress spacing was confined to the multiple-arch and multiple-dome types of dam. However, the unsuitability of these types to faulted, or otherwise poor, foundations has led to the improvements of the well-known flexible, "articulated," type of dam, using thick, widely spaced buttresses instead of the relatively thin, closely spaced buttresses that have been common to this type. Fortunately, the characteristics of massiveness and wide spacing have been found to be as economical for articulated dams as they were for the rigid types and, in addition, the flexibility of this type makes it suitable for sites with poor foundations, such as are frequently encountered, and for those subjected to earthquake shocks or other foundation movements.

The use of thick buttresses and wide spacing has introduced new problems in the design of the water-bearing members or decks and the haunches. Two types of flexible water-bearing members are suitable for use in connection with long spans, the first of which (Fig. 1(*b*)), consists of a gradually

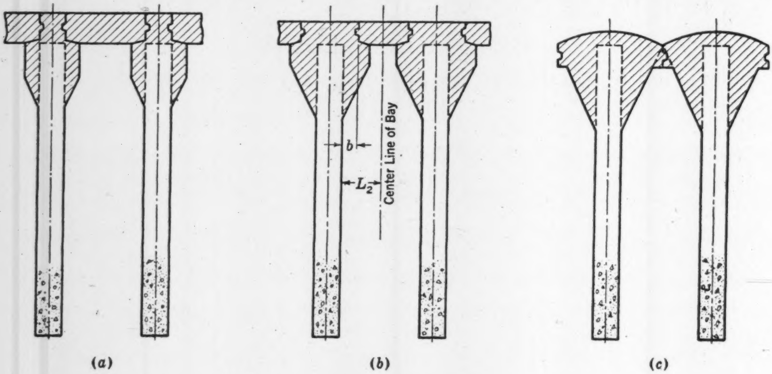
---

Note.—Published in September, 1933, *Proceedings*.

[1] Designing Engr., Ambursen Dam Co., New York, N. Y.

flaring buttress section connected with a short reinforced concrete slab[2]; and the other (Fig. 1(*c*)), is the round-head type.[3] For purposes of comparison a standard Ambursen type deck is shown in Fig. 1(*a*). It will be noted (Fig. 1(*b*)) that for the dimension, $b = 0$, this type will be identical with the original type shown in Fig. 1(*a*), and for $b = L_2$ (see Fig. 1(*b*)), the deck will be replaced entirely by the enlarged haunches shown in (Fig. 1(*c*)).

Heretofore, the economic limits of each of the three types shown in Fig. 1 have been determined by the tedious method of trial designs. It is a matter of considerable economic importance to determine the correct relations between length of span, bearing surface of slab, depth of haunch, slope of haunch, the height at which the deck slab may be omitted, and the height at which the flared buttress sections may be brought in contact to form a round-head type of water-bearing member. In order to facilitate the economic design of these flexible water-bearing members, equations and curves have been developed, through which the relations outlined in the foregoing are easily and quickly obtained.



(a) (b) (c)

FIG. 1.

NOTATION

The following symbols adopted for use in this paper, are listed for the guidance of discussers:

a = width of haunch bearing (Fig. 2).

b = one-half the difference between tongue and buttress thickness (Fig. 1(*b*)).

c = one-half the buttress thickness (Fig. 4(*b*)).

d = effective depth: d_1, at the outer face; and d_2, the depth of deck (Fig. 4(*b*)).

e = (a ratio, multiplied by 100) the increase in percentage of steel due to bent-up bars and hooks: e_1, haunch steel; and e_2, deck steel (Equation (34)).

[2] "Recent Advances in Buttress Type Dams," by Calvin V. Davis, M. Am. Soc. C. E., *Civil Engineering*, February, 1931.

[3] "The Design and Construction of Dams," by Edward Wegmann, M. Am. Soc. C. E.

f = allowable unit stress: f_c, in concrete; and f_s, in steel (Equation (35)).
i = depth of cover for steel: i_1, in haunch; and i_2, in deck (Equation (18)).
j = factor of distribution of shear: j_1, in haunch; and j_2, in deck.
p = unit loading: p_0, maximum on haunch, from the deck (Equation (1)).
s = tangent of the slope of the under side of the haunch on sections normal to the deck (Fig. 2).
x = variable distance along an X-axis.
A = substitution factor, with appropriate subscript (Equation (8)).
B = substitution factor, with appropriate subscript (Equation (25)).
C = total cost, in dollars: C_c, of concrete in deck and haunch; C_h, of steel in haunch; C_d, of steel in deck; C_t, of concrete and steel in deck and haunch.
D = unit cost: D_c, of concrete, in dollars per unit volume; D'_c, of concrete, in dollars per cubic yard; D_s, of steel, in dollars per unit volume; D'_s, of steel, in dollars per pound.
E = modulus of elasticity.
F = substitution factor, with appropriate subscript.
G = substitution factor, with appropriate subscript.
H = depth below maximum high-water level to the under side of the deck.
J = substitution factor, with appropriate subscript.
K = substitution factor, with appropriate subscript.
L = one-half span: L_1 = one-half the clear deck span; and L_2, one-half the clear buttress spacing.
M = bending moment.
N = substitution factor, with appropriate subscript.
Q = substitution factor, with appropriate subscript.
R = area of steel: R_1 = area required for a given bending moment.
V = volume: V_c, of concrete in deck and haunch; V_h, of steel in haunch; and V_d, of steel in deck.
W = loading on deck per unit area.
τ = allowable shear in haunch.
μ = coefficient of friction.
ν = allowable shear in deck; $\nu_{max.}$ = maximum shear.
σ = principal stress: σ_1 equals first principal stress in buttress.

The symbols for costs and volumes of materials in haunch and deck are given for one-half a bay, and per unit length of deck and haunch (see Fig. 4).

RELATION OF HAUNCH DIMENSIONS TO LOADING DISTRIBUTION AND HAUNCH SLOPE

The haunch may be considered as a cantilever beam with length, a (see Fig. 2). The loading from the deck is assumed to be triangularly distributed with a maximum value of p_0. The effective depth of the haunch at the outside face is equal to d_1 and the cover for the steel is equal to i_1. As the length of this beam will be small compared with the depth, the maximum allowable shear will govern the dimensions. The location of the section in the haunch where the shear is maximum must be determined, and the haunch

designed considering the shear at this section. For example, consider the part of the haunch between the plane, *A-A* (Fig. 2), and the outer face of the haunch.

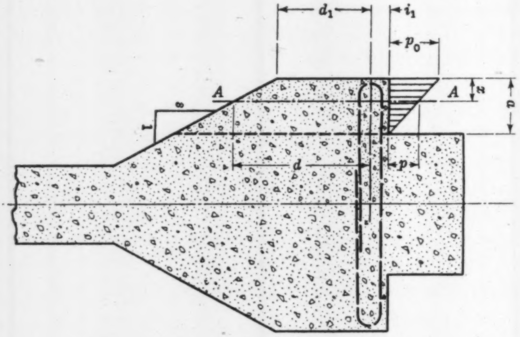

FIG. 2.—NORMAL SECTION THROUGH HAUNCH.

Let τ = shear along the plane, *A-A*; p = unit loading at the plane, *A-A*; and d = effective depth of haunch at the plane, *A-A*. Then,

$$p = p_0 - \frac{x}{a} p_0 \quad \text{. . . . .} \quad (1)$$

and,

$$d = d_1 + s x \quad \text{. . . . .} \quad (2)$$

Summing up the vertical forces for the element of haunch limited by the plane, *A-A*, will give Equation (3):

$$\tfrac{1}{2} (p + p_0)\, x - j_1 \tau d = 0 \quad \text{. . . . .} \quad (3)$$

Combining Equations (1), (2), and (3) and re-arranging,

$$j_1 \tau d_1 = x (p_0 - \tau j_1 s) - \tfrac{1}{2} p_0 \frac{x^2}{a} \quad \text{. . . . .} \quad (4)$$

The distance, x, should be determined so that the depth, d_1, becomes a maximum. Therefore,

$$\frac{\partial d_1}{\partial x} = 0 \quad \text{. . . . .} \quad (5)$$

From Equations (4) and (5), by differentiating and solving for x,

$$x = \left(1 - \frac{j_1 \tau s}{p_0}\right) a \quad \text{. . . . .} \quad (6)$$

Substituting this value of x in Equation (4) and solving for d_1 will give,

$$d_1 = \tfrac{1}{2} \frac{j_1 \tau}{p_0} \left(\frac{p_0}{j_1 \tau} - s\right)^2 a = A a \quad \text{. . . . .} \quad (7)$$

Cancelling a in Equation (7):

$$2 \frac{p_0}{j_1 \tau} A = \left(\frac{p_0}{j_1 \tau} - s\right)^2 \quad \text{. . . . .} \quad (8)$$

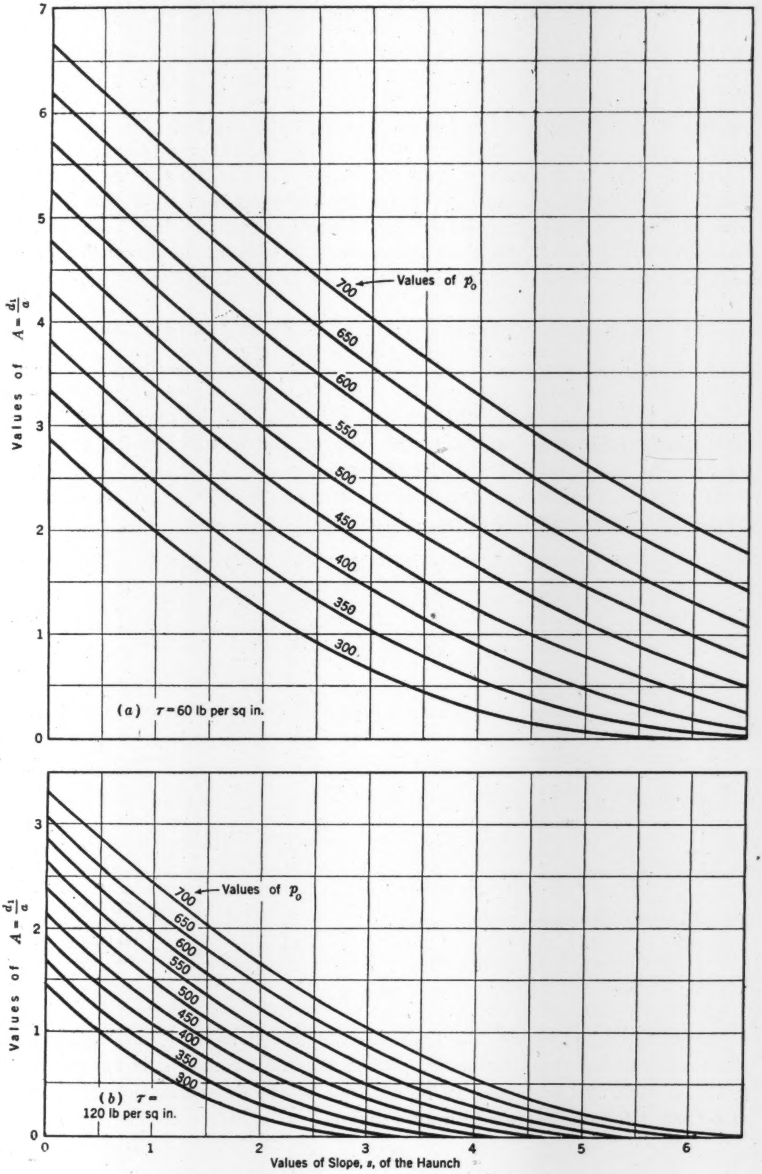

FIG. 3.—VALUES OF A IN EQUATION (8).

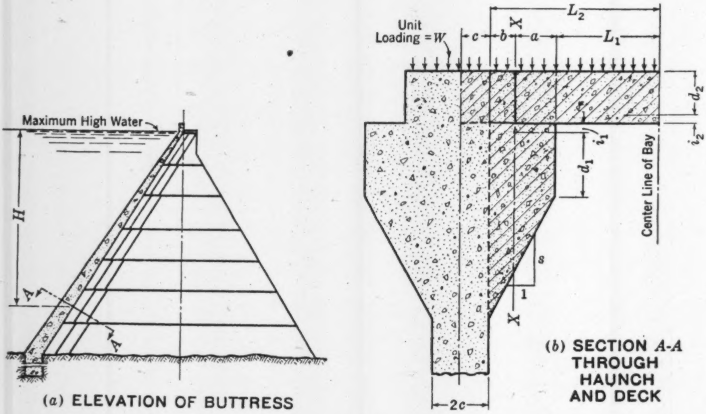
For p_0, j_1, and τ being constants, and A and s being variables, Equation (8) will represent analytically a parabola with its top in the point, $s = \frac{p_0}{j_1 \tau}$ and $A = 0$.

In Fig. 3, Equation (8) is represented in curves for two cases of allowable shear in the haunch, namely, $\tau = 60$ lb per sq in., and $\tau = 120$ lb per sq in. When the maximum bearing pressure, p_0, is known, the factor, A, may be found conveniently from these charts for different values of shear, τ, and haunch slope, s. The factor, j_1, for shear distribution has been assumed constant at $j_1 = 0.875$. When the value of A is known, the dimensions of the haunch are determined by the aid of $d_1 = Aa$ (Equation (7)).

ECONOMICAL RELATIONS OF DECK AND HAUNCH DIMENSIONS TO HEIGHT OF DAM

In the following analysis of the economic proportions of water-bearing members, only the costs of the concrete and steel will be considered because, with the same buttress spacing, the cost of forms will remain practically constant for the three types under discussion.

It will be convenient to introduce the distance, b (Fig. 4), as a variable and then express other variable dimensions as functions of b. The total volume of concrete and steel may be expressed as functions of b, and so may also the total costs of these elements. When the total cost, C_t, is expressed as a function of b, the problem will be confined to the determination of the value of b that will make C_t a minimum; that is,



(a) ELEVATION OF BUTTRESS

(b) SECTION A-A THROUGH HAUNCH AND DECK

FIG. 4.

$$\frac{\partial C_t}{\partial b} = 0 \quad \text{.........................} \quad (9)$$

Let V_c = the volume of concrete in deck and haunch; D_c, the cost of concrete per unit volume; and C_c the total cost of concrete in deck and haunch. Then,

$$C_c = D_c V_c \qquad (10)$$

In the same manner, the cost of the steel in the haunch will be expressed by the equation,

$$C_h = D_s V_h \qquad (11)$$

in which, V_h = the volume of steel in the haunch; D_s, the cost per unit volume of steel; and C_h, the cost of steel in the haunch. For the deck steel, the equation will be:

$$C_d = D_s V_d \qquad (12)$$

in which, V_d = the volume of steel in the deck; and C_d, the cost of the steel in the deck. The total cost, C_t, of concrete and steel in haunch and deck will be determined by the equation,

$$C_t = C_c + C_h + C_d = D_c V_c + D_s (V_h + V_d) \qquad (13)$$

Applying Equation (9) to Equation (13),

$$D_c \frac{\partial V_c}{\partial b} + D_s \left(\frac{\partial V_h}{\partial b} + \frac{\partial V_d}{\partial b} \right) = 0 \qquad (14)$$

SOLUTION OF EQUATION (14)

There will be two general cases of analysis: Case I, in which shear governs the thickness of the deck; and Case II, in which bending governs the thickness of the deck.

Case I: Determination of $\frac{\partial V_c}{\partial b}$.—The volume of concrete in haunch and deck per unit of length (see hatched area in Fig. 4(*b*)) = V_c:

$$V_c = (L_2 + c) i_2 + (L_2 + c) d_2 + (a + b) i_1 + (a + b) d_1 + \tfrac{1}{2} (a + b)^2 s \qquad (15)$$

Let,

$$i_1 + d_1 = K_1 d_1 \qquad (16)$$

then, Equation (15) becomes,

$$V_c = (L_2 + c) i_2 + (L_2 + c) d_2 + (a + b) K_1 d_1 + \tfrac{1}{2} (a + b)^2 s \qquad (17)$$

The width of the haunch bearing, a, is determined by the equation,

$$a = \frac{2 W (L_2 - b)}{p_0} \qquad (18)$$

One-half the clear deck span is determined by the equation,

$$L_1 = L_2 - (a + b) \qquad (19)$$

Substituting the value of a (Equation (18)), in Equation (19),

$$L_1 = \frac{(L_2 - b)(p_0 - 2 W)}{p_0} \qquad (20)$$

The effective depth, d_2, of the deck as required for maximum shear, ν, is determined by the usual equation,

$$d_2 = \frac{W L_1}{\nu\, j_2} = \frac{W}{\nu\, j_2} \; \frac{(L_2 - b)\;(p_o - 2\,W)}{p_o} \quad \ldots\ldots\ldots\ldots\ldots (21)$$

The effective depth, d_1, of the haunch is determined by Equation (7), thus $d_1 = A a$. Substituting the value of a (Equation (18)), in Equation (7) will give, as a result, the equation,

$$d_1 = A \; \frac{2\,W\,(L_2 - b)}{p_o} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Combining Equations (18), (20), (21), and (22) with Equation (17), and re-arranging,

$$V_c = \left(1 + \frac{c}{L_2}\right) i_2\, L_2 + (p_o - 2\,W)\,\frac{W}{p^2_o}\left[B + G\,\frac{b}{L_2} - \tfrac{1}{2}\,J\,\frac{b^2}{L^2_2}\right] L^2_2 \,\ldots (23)$$

in which,

$$B = \frac{4\,K_1\,A + 2\,s}{p_o - 2\,W}\; W + \frac{p_o}{\nu_{\mathrm{max.}}\, j_2}\left(1 + \frac{c}{L_2}\right) \quad \ldots\ldots\ldots\ldots (24)$$

$$G = 2\,K_1\,A\;\frac{p_o - 4\,W}{p_o - 2\,W} + 2\,s - \frac{1 + \dfrac{c}{L_2}}{j_2}\;\frac{p_o}{\nu_{\mathrm{max.}}} \quad \ldots\ldots\ldots\ldots (25)$$

and,

$$J = 4\,K_1\,A - s\left(\frac{p_o}{W} - 2\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Differentiating V_c with respect to b will result in the equation,

$$\frac{\partial V_c}{\partial b} = (p_o - 2\,W)\,\frac{W}{p^2_o}\left[G - J\,\frac{b}{L_2}\right] L_2 \ldots\ldots\ldots\ldots\ldots (27)$$

Case I: Determination of $\dfrac{\partial V_h}{\partial b}$.—Let M equal the bending moment in the haunch at Section X-X (Fig. 4(b)), and d, the effective depth of the haunch at Section X-X; then,

$$M = (L_2 - b)\,W\,\frac{2\,a}{3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

and,

$$d = d_1 + a\,s \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

or, by substituting the value for d_1 from Equation (7), $d = a\,(A + s)$.

Let R_1 equal the steel area required for the bending moment,

$$R_1 = \frac{2}{3}\;\frac{(L_2 - b)\;W}{(A + s)\,j_1\,f_s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

in which, j_1 is the distribution factor for shear, and f_s, the allowable tensile stress in steel. (For other symbols, see Fig. 4.)

For movements in the deck, caused by temperature changes, etc., a pull will be exerted on the haunch due to friction between the deck and the haunch surfaces. If μ is the coefficient of friction between deck and haunch and if R_2 is the steel area required for this pull, the following equation results for the steel area required,

$$R_2 = \frac{\mu (L_2 - b) W}{f_s} \quad \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

Let R_h equal the total steel area required in the haunch for bending moment and pull from the deck. Then,

$$R_h = R_1 + R_2 = \frac{L_2 - b}{f_s} W \left[\frac{2}{3 j_1 (A + s)} + \mu\right] \ldots\ldots\ldots (32)$$

Now the volume of the haunch steel is determined by the equation,

$$V_h = (1 + e_1)(a + b + c) \frac{L_2 - b}{f_s} W \left[\frac{2}{3 j_1 (A + s)} + \mu\right] \ldots\ldots (33)$$

in which, e_1 is a factor for the increase in steel due to hooks, shear bars, etc., in the haunch. Let,

$$N = (1 + e_1) \frac{p_0}{f_s} \left[\frac{2}{3 j_1 (A + s)} + \mu\right] \ldots\ldots\ldots\ldots\ldots (34)$$

Introducing the value of a in Equation (33), it may be written,

$$V_h = (p_0 - 2W) \frac{W}{p_0^2} \left[\frac{p_0 \frac{c}{L_2} + 2W}{p_0 - 2W} + \frac{p_0\left(1 - \frac{c}{L_2}\right) - 4W}{p_0 - 2W} \frac{b}{L_2} - \frac{b^2}{L_2^2}\right] N L_2^2 \ldots (35)$$

Differentiating V_h with respect to b:

$$\frac{\partial V_h}{\partial b} = (p_0 - 2W) \frac{W}{p_0^2} \left[\frac{p_0\left(1 - \frac{c}{L_2}\right) - 4W}{p_0 - 2W} - 2\frac{b}{L_2}\right] N L_2 \ldots\ldots (36)$$

Case I: Determination of $\frac{\partial V_d}{\partial b}$.—The bending moment in the center of the deck span is expressed by,

$$M = \frac{1}{8} W [2(L_2 - b) - a]^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

and the steel area required for this bending moment is,

$$R_d = \frac{W [2(L_2 - b) - a]^2}{8 j_2 d_2 f_s} \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

Introducing values for a and d_2 from Equations (18) and (21), and simplifying:

$$R_d = \frac{1}{2 f_s} \frac{\nu}{p_0} \frac{(p_0 - W)^2}{p_0 - 2W} (L_2 - b) \ldots\ldots\ldots\ldots\ldots\ldots (39)$$

Let V_d equal the volume of steel in the deck slab; then,

$$V_d = \frac{1}{2} (p_0 - 2W) \frac{W}{p_0^2} F (L_2 - b)^2 \ldots\ldots\ldots\ldots\ldots (40)$$

in which,

$$F = (1 + e_2)\,\frac{v}{f_s}\,\frac{p_0}{W}\left(\frac{p_0 - W}{p_0 - 2\,W}\right)^2 \ldots\ldots\ldots\ldots\ldots (41)$$

and e_2 is the factor for increase in steel due to hooks and bent-up bars in the deck slab.

Differentiating Equation (40) with respect to b:

$$\frac{\partial V_d}{\partial b} = -\,(p_0 - 2\,W)\,\frac{W}{p_0^2}\,F\left(1 - \frac{b}{L_2}\right)L_2 \ldots\ldots\ldots\ldots (42)$$

Introducing the values of $\frac{\partial V_c}{\partial b}$, $\frac{\partial V_h}{\partial b}$, and $\frac{\partial V_d}{\partial b}$ from Equations (27), (36) and (42) into Equation (14), will result in the following equation:

$$(p_0 - 2\,W)\,\frac{W}{p_0^2}\left[D_c\left(G - J\,\frac{b}{L_2}\right) + D_s\left(N\,\frac{p_0\left(1 - \frac{c}{L_2}\right) - 4\,W}{p_0 - 2\,W} - 2\,N\,\frac{b}{L_2} + F\,\frac{b}{L_2} - F\right)\right]L_2 = 0 \ldots\ldots\ldots\ldots (43)$$

From the expression within the square brackets, b, may be solved, thus:

$$b = \frac{G + \left(\frac{p_0\left(1 - \frac{c}{L_2}\right) - 4\,W}{p_0 - 2\,W}\,N - F\right)\frac{D_s}{D_c}}{J + (2\,N - F)\,\frac{D_s}{D_c}}\,L_2 \ldots\ldots\ldots\ldots (44)$$

Case II.—Determination of $\frac{\partial V_c}{\partial b}$.—Let L_b equal the bending span for the deck slab. Then,

$$L_b = 2\left(L_1 + \frac{a}{2}\right) = \frac{2}{p_0}\,(p_0 - W)\,(L_2 - b) \ldots\ldots\ldots (45)$$

The maximum bending moment for the deck is expressed by,

$$M = \frac{1}{2}\,\frac{W}{p_0^2}\,(p_0 - W)^2\,(L_2 - b)^2 \ldots\ldots\ldots\ldots\ldots (46)$$

The deck thickness, d_2, may now be determined from the usual formula,

$$M = K\,b\,d_2^2 \ldots\ldots\ldots\ldots\ldots\ldots (47)$$

Combining Equations (46) and (47) and solving for d_2 will result in the equation,

$$d_2 = \frac{p_0 - W}{p_0}\sqrt{\frac{W}{2\,K}}\,(L_2 - b) \ldots\ldots\ldots\ldots\ldots (48)$$

Introducing this value of d_2 in Equation (17) will result in an equation identical with Equation (23), but in which:

$$B' = \frac{W}{p_0 - 2\,W}\left[4\,K_1\,A + 2\,s + (p_0 - W)\,\frac{p_0}{W^2}\sqrt{\frac{W}{2\,K}}\left(1 + \frac{c}{L_2}\right)\right] \ldots (49)$$

and,

$$G' = -\frac{p_0 - W}{p_0 - 2W}\frac{p_0}{W}\sqrt{\frac{W}{2K}}\left(1 + \frac{c}{L_2}\right) + 2K_1 \; A \; \frac{p_0 - 4W}{p_0 - 2W} + 2s \;.\,.\; (50)$$

Differentiating V_c with respect to b as before, will result in an equation identical with Equation (27), but in which the values of B', G', and J, in Equations (49), (50), and (26), respectively, are substituted. The volume of steel in the haunch will have the same value as before under Case I.

Case II.—Determination of $\frac{\partial V_d}{\partial b}$.—The steel area in the deck required for bending moment will be,

$$R_d = \frac{1}{j_2 f_s}\frac{p_0 - W}{p_0}\sqrt{\frac{WK}{2}}\,(L_2 - b) \;.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\; (51)$$

The volume of the steel in the deck will then have the value,

$$V_d = \tfrac{1}{2}\,(p_0 - 2W)\,\frac{W}{p_0^2}\,F'\,(L_2 - b)^2 \;.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\; (52)$$

in which,

$$F' = 2\,(1 + e_2)\,\frac{p_0 - W}{p_0 - 2W}\frac{p_0}{W}\sqrt{\frac{W}{2K}}\,\frac{K}{j_2 f_s} \;.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\; (53)$$

Differentiating:

$$\frac{\partial V_d}{\partial b} = -\,(p_0 - 2W)\,\frac{W}{p_0^2}\,F'\,(L_2 - b) \;.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\,.\; (54)$$

Substituting these values for $\frac{\partial V_c}{\partial b}$, $\frac{\partial V_h}{\partial b}$, and $\frac{\partial V_d}{\partial b}$, in Equation (14) and solving for b, an equation identical to Equation (44) is derived, but in which F' from Equation (53) is substituted.

Equation (44) determines the value of b that will result in the most economical design. It will be noted, that for a constant head the ratio, $\frac{b}{L_2}$, will be independent of the clear buttress spacing. Therefore, for a certain set of stresses and values of the coefficients, this ratio may be solved as a function of the height, H, and then used for any buttress spacing desired.

In the following is presented a typical example, illustrating the solution of Equation (44) for varying heights of the dam and when using values of stresses and coefficients that are customary for this type of structure.

The following stresses and values of the coefficients have been used: $p_0 = 600$ lb per sq in.; $f_c = 650$ lb per sq in.; $f_s = 16\ 000$ lb per sq in.; $\tau = 120$ lb per sq in.; $\nu = 120$ lb per sq in.; $\sigma_1 = 500$ lb per sq in.; $K = 107.7$; $j_1 = 0.875$; $j_2 = 0.875$; $\mu = 0.33$; $e_1 = 0.5$; $e_2 = 0.2$; $K_1 = 1.1$; and $\frac{D'_s}{D'_c} = 0.005$, in which, D'_s is the cost of steel, in dollars per pound, and D'_c is the cost of concrete, in dollars per cubic yard. Then $\frac{D_s}{D_c} = 13\ 200\,\frac{D'_s}{D'_c} = 66$.

The loading on the deck, W, in pounds per square inch, may be written,

$$W = 0.434\ H \qquad (55)$$

in which, H is the height, in feet, from the under side of the deck to maximum high-water level. For a general case, the buttress thickness, $2c$, may be determined approximately from the equation,

$$(L_2 + c)\ W = c\sigma_1 \qquad (56)$$

in which, σ_1 is the first principal stress in the buttress. Solving for $\frac{c}{L_2}$ there results,

$$\frac{c}{L_2} = \frac{W}{\sigma_1 - W} \qquad (57)$$

The maximum allowable bending stresses will determine the deck thickness at the top of the dam. The height of dam below which shear governs the deck thickness may be determined by combining Equations (21) and (48), which will result in the equation,

$$\frac{W}{\nu\, j_2}\ \frac{(L_2 - b)\ (p_0 - 2\,W)}{p_0} = \frac{p_0 - W}{p_0} \sqrt{\frac{W}{2\,K}}\ (L_2 - b) \qquad (58)$$

This height does not depend upon the span as the factor, $L_2 - b$, will disappear. Solving for W and remembering that $W = 0.434H$, the value of the height below which the shear governs the deck thickness will be for the conditions assumed, namely, $H = 155$ ft. Therefore, b may be determined from Equation (44), with substitution factors, G, J, N, and F, for $H < 155$ ft, and from Equation (44) for $H > 155$ ft, with substitution factors, G', F', J, and N. The results obtained by solving Equation (44) are shown graphically by Fig. 5, for five values of s. For a certain slope of the under side of the haunch, these curves will give directly the most economical ratio of $\frac{b}{L_2}$.

Fig. 5 shows how the ratio, $\frac{b}{L_2}$, for a constant haunch slope is increasing with the head. This indicates that the use of enlarged haunches and shortened deck will be more economical as the height of the dam increases until, finally, below a certain height the best economy will be obtained by omitting the deck entirely and using the round-head type. These limiting heights, below which the round-head type is the most economical, are indicated by horizontal dashed lines in Fig. 5.

The equation for total cost, C_t, of haunch and deck will be of the second degree with respect to b. Therefore, it will have only one minimum and C_t will increase continuously if the value of b is departing from that determined by Equation (44), or as shown by Fig. 5. Thus, if for practical reasons this value of b cannot be used, the best economy will be attained by having the actual value of b approach as nearly as possible the value of b determined from the equations.

A comparison of the cost of the water-bearing members for different values of the ratio, $\frac{b}{L_2}$, would indicate the saving effected by using values as determined by the equations. It may be done by introducing the values, V_c, V_h, and V_d, in Equation (13) from which the total cost, C_t, may be solved under the different assumptions. This equation will be of the form,

$$C_t = \left(1 + \frac{c}{L_2}\right) i_2 D_c L_2 + f\left(\frac{b}{L_2}\right) L_2^2 \ldots\ldots\ldots\ldots\ldots (59)$$

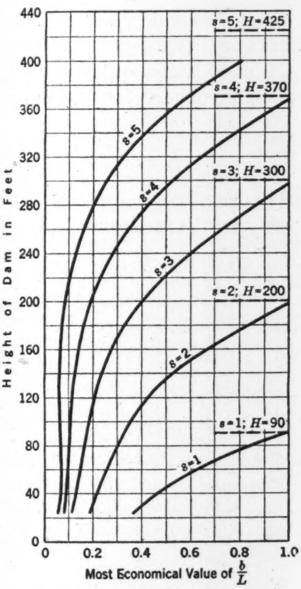


FIG. 5.—MOST ECONOMICAL VALUE OF $\frac{b}{L_2}$.

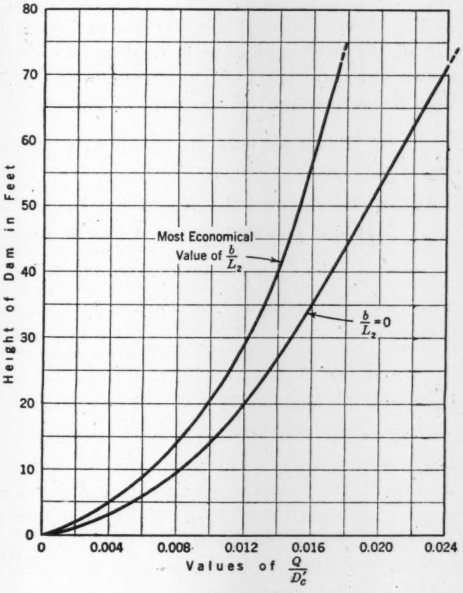

FIG. 6.—VALUES OF Q FOR $s = 1$.

The first term for the value of C_t will be small in comparison with the second one; also, it will be independent of the ratio, $\frac{b}{L_2}$, and, therefore, it may be omitted for this comparison; hence,

$$C_t = f\left(\frac{b}{L_2}\right) L_2^2 = QL_2^2 \ldots\ldots\ldots\ldots\ldots\ldots (60)$$

Fig. 6 shows the values of Q for $s = 1$, the values of Q being for the following values of the ratio, $\frac{b}{L_2}$: First, $\frac{b}{L_2} = 0$; that is, the tongue has the same thickness as the buttress (Fig. (1(*a*)); and, second, $\frac{b}{L_2}$ as determined from Equation (44). This coefficient will give the minimum cost when introduced in Equation (60). Curves similar to Fig. 6 for other values of s can be prepared as the need occurs.

When the cost of concrete, D'_c (in dollars per cubic yard), is known, the coefficient, Q, is determined by the curves in Fig. 6. Introducing this value of Q in Equation (60), this equation will give the cost, C_t, directly in dollars per foot length of deck and haunch for any span, L_2, desired (L_2 = one-half the clear buttress spacing, in feet). Therefore, the curves in Fig. 6 will indicate directly the savings effected by economical proportioning of the deck and haunch dimensions, as outlined in this paper. Table 1 shows, for different heights and haunch slopes, the magnitudes of these savings in percentage of the cost of the water-bearing members for the case, $\frac{b}{L_2} = 0$. These savings are given as a percentage of the cost of the water-bearing members. The cost, C_t, of these members is a function of the square of the buttress spacing (see Equation (60)), and when the buttress spacing is small, say, 15 to 20 ft, this cost will be relatively small; but as the buttress spacing increases, the cost C_t, of the deck and haunches will increase rapidly (in proportion to the square of the buttress spacing), and will be an important factor in the total cost of the dam. Therefore, in the case of wide buttress spacing, the savings in cost of the water-bearing members made possible by proportioning them according to the procedure outlined in this paper will materially affect the total cost of the dam.

TABLE 1.—SAVINGS EFFECTED BY ECONOMICAL PROPORTIONS OF DECK AND HAUNCH DIMENSIONS (IN PERCENTAGE OF COST OF WATER-BEARING MEMBERS, FOR THE CASE, $\frac{b}{L_2} = 0$).

3...........	5.3	5.2	5.0	5.2	5.2	5.4	8.1	12.8

CONCLUSIONS

The equations developed in this paper are sufficient for the precise determination of the most economical proportions of the decks and haunches of articulated buttress dams. The most economical relation between the span of the deck and the clear buttress spacing is shown to be independent of the buttress spacing for a given height of dam. Furthermore, the quantities of concrete and steel in the decks and haunches, as well as the total cost of these members, are shown to be in direct proportion to the square of the buttress spacing. The examples clearly indicate that for dams of great height for which the buttress spacing generally is large, the savings effected by the proportioning as outlined are of major economical importance.

Although the mathematical developments may seem formidable the results as presented in the final simplified equations, and curves may be applied easily and quickly to actual design problems. Fortunately, the flexible, articulated buttress dam is subject to an exact mathematical analysis of both economy and stresses, as there are no statically indeterminate elements introducing mathematical and structural uncertainties.

DISCUSSION

R. A. SUTHERLAND,[4] ASSOC. M. AM. SOC. C. E. (by letter).—Articulated buttress dams are applicable to a wide variety of foundation conditions, showing in many cases greater economy and in almost all cases greater security than gravity dams. In certain cases, the choice of this type may be indicated by considerations not entirely economic (such, for example, as the likelihood of earth movements), and it is in such cases that the value of the author's results is greatest, in that they then enable the parts of the structure to be proportioned in the best manner.

In other cases, a comparison between the buttress type of dam and other types (in particular the gravity dam), may be the deciding consideration, and the writer recently had occasion to make such a comparison. He was impressed by the fact that the shape of the dam site largely influences the relative merits of the two types on the score of economy. In Fig. 5, certain heights are shown concerning which the author states "the best economy will be obtained by omitting the deck entirely and using the round-head type." The writer will confine his remarks to a comparison between a round-head type of dam and a gravity dam. The dimensions of the round-head type for comparison are shown in Fig. 7.[5]

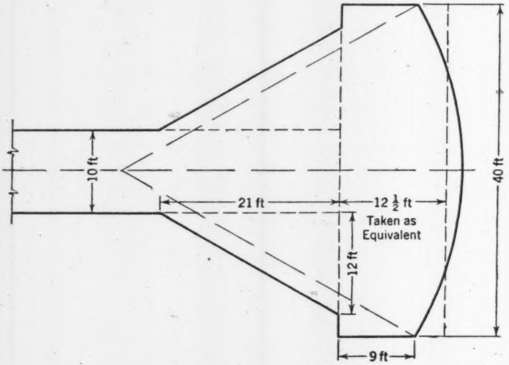

FIG. 7.—SECTION OF ROUND HEAD AT CREST LEVEL.

In Table 2 one buttress and round head is compared with a 40-ft slice of a gravity dam with total batter equal to 0.8. The batter of the buttress is 0.6 both up stream and down stream; the crest thickness is 10 ft, increasing at the rate of 1 ft for every 30 ft of height. In both cases, no consideration is given to additional material in the crest of dam, it being assumed that the extra material in the crest of the gravity dam will cost about the same as the roadway, etc., on the crest of the buttress dam. The volume of the haunches and the buttress proper has been computed by the prismoidal rule.

---

[4] Berkeley, Calif.

[5] *Engineering News-Record,* February 11, 1932, p. 212, Fig. 3.

It will be seen that if the height of the dam were uniform throughout, economy of material is shown only for structures higher than 95 ft, and economy of cost only for even greater heights. No dam, however, is of uniform height throughout, and economy in the entire dam will depend greatly on whether a large part of it is of a considerable height, or whether it spans a relatively narrow gulch with long flanks of lower height; in other words, economy will depend on the value of *n* as used by the writer elsewhere[6] as an index of the shape of the site. Using a procedure described elsewhere[6] the writer was able to develop a simple expression to determine the height above which the buttress dam showed a given degree of economy, as compared with a gravity dam. However, this was only for the assumption of parallel-sided buttresses, as the consideration of tapered buttresses led to expressions which are not readily integrable.

TABLE 2.—COMPARISON OF BUTTRESS AND ROUND-HEAD DAM, WITH A 40-FOOT SLICE OF A GRAVITY DAM

Height of buttress, in feet	Volume of buttress, etc., in cubic feet	Volume of gravity slice, in cubic feet
30	31 260	14 400
60	74 080	57 600
90	130 700	129 600
120	202 200	230 400

On grounds similar to the foregoing comparison with a gravity dam, the writer would suggest that the limits shown in Fig. 5 (limits above which the round-head type should be used), while perfectly legitimate in considering an individual buttress, should be modified in considering the entire dam, for the reason that if the round head is decided on, the entire dam must generally be of that type. The round-head buttress does not lend itself to combination with the slab type, nor with a gravity dam. The writer would be glad to know whether the author has considered the desirability of reducing buttress spacing toward the flanks of the dam, particularly with the round-head type. With this type there seems to be no inherent reason for a uniform spacing, if economical considerations dictate otherwise.

P. WILHELM WERNER,[7] ASSOC. M. AM. SOC. C. E. (by letter).—The economic principles involved in this study are of importance for structures other than buttress dams. The author has assumed the factor of distribution of shear, *j*, to be constant. It is questionable, however, whether this is true for the haunches, the depth, *d*, of which is great in relation to their span, *a*. Investigations made by the writer seem to indicate that for such beams the shear distribution is dependent to a considerable degree, on the ratio, $\frac{d}{a}$, although sufficient investigations are not yet available to give a definite quantitative answer.

[6] "Some Aspects of Water Conservation," *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 157.

[7] Civ. Engr., Stockholm, Sweden.

In his determination of $\frac{\partial V_h}{\partial b}$, Mr. Birke has included in the cost of the haunch a steel area, R_2, for the pull due to the friction between the deck and the haunch surfaces to allow for a possible movement in the deck (Equation (31)). As far as the writer is aware, no corresponding steel area is included in the cost of the deck (Equation (39)), where it is evident that there must be a reactive pull of the same magnitude due to the pull in the haunches. Probably, there is some reason for omitting the corresponding steel in the deck, and, if so, it would be interesting to know it.

Mr. Birke has investigated the relative economy of the deck and the haunches, without going into the economy of each member separately, except to use stresses that are customary for the type of structures under consideration. It is well known that, in a slab in flexure, there is a certain economic relation between the steel and the concrete. It would seem logical in this connection to consider this relation, especially in view of the fact that for the type of structures in question the space available for the depth of the deck is not restricted by influences other than those of economy. The point may also be of interest in view of the present trend toward revising standard specifications for maximum allowable stresses in reinforced concrete.

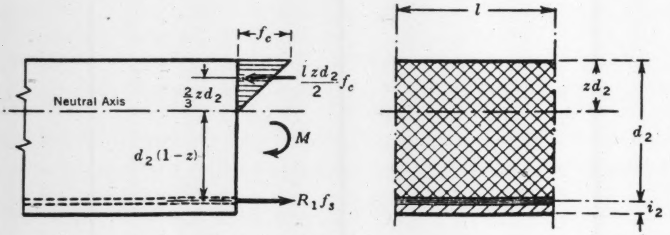

FIG. 8.

Considering the slab shown in Fig. 8, and using the nomenclature of the paper as far as possible, the following well-known relation is obtained,

$$\frac{f_s}{f_c} = \frac{E_s}{E_c} \frac{1-z}{z} \qquad \text{......................(61)}$$

or, with $\frac{f_s}{f_c} = \beta$ and $\frac{E_s}{E_c} = n$,

$$\beta = n \frac{1-z}{z} \qquad \text{......................(62)}$$

The equilibrium condition for the moments gives, $M = z\,(3 - z)\,\frac{l d_2^2}{6} f_c$; from which,

$$d_2 = \sqrt{\frac{6\,M}{l\,f_c}} \frac{1}{\sqrt{z\,(3-z)}} \qquad \text{..................(63)}$$

The equilibrium condition for horizontal forces gives, $\frac{l\,z\,d_2}{2}\,f_c = R_1\,f_s$; from which,

$$R_1 = \frac{l\,z\,d_2}{2\,\beta} \quad \text{.........................} (64)$$

The cost of the concrete, C_{cd}, is determined by Equation (65) (the volume occupied by the steel and the steel cover, i_2, which is practically constant, are not taken into account):

$$C_{cd} = d_2\,l\,L\,D_c \text{.........................} (65)$$

and the cost of the steel, C_{sd}, by the equation:

$$C_{sd} = (1 + e_2)\,\frac{z\,d_2}{2\,\beta}\,l\,L\,D_s \text{...................} (66)$$

Thus, the total cost, C_{td}, of the slab, except the cost of the forms and other practically constant items, is:

$$C_{td} = C_{cd} + C_{sd} = d_2\left[1 + (1 + e_2)\,\frac{D_s}{D_c}\,\frac{z}{2\,\beta}\right] l\,L\,D_c \text{ ....} (67)$$

Letting,

$$\kappa = \frac{1 + e_2}{2\,n}\,\frac{D_s}{D_c} \quad \text{.........................} (68)$$

and substituting the values of β (Equation (62)), and of d_2 (Equation (63)), in Equation (67):

$$C_{td} = \frac{1}{\sqrt{z\,(3 - z)}}\left(1 + \kappa\,\frac{z^2}{1 - z}\right)\sqrt{\frac{6\,M}{l\,f_c}}\;l\,L\,D_c \text{........} (69)$$

or, if $Z = \frac{1}{\sqrt{z\,(3 - z)}}\left(1 + \kappa\,\frac{z^2}{1 - z}\right)$.

$$C_{td} = Z\,\sqrt{\frac{6\,M}{l\,f_c}}\;l\,L\,D_c \quad \text{......................} (70)$$

Equation (70) is evaluated in Fig. 9, which shows the cost of the slab for various ratios, $\frac{D_s}{D_c}$, at constant value of f_c.

The value of z that will make C_{td} a minimum is controlled by the condition,

$$\frac{\partial C_{td}}{\partial z} = 0 \quad \text{.........................} (71)$$

By differentiating the expression for C_{td} in Equation (69) (in which, f_c is assumed constant), substituting in Equation (71), and reducing, the following equation is obtained:

$$(5\,\kappa - 2)\,z^3 + (7 - 9\,\kappa)\,z^2 - 8\,z + 3 = 0 \quad \text{...........} (72)$$

For $e = 0.2$ and $n = 15$, Equation (68) becomes,

$$\kappa = 0.04\,\frac{D_s}{D_c} \quad \text{.........................} (73)$$

For different values of the ratio, $\frac{D_s}{D_c}$, the most economical ratio, $\beta = \frac{f_s}{f_c}$, at constant f_c, can now be computed by solving Equation (72) for z and substituting these values of z in Equation (62). The result is shown in Fig. 10, for values of the ratio, $\frac{D_s}{D_c}$, between 20 and 100, which probably represent practical limits of the ratio between the costs of steel and concrete.

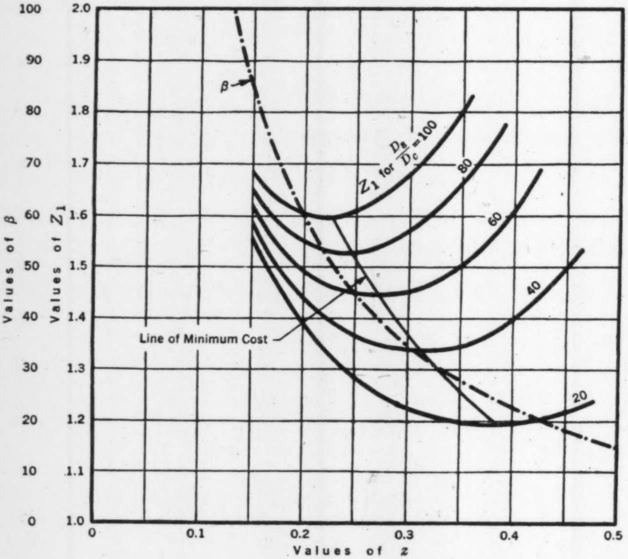

FIG. 9.—COST OF DECK SLAB IN FLEXURE FOR VARIOUS RATIOS OF $\frac{D_s}{D_c}$ AT CONSTANT f_c

Taking $\frac{D_s}{D_c} = 60$, for instance, it is seen from Fig. 9 that the most economical ratio between the stresses, f_s and f_c, is $\beta = 40$. With a concrete stress of $f_c = 650$ lb per sq in., as used by the author, the steel stress would then be $f_s = 24\,000$ lb per sq in. For $\frac{D_s}{D_c} = 40$, the corresponding values would be $\beta = 34$ and $f_s = 22\,000$ lb per sq in. These values exceed, greatly, the allowable steel stress of 16 000 lb per sq in. used, and are in any case out of the question in structures of the type under consideration, especially in view of the necessity of avoiding cracks in the concrete. It is, therefore, of greater interest in this connection to investigate the problem under the assumption of a constant steel stress.

By substituting the value of f_c (Equation (62)), in Equation (69), C_{td} becomes,

$$C_{td} = \frac{1}{z} \sqrt{\frac{1-z}{3-z}} \left(1 + \kappa \frac{z^2}{1-z}\right) \sqrt{\frac{6M}{l f_s}} \, n \, l \, L \, D_c \; \ldots\ldots\ldots (74)$$

in which, $\frac{1}{z} \sqrt{\frac{1-z}{3-z}} \left(1 + \kappa \frac{z^2}{1-z}\right) = Z$

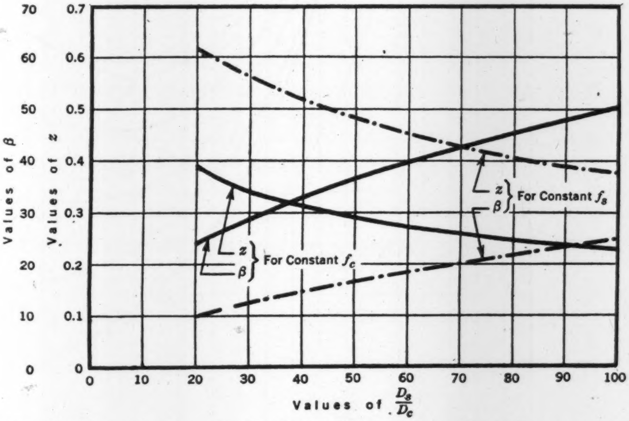

FIG. 10.—ECONOMIC DIMENSION AND STRESS RELATION OF DECK SLAB IN FLEXURE AT CONSTANT f_c OR CONSTANT f_s

This equation is evaluated in Fig. 11, showing the cost of the slab for various ratios, $\frac{D_s}{D_c}$, at constant f_s.

The value of z that will make C_{td} in Equation (74) a minimum is obtained under the condition expressed by Equation (71). By differentiating the expression for C_{td} in Equation (74) (in which, f_s is assumed constant), and substituting in Equation (71), and reducing, the following equation is obtained:

$$(1 - 2\kappa) z^3 + [(3\kappa - 4) z^2 + 6z - 3] = 0 \; \ldots\ldots\ldots\ldots (75)$$

Using the value of κ given in Equation (73) the most economical ratio, $\beta = \frac{f_s}{f_c}$, at constant f_s, can now be obtained by solving Equation (75) for z and substituting the resultant values of z in Equation (62). The result is shown by dash-dotted lines in Fig. 10.

In the typical example introduced by Mr. Birke, with $f_s = 16\,000$ and $f_c = 650$ lb per sq in., the value of β is $\beta = 24.6$. Thus, for $\frac{D_s}{D_c} = 66$, the point, A, in Fig. 11, is obtained. The minimum cost is obtained for $\beta = 20$, corresponding to the point, B, in the diagram. It is seen that the values of the stresses used by the author very nearly give the best economy with the ratio, $\frac{D_s}{D_c} = 66$. It should be noted that using a lower value of β than about 20 (Point *B*, Fig. 11) will only increase the cost.

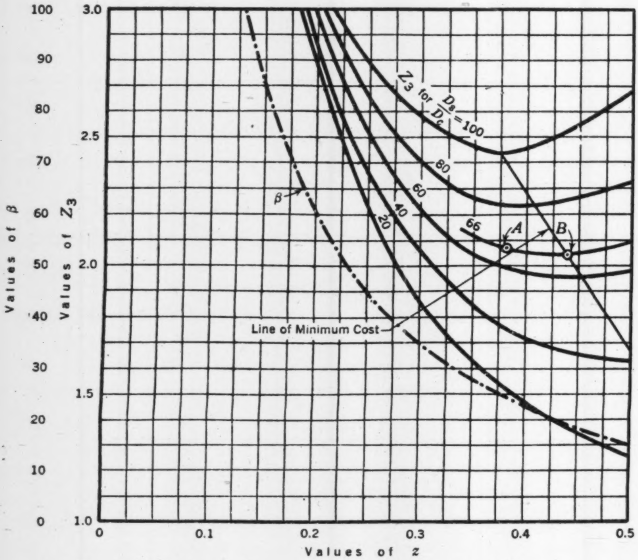

FIG. 11.—COST OF DECK SLAB IN FLEXURE FOR VARIOUS RATIOS, $\frac{D_s}{D_c}$, AT CONSTANT f_s

CHARLES P. WILLIAMS,[8] M. AM. SOC. C. E. (by letter).—Only within the last few years, have attempts been made to determine directly the most economic proportions of the class of structures treated in this paper, and economy of design has been secured only by the comparison of several designs, in which many of the controlling dimensions were selected arbitrarily. It has been the custom to select an "out-to-out" length of deck span equal to the clear spacing of buttresses. The author demonstrates that, in many cases, this is not economical, and, moreover, that at a determinable distance below the top of the dam, it is more economical to omit the deck altogether, substituting for the "articulated buttress" type of dam, the "round-head buttress" type, devised by the late Fred A. Noetzli, M. Am. Soc. C. E.

While Mr. Birke's analysis is presented in a logical and ingenious manner, a few of his assumptions are in error. His analysis of haunch stresses is based on the commonly used formulas for a beam of uniform depth, which, when a unit width of beam is considered, are as follows:

$$j = 1 - \frac{k}{3} = 1 - \frac{n f_c}{3 (f_s + n f_c)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (76)$$

---

[8] Cons. Engr., Los Angeles, Calif.

$$\tau\ (\text{max.}) = \frac{S}{j\,d} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

$$f_c = \frac{2\,M}{j\,k\,d^2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (78)$$

and,

$$R_1\,f_s = \frac{M}{j\,d} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

in which, in addition to the notation of the paper: n = the ratio of the coefficient of elasticity of steel to that of concrete; and k = a coefficient such that $k\,d$ equals the distance from the neutral axis to the extreme compression element, measured in the direction of the applied external load.

Equations (76), (77), (78), and (79) are applicable only when the tensile steel and the extreme compression filament are each perpendicular to the direction of the external load. The late William Cain, M. Am. Soc. C. E., has given[9] an approximate solution of the case, in which either or both the tensile steel and the extreme compression filament are inclined to the direction of the external load.

In the following discussion, the terms, shear, unit shear, and total shear, signify shear in the plane, *A-A*, Fig. 12, unless otherwise expressly stated.

In a beam having parallel tensile and compressive elements, each perpendicular to the direction of the external load, the unit shear in any plane parallel to the direction of the loading (assuming the concrete to carry no tension) is uniform on the tensile side of the neutral axis, and is the maximum unit shear in the section. On the opposite side of the neutral axis, the unit shear decreases at a rate proportional to the square of the distance from that axis, becoming zero at the extreme compression filament.

In the case of a beam having the tensile element perpendicular to the direction of the external load, but having its compression face inclined thereto, making the angle, ϕ, with the tensile element, as shown in Fig. 12, it can be shown that the factor, j, the unit shear, τ_1, at all points on the tension side of the neutral axis, the unit shear, τ_2, on the opposite side of the neutral axis, at a point distant y therefrom, and the unit shear, τ_3, at the extreme compression filament, are given by the following equations:

$$j = 1 - \frac{k}{3} = 1 - \frac{n\,f_c \cos^2\phi}{3\,(f_s + n\,f_c \cos^2\phi)} \quad\ldots\ldots\ldots\ldots (80)$$

$$\tau_1 = \frac{1}{j\,d}\,\left(S - \frac{M}{d}\tan\phi\right) \quad\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

$$\tau_2 = \tau_1 - \frac{\tau_1}{k^2\,d^2}\,y^2 + \frac{2\,M\tan\phi\,y}{k^2\,j\,d^3} \quad\ldots\ldots\ldots\ldots (82)$$

and,

$$\tau_3 = f_c \sin\phi\cos\phi = \frac{2\,M\tan\phi}{k\,j\,d^2} \quad\ldots\ldots\ldots\ldots (83)$$

---

[9] "Earth Pressures, Retaining Walls, and Bins," by William Cain, p. 239 *et seq.*, N. Y., John Wiley & Sons.

The values of τ_1 and τ_2, in Equations (81) and (82), are approximations, based on the assumption that j is constant throughout a strip of infinitesimal width at the section, *A-A*, considered. The total shear at the section is S. The error in the approximation may be indicated by computing the total shear from the equations for unit shear. Designating by S_c, the total shear, computed from Equations (80) and (81), the following equation is obtained:

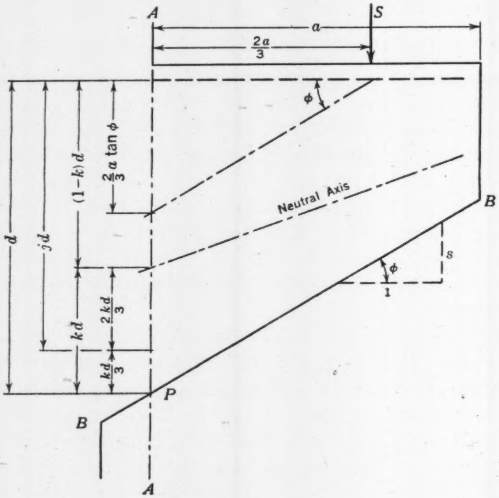

FIG. 12.

$$S_c = (1 - k)\, d\, \tau_1 + \int_0^{kd} \tau_2\, \partial y \qquad (84)$$

Substituting for τ_1 and τ_2, their approximate values, performing the operations indicated, and reducing, the computed total shear is found to be:

$$S_c = S + \frac{1 - j}{j\, d} M \tan \phi \qquad (85)$$

Substituting for M its value, $\frac{2}{3}\, a\, S$, and reducing:

$$S_c = S \left\{ 1 + \left(\frac{1 - j}{j} \right) \frac{2\, a \tan \phi}{3\, d} \right\} \qquad (86)$$

Assuming $f_c = 650$ lb per sq in.; $f_s = 16\,000$ lb per sq in.; and $n = 15$, the value of j will range from 0.922 for $s = \tan \phi = 1$, to 0.992 for $s = 5$. For s ranging from 1 to 5, then, the value of $\frac{1 - j}{j}$ will range from 0.085 to 0.008. From Fig. 12, it will be observed that, $a \tan \phi < d$; hence, $\frac{2\, a \tan \phi}{3\, d} < \frac{2}{3}$. The error in the computed value of S_c, then, is less than 0.057 S when $s = 1$, and less than 0.005 S, when $s = 5$. For haunches in which $\frac{d}{a}$ is large, the error will be much less.

The distance from the neutral axis, corresponding to the point of maximum shear, is found from Equation (82) by placing the first derivative (as to y) of τ_2, equal to zero and solving for y. Performing these operations, it is found that the value of y at which the shear is a maximum, is:

$$y = \frac{M \tan \phi}{S - \frac{M}{d} \tan \phi} = \frac{M \tan \phi}{j\, d\, \tau_1} \qquad \text{.................(87)}$$

It may be found that the point, determined by this value of y, is outside the structure, in which case the maximum unit shear is τ_3, as given in Equation (83). If, however, the point falls within the structure, the value of y is substituted for y in Equation (82), and reducing, the maximum unit shear is found to be:

$$\tau_3 \,(\text{max.}) = \tau_1 + \frac{(M \tan \phi)^2}{k^2\, j^2\, d^4\, \tau_1} \qquad \text{.................(88)}$$

The maximum unit shear may exceed greatly the unit shear on the tension side of the neutral axis.

At the point, P, in the section, A-A, Fig. 12, the compressive stress is the first principal stress. The direction of the maximum unit shear is at an angle of 45° with the direction of the principal stress. If, then, $\phi = 45°$, the maximum unit shear at P is in the plane, A-A. Between P and the neutral axis the maximum unit shear is approximately in that plane. If, however, ϕ is greater or less than 45°, the unit shear in the plane, A-A, at the point, P, will not be the maximum unit shear at that point, and the same will be true approximately for other points in the plane, A-A, between P and the neutral axis.

From the foregoing it might appear that there is greater danger of failure from excessive shear on the compression side of the neutral axis than on the tension side. This is not the case, however, since usually failure occurs from diagonal tension, incident to the shear, and not from direct shear.

The compressive forces below the neutral axis may be resolved into two components, one normal to the plane, A-A, and causing compression, and one parallel thereto and causing shear in the direction of the plane, and also in the direction perpendicular to it. The variation of shear below the neutral axis is due to the compressive forces, which are assumed to increase uniformly from the neutral axis to the extreme filament. The uniform increase in the normal component results in a decrease in the unit shear, in proportion to the square of the distance from the neutral axis, and the uniform increase in the parallel component results in a uniform increase in the unit shear. Any net increase in the unit shear is due to the excess of the effect of the parallel component over that of the normal component. Now, it can be shown that these compressive forces do not cause diagonal tension, hence any increase in shear below the neutral axis will not result in diagonal tension. The unit shear above the neutral axis, as given by Equation (81), may be taken as a measure of the diagonal tension.

The author determines the depth of the haunch, d_1, by Equation (7), assuming values for j_1 and τ. He then determines the area of steel, R_1, required to resist the bending moment, by Equation (30), assuming a value for f_s. Not more than two of the three variables, j, τ, and f_s can be assumed, which is demonstrated as follows: In order to simplify the equations, assume a beam with parallel tension and compression faces; that is, $\phi = 0$; then,

$$\tau = \frac{S}{j\,d} \quad \text{(89)}$$

and,

$$M = \frac{f_c}{2}\,kd\;jd = \frac{3}{2}\,f_c\,(1 - j)\,jd^2 \quad \text{(90)}$$

From Equation (89),

$$d = \frac{S}{j\,\tau} \quad \text{(91)}$$

and from Equation (90):

$$d_2 = \frac{2\,M}{3\,f_c\,(1 - j)\,j} = \frac{4\,a\,S}{9\,f_c\,(1 - j)\,j} \quad \text{(92)}$$

Hence,

$$\frac{S}{\tau^2\,j} = \frac{4\,a}{9\,f_c\,(1 - j)} \quad \text{(93)}$$

and,

$$f_c = \frac{4\,a\,\tau^2\,j}{9\,(1 - j)\,S} \quad \text{(94)}$$

The value of j is determined by the equation:

$$j = 1 - \frac{n\,f_c}{3\,(f_s + n\,f_c)} \quad \text{(95)}$$

from which may be derived the equation:

$$f_c = \frac{3\,(1 - j)\,f_s}{n\,(3j - 2)} \quad \text{(96)}$$

Substituting this value of f_c for f_c in Equation (94):

$$\frac{3\,(1 - j)\,f_s}{n\,(3j - 2)} = \frac{4\,a\,\tau^2\,j}{9\,(1 - j)\,S} \quad \text{(97)}$$

The variables in Equation (97) are j, τ, and f_s. Therefore, when any two are assumed, the other is fixed.

In Equation (55), Mr. Birke assumes the load per unit area of deck to be the water-load only. The haunch must carry, not only the water-load, but also the normal component of the weight of the deck and of the haunch itself. For an Ambursen dam, having a buttress spacing of 22 ft, center to center, the normal component of the weight of the deck varies from 0.16 W, at 30 ft below the top, to 0.05 W, at a depth of 180 ft. The weight of the deck is a function not only of the depth below the water surface, but also of the span. An increase in the dimension, b, will result in a decrease of the thickness of the deck, and its consequent weight; however, the weight of the haunch will be increased.

Referring to Equation (44), the author states that "for a constant head, the ratio, $\frac{b}{L_2}$, will be independent of the clear buttress spacing." For this to be true, $\frac{c}{L_2}$ must be constant. It is constant as to the water-load, but not as to the weight of the deck.

PAUL BAUMANN,[10] M. AM. SOC. C. E. (by letter).—The deductions in this paper are based on the premise of a triangular distribution of bearing pressure on the haunches. All mathematical operations, based on this premise, lead to correct results, provided the premise is correct. The exact solution of the bearing-pressure problem on yielding supports is no simple one and leads to terms that would be entirely too complicated for the purpose of showing economy features of water-bearing members of buttressed dams.

The use of a simple, geometrical shape of the bearing pressure area, therefore, is justified, provided this shape—in this case a triangle—is a close approximation of the actual shape. If it is a close approximation, then the yield of the haunch, due to p at any distance, x, from a Y-axis through the end of the face slab (Fig. 4(b)) must be substantially equal to the deflection of the face slab due to p and W.

For the elastic line of the face slab between $X = 0$ and $X = a$, due to bending:

$$E_1 I \frac{d^2y}{dx^2} = -M \quad \text{......................(98)}$$

and for $M = \frac{p\,x^3}{6} - \frac{W\,x^2}{2}$:

$$E_1 I \frac{d^2y}{dx^2} = -\frac{1}{2}\left\{\frac{p_0\,x^4}{3\,a} - W\,x^2\right\} \quad \text{................(99)}$$

in which, $\frac{p_0\,x}{a} = p$. Integrating Equation (99):

$$E_1 I \frac{dy}{dk} = -\frac{1}{2}\left\{\frac{p_0\,x^5}{15\,a} - \frac{W x^3}{3}\right\}_0^a + C_1 \quad \text{............(100)}$$

For $x = a$, the slope, $\frac{dy}{dk}$, may be determined by cutting the face slab in two at mid-span and by applying the stresses there as external forces the resultant of which is the maximum moment; thus:

$$M_0 = \frac{W}{6}\left[L_1(s\,a + 3\,L_1) - a^2\right] \quad \text{..............(101)}$$

---

[10] Asst. Engr., in Chg., Mountain Div., Los Angeles County Flood Control Dist., Los Angeles, Calif..

which differs from the author's Equations (37) and (46), because the latter are based on a uniform distribution of bearing pressure which is in contradiction to the basic assumption of a triangular distribution.

The moment at any section between $x = a$ and $x = L_1 + a$, is:

$$M = M_0 - \frac{W\,(L_1 + a - x)^2}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (102)$$

Therefore,

$$E_1 I\,\frac{d^2y}{dx^2} = \left\{M_0 - \frac{W}{2}\left[(L_1 + a)^2 - 2\,(L_1 + a)\,x + x^2\right]\right\}$$

and,

$$E_1 I\,\frac{dy}{dx} = \left\{M_0\,x - \frac{W}{2}\left[(L_1 + a)^2\,x - (L_1 + a)\,x^2 + \frac{x^3}{3}\right]\right\}_a^{L_1 + a} + C \;..(103)$$

The constant, C, follows from the condition that $\frac{dy}{dx}$ at mid-span must be zero; thus:

$$C = (L_1 - a)\left[\frac{W}{6}\,(L_1 + a)^2 - M_0\right] \ldots\ldots\ldots\ldots\ldots (104)$$

and for $x = a$:

$$E_1 I\,\frac{dy}{dx} = -\left\{a\left[M_0 - \frac{W}{2}\left((L_1 + a)^2 - (L_1 + a)\,a + \frac{a^2}{3}\right)\right] + (L_1 + a)\left[\frac{W}{6}\,(L_1 + a)^2 - M_0\right]\right\} \ldots\ldots\ldots\ldots\ldots (105)$$

Introducing Equation (105) in Equation (100):

$$C_1 = \frac{1}{E_1 I}\left\{a\left[M_0 - \frac{W}{2}\left((L_1 + a)^2 - (L_1 + a)\,a + \frac{a^2}{3}\right)\right.\right. \left. + (L_1 + a)\left[\frac{W}{6}\,(L_1 + a)^2 - M_0\right] + \frac{1}{2}\left[\frac{p_0\,a^4}{15} - \frac{W a^3}{3}\right]\right\} \;\ldots..(106)$$

Integrating again, the resulting simplified formula is the equation of the elastic line of the face slab due to bending; thus:

$$E_1 I y = -\frac{x^4}{12}\left\{\frac{p_0\,x^2}{15\,a} - \frac{W}{2}\right\} + x\left\{\frac{W}{6}\left[L_1^3 - a^3 + 12\,L_1\,a^2\right] - M_0\,L_1 + \frac{p_0\,a^4}{30}\right\} ..(107)$$

The deflection, $\Delta\, y_s$, due to shear of the face slab is:

$$\Delta\, y_s = \frac{1}{j_1\,G_1\,d_2}\left\{\frac{p_1\,x^4}{8\,a} - \frac{W\,x^2}{2}\right\} \ldots\ldots\ldots\ldots\ldots\ldots (108)$$

Adding Equation (108) to the deflection due to bending:

$$E_1 I\,(y + \Delta\, y_s) = E_1 I\,y_F = -\frac{x^4}{12}\left\{\frac{p_0\,x^2}{15\,a} - \frac{W}{2}\right\} + x\left\{\frac{W}{6}\,(L_1^3 - a^3 + 12\,L_1\,a^2)\right. \left. - M_0 L_1 + \frac{p_0\,a^4}{30}\right\} + \frac{1}{0.30\,j_1\,d_2}\left\{\frac{p_0\,x^4}{8\,a} - \frac{W\,x^2}{2}\right\} \ldots\ldots\ldots (109)$$

Neglecting the influence of bending as suggested by the author, the elastic yield of the haunch due to shear, Q, is:

$$y_H = -\frac{1}{j_2 G_2}\int_0^a \frac{Q\,Q_A}{d}\,dx \quad\ldots\ldots\ldots\ldots\ldots\ldots(110)$$

in which, $Q = \frac{p_0\,(a^2 - x^2)}{2\,a}$; $Q_A = 1$; and, $d = d_1 + S\,(a - x)$. Introducing these values in Equation (110):

$$y = \frac{-p_0}{2\,a j_2\,G_2}\int_0^a \frac{a^2 - x^2}{d_1 + s\,(a - x)}\,dx = -K\int_0^a \frac{a^2 - x^2}{d_1 + s\,(a - x)}\,dx$$

$$= -K\left\{\int \frac{a^2}{d_1 = s\,(a - x)}\,dx - \int \frac{x^2}{d + s\,(a - x)}\,dx\right\} \quad\ldots\ldots(111)$$

Considering each integral separately:

$$\int \frac{a^2}{d_1 + s\,(a - x)}\,dx = -\frac{1}{s}\,l\,n\left\{d_1 + s\,(a - x)\right\} \quad\ldots\ldots\ldots(112)$$

and, if v is substituted for $a - x$:

$$\int \frac{x^2}{d_1 + s\,(a - x)}\,dx = a^2\int \frac{-\,dv}{d_1 + sv} - 2a\int \frac{-v\,dv}{d_1 + sv} + \int \frac{v^2\,dv}{d_1 + sv} \quad .(113)$$

Then Equation (111) may be written:

$$y = -K\left[-\frac{2\,a}{s^2}\left\{d_1 + s\,(a - x) - d_1\,l\,n\left[d_1 + s\,(a - x)\right]\right\}\right.$$

$$+\frac{1}{s^3}\left\{\frac{1}{2}\left[d_1 + s\,(a - x)\right]^2 - 2\,d_1\left[d_1 + s\,(a - x)\right]\right.$$

$$\left.\left. + d_1^2\,l\,n\left[d_1 + s\,(a - x)\right]\right\}\right] + C \quad\ldots\ldots\ldots\ldots\ldots\ldots(114)$$

For $x = 0$, $y = 0$, and:

$$C = \frac{2\,a}{s^2}\left\{d_1 + s\,a - d_1\,l\,n\left[d_1 + s\,a\right]\right\} - \frac{1}{s^3}\left\{\frac{1}{2}\left[d_1 + s\,a\right]^2\right.$$

$$\left. - 2\,d_1\left[d_1 + s\,a\right] + d_1^2\,l\,n\left[d_1 + s\,a\right]\right\} \quad\ldots\ldots\ldots\ldots(115)$$

After reducing and re-arranging:

$$y_H = \frac{-p_0}{2\,a\,j_2\,G_2\,s}\left\{\frac{d_1}{s}\left[l\,n\,\frac{d_1 + s\,(s - x)}{d_1 + s\,a}\right]\left(\frac{d_1}{s} + 2\,a\right)\right.$$

$$\left. + \left[\frac{x^2}{2} - a\,x + \frac{d_1\,x}{s}\right]\right\} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(116)$$

which obviously does not conform to Equation (109).

A numerical example will serve to check this. In Fig. 3 (*a*), let $H = 100$ ft; $W = 43.40$ lb per sq in.; $s = 3$; $p_0 = 700$ lb per sq in.; $\tau = 60$ lb per sq in.; and, $L_2 = 240$ in. Furthermore, let $A = \frac{d_1}{a} = 4$ and $b = 0$; then, from Equation (18), $a = \frac{2\,W\,L_2}{p_0} = 29.80$ in., and, therefore, $d_1 = 4 \times 29.80 = 119.20$ in. With these values, Equation (109) gives, for $x = a$:

$$E_1\,y_F = \left\{\frac{3\,400}{I} + \frac{8.70}{d_2}\right\} 10^6$$

With sufficient approximation:

$$I = \frac{(d_2 + e_2)^3}{12} = \frac{(0.0625\,\sqrt{M_0} + 2.5)^3}{12} = 24\,200 \text{ in.}^4$$

in which, $0.0625\,\sqrt{M_0} = d_2 = 63.70$ in. Finally, $E_1\,y_F = 0.278 \times 10^6$ lb per in.

Introducing the same values in Equation (116) with $x = a$ and $G_2 = G_1 = 0.30\,E_1$:

$$E_1\,y_H = \frac{-\,700}{0.60 \times 29.80 \times 0.875 \times 3}\left\{-\,9\,509\right\} = 0.1415 \times 10^6 \text{ lb per in.}$$

which is roughly one-half as great as $E_1\,y_F$. The deflection of the haunch due to bending is of the order of magnitude of 0.002×10^6 and, therefore, would not appreciably adjust the discrepancy.

The distribution of the bearing pressure, p, on the haunch could readily be ascertained by means of photo-elastic tests on models for various, relative rigidities of haunch and face slab, and new equations for the configuration of the haunch could be derived based on the results thereof, which would establish compatibility between the two members of the structure.

A. Floris,[11] Esq. (by letter).—Some of the statements in this interesting paper, do not appear to be well founded. The claim, for instance, that buttressed dams with deck slabs are less expensive that multiple-arch dams, is not quite obvious. The very purpose of arches is to reduce the bending moment caused by the water pressure; whereas deck slabs must develop considerable resisting moment to support the same pressure. If the mass concrete of buttressed dams is more economical, multiple-arch dams can also be built with thick buttresses using the same kind of concrete.

That the buttressed dams with freely supported deck slabs will be safer in an earthquake than multiple-arch dams is not at all a proved fact. Loosely connected members of a structure cannot be stronger against lateral forces than a monolithic structure. If the earthquake movement is propagated along the longitudinal axis of a multiple-arch dam, the flexible arches will act like springs or shock absorbers, thus relieving the structure of excessive stresses. The same action cannot be claimed in the case of buttressed dams.

In his analysis Mr. Birke determines the minimum cost of the deck slabs supported by buttresses with large heads. He considers these heads as cantilevers and applies the beam theory of prismatic bars. It cannot be taken for granted that the stress distribution in these large buttress heads will be the same as in a simple cantilever beam. Therefore, the conclusion that buttressed types of dams (including round-head buttresses), can be subjected to an exact mathematical analysis, may be seriously questioned. This being the case, the painstaking cost analysis of buttressed dams given in this paper appears to be of restricted usefulness to engineers engaged in the design of dams.

---

[11] Los Angeles, Calif.

HAKAN D. BIRKE,[12] ASSOC. M. AM. SOC. C. E. (by letter).—An excellent group of discussions has been presented in connection with this paper. It is gratifying that the importance of establishing the principles of economic design of articulated buttress dams has been recognized by such competent authorities.

Aside from its merits in the field of economy and its high factor of safety, the principal advantage of the articulated buttress dam, as pointed out by Mr. Sutherland, is its adaptability to a wide variety of foundation conditions. The increasing scarcity of sites with sound rock foundations will undoubtedly lead to a more widespread use of this type of dam and, therefore, a detailed knowledge of its economic limits becomes of major importance.

In attempting to establish such economic limits Mr. Sutherland has compared a round-head buttress type dam, 120 ft. high, having a buttress spacing of 40 ft, center to center, with a gravity type dam of the same height. The buttress dam is found to be somewhat more economical than the gravity dam although Mr. Sutherland found the reverse to be true for all heights less than 90 ft. His analysis gave rise to the inquiry as to whether a reduction of buttress spacing at the flanks of the dam would be more economical than the use of the same buttress spacing throughout.

In answer to this inquiry it may be stated that there are several definite objections to changing the buttress spacing. In the first place, a change of spacing throws a heavy eccentric loading on the buttress at the point of transition. Such a transition is necessarily a heavy structure and the additional concrete required goes a long way toward offsetting the small economy that would be gained by changing the buttress spacing. A second and perhaps more serious objection is that a change in spacing would increase the cost of form work considerably. One of the advantages in the buttress type of construction is that standard forms may be used throughout the entire dam. This leads to an appreciable economy in construction costs.

In determining the most economic type and buttress spacing for a dam at a given site, the proper procedure is first to establish the mean height of the dam. Comparisons may be made of the mean heights for the various types; but it will be found, in general, that these heights will agree closely and will not be far enough apart to affect the selection of type. The mean height may then be used to determine the most economical height and the correct buttress spacing.

If Mr. Sutherland had investigated other types and buttress spacings, he would have found that a considerably closer spacing than 40 ft and an Ambursen type of deck and haunch would have shown a much greater saving than the round-head dam or the gravity dam used in his example for heights even as low as 25 ft.

---

[12] Designing Engr., Ambursen Dam Co., New York, N. Y. Elected an Associate Member, Am. Soc. C. E., on July 25, 1932.

Mr. Werner makes an analysis of the economical stress relations in concrete and steel (f_c and f_s) for a deck slab in flexure. By his analysis he demonstrates that in the example introduced by the writer (in which, $f_s = 16\,000$; $f_c = 650$ lb per sq in.; and $\beta = 24.6$), better economy would have been obtained by using $\beta = 20$; but this value of β will yield a concrete stress, that is in contradiction to the assumption. Mr. Werner's analysis is based on a constant value of f_s, and, therefore, using his suggested value of β would make $f_c = \frac{16\,000}{20} = 800$ lb per sq in., which is in excess of the assumed maximum allowable concrete stress, $f_c = 650$ lb per sq in.

Generally, in design problems, maximum allowable stresses are used regardless of their economic relations. Mr. Werner has shown how the greatest economy for a deck slab in flexure may be attained when one of the stresses is kept constant and the other, varied. It is of equal interest to determine the economic effect of varying the stresses independently of each other. Consider, for example, Equation (69), as developed by Mr. Werner, and let,

$$Y = \frac{1}{\sqrt{z\,(3 - z)}} \left(1 + H\, \frac{z^2}{1 - z}\right) \frac{1}{\sqrt{f_c}} \qquad \text{(117)}$$

or, by introducing:

$$z = \frac{n}{\beta + n} \qquad \text{(118)}$$

the result will be:

$$Y = \frac{\beta\,(\beta + n) + H\,n^2}{\beta \sqrt{n\,(3\,\beta + z\,n)\,f_c}} \qquad \text{(119)}$$

and,

$$C_{ts} = Y \sqrt{\frac{6\,M}{l}}\; l\, L\, D_c \qquad \text{(120)}$$

For a certain ratio, $\frac{D_s}{D_c}$, the cost of the slab may be determined from Equation (119) for various stress values.

Assuming that $C = 0.2$, $n = 15$, and $\frac{D_s}{D_c} = 66$, Equation (119) has been evaluated for $f_s = 10\,000$ to $20\,000$ lb per sq in., and $f_c = 400$ to 800 lb per sq in. The results have been plotted and then curves of equal costs have been drawn, as shown by Fig. 13.

The stress condition introduced by the writer in his typical example (that is, $f_s = 16\,000$ and $f_c = 650$ lb per sq in.), is represented by Point *A* in Fig. 13. It may be seen that reducing any or both of the stresses would only increase the cost of the slab. Any increase in the stresses is out of the question as these values were assumed to be the highest allowable. Thus, it is proved that the stress condition used by the writer was the most economical one.

Fig. 13 demonstrates some interesting facts about the economy of different stress relations for a slab in flexure. Thus, for a low value of the stress in concrete, such as, $f_c = 450$ lb per sq in., little economy would be gained by stressing the steel above 14 000 lb per sq in. In the same way, for a value of $f_c = 13\,000$ lb per sq in., no economy will be gained by stressing the concrete above 600 lb per sq in.

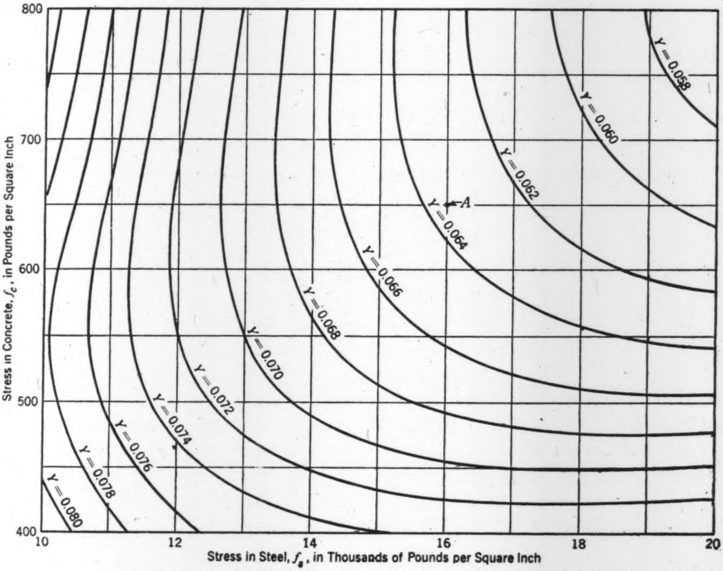

Fig. 13.—Curves of Equal Cost for Deck Slab in Flexure at Various Values of Stresses in Steel and Concrete Ratio, $\frac{D_s}{D_c} = 66$.

The object of the paper was to demonstrate the conditions under which maximum economy would be attained for the water-bearing members of articulated buttress dams. The economic equations were based on ordinary designing assumptions which, in some cases, are somewhat approximate. This has been pointed out by some of the discussers, and, therefore, it is necessary to consider the designing methods presented by the writer in the light of these criticisms.

Mr. Williams has pointed out that the equations developed in the paper are based on the conventional formulas for designing beams of uniform depth, and then demonstrates the differences between these and the formula for wedge-shaped beams as developed by the late William Cain, M. Am. Soc. C. E.

If the haunch is designed as a wedged beam by the methods introduced by Professor Cain, the shear stress on the tensile side of the neutral axis is determined by Equation (81), as presented by Mr. Williams. This shear stress,

τ_1, generally will control the depth of the section because the shear stresses on the compressive side of the neutral axis are combined with compressive normal stresses and hence will not cause any diagonal tension.

The total shear, S, at Section A-A, Fig. 12, will be equal to $\frac{1}{2}\ p\ o\ a$ and the moment, M, will be equal to $\frac{1}{3}\ p\ o\ a^2$. If these values are introduced in Equation (81), and d is eliminated by combining Equations (81) and (83):

$$\tau_1 = \frac{\cos\ \phi}{2} \sqrt{\frac{3\ k\ f_c\ p_o}{2\ j}} - \frac{k\ f_c \sin \phi \cos \phi}{2} \quad \ldots\ldots\ldots\ldots (121)$$

If the haunch is designed as a beam of uniform depth the shear, τ, will have the value:

$$\tau = \frac{S}{j_1\, d} = \frac{p_o\, a}{2\ j_1\ d} \quad \ldots\ldots\ldots\ldots (122)$$

or, by combining with Equation (83),

$$\tau = \frac{\cos\ \phi}{2\ j_1} \sqrt{\frac{3\ k\ j\ p_o\, f_c}{2}} \quad \ldots\ldots\ldots\ldots (123)$$

From Equations (80), (121), and (123):

$$\frac{\tau_1}{\tau} = \frac{j_1}{j} - j_1 \sqrt{\frac{6\, f_s\, (1 - j)^2}{p_o\, n\, j\, (3\, j - 2)}}\ \tan \phi \quad \ldots\ldots\ldots\ldots (124)$$

In Equation (124), τ_1 designates the shear when the haunch is designed as a wedged beam and, τ, the shear in the haunch computed as for a beam with uniform depth. Thus, Equation (124) gives the relation between the controlling shear stresses under these different assumptions.

In the economy problem, the factors, f_s, p_o, n, and ϕ are constants and thus the only variables in the expression for $\frac{\tau_1}{\tau}$ (Equation 124) will be j_1 and j, which are the distribution factors for shear. As the variations in j_1 and j will be negligible, the relation will be nearly constant. If the haunch is to be designed for a certain value of τ_1 (controlling shear when computed as a wedged beam), from Equation (124) the corresponding value of τ (controlling shear when the haunch is designed as a beam of uniform depth) may be determined. Using this value of shear, the depth of the haunch may be determined as if it were a beam of uniform depth, and the formulas developed will still apply.

Mr. Williams demonstrates, that in determining the depth of the haunch only two of the three factors j, τ, and f_s can be assumed. However, that should not restrict the use of Equation (30) for determining the steel area in the haunch for bending moment. For instance, if the expression, $S = \frac{p_o\ a}{2}$, is introduced in Equation (97), as presented by Mr. Williams, the result will be:

$$\frac{(1 - j)^2}{3\, j - 2} = \frac{8}{27} \frac{n}{f_s} \frac{\tau^2}{p_o} \quad \ldots\ldots\ldots\ldots (125)$$

in which, the maximum pressure p_o, on the haunch, is constant. If the values of τ and f_s are assumed, it is a simple matter to solve Equation (125) and determine the value of j. There is then no objection to using Equation (30).

The load the deck must carry, in pounds per square inch, may be written as follows (see Fig. 4(a), and Fig. 14):

Water Load:

$$62.5\,(H - t\cos\alpha) \ldots\ldots\ldots\ldots\ldots (126)$$

Weight of Structure:

$$150\,t\cos\alpha \ldots\ldots\ldots\ldots\ldots (127)$$

Total load:

$$W = 62.5\,H + 87.5\,t\cos\alpha \ldots\ldots\ldots\ldots\ldots (128)$$

If, as an approximation, the total load is assumed as, $W = 62.5\,H$, it does not mean, as stated by Mr. Williams, that the water-load alone has been taken into account (compare Equation (126)). It only means that the last term in Equation (128) has been neglected. For the Ambursen dam introduced as an example by Mr. Williams, having a buttress spacing of 22 ft, on centers, the last term in Equation (128) varies from the value 0.06 W, at 30 ft below the top, to 0.03 W at a depth of 180 ft. At greater heights, where the cost of the water-bearing members is a more important item, the last term will be entirely negligible when compared to the first.

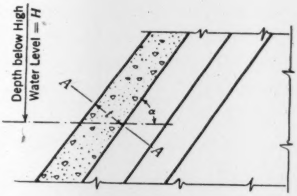

FIG. 14.—VERTICAL SECTION THROUGH DECK OF AMBURSEN DAM.

Mr. Baumann has demonstrated the difficulties of determining the exact bearing-pressure distribution on the haunch. The writer assumed a triangular bearing pressure area according to the common practice for this kind of structure. Actually, the character of this pressure distribution will vary with the relative rigidities of the haunch and deck. The writer is of the opinion, however, that an assumption of triangular distribution is on the safe side.

Mr. Baumann has made a check on the result of this assumption by comparing the deflection of the deck with the yield of the haunch at corresponding points. It may be noted that the formulas for these deflections are based on an assumed straight linear distribution of the stresses. Actually, in the deck above the bearing area of the haunch, the distribution of the stresses is not nearly as simple as straight-lined diagrams would indicate. In view of this, the results of Mr. Baumann's computations do not offer sufficient evidence to justify changing the assumption of triangular bearing pressure on the haunches.

It is quite true, as Mr. Floris states, "that the buttressed dams with freely supported deck slabs will be safer in an earthquake than multiple-arch dams. is not at all a proved fact." Neither is the converse a proved fact. Under some conditions, loosely connected members of a structure will not be as strong against lateral forces as a monolithic structure, but it is not a fact that loosely connected members cannot be stronger, against all forces acting, than a monolithic structure. To be stable a monolithic structure must have sufficient strength, in all its parts, to resist all the loads to which it will be subjected. In many cases, construction joints, properly located, render a structure safe, whereas, if the joints were not provided, the structure would be unsafe. This is a well recognized and generally accepted fact in structural design.

Mr. Floris states that: "If the earthquake movement is propagated along the longitudinal axis of a multiple-arch dam, the flexible arches will act like springs or shock absorbers, thus relieving the structure of excessive stresses". This description might be correct, possibly, if the earth tremors were slight; however, the arches could scarcely withstand a severe shock without being overstressed, and it is improbable that they could withstand the torsional stresses that frequently accompany earthquakes. Even assuming that the only earth movement is in the direction of the longitudinal axis, the members connecting the buttresses, in transmitting the shock, would act as columns. It is inconceivable that a curved column composed of arch barrels would transmit a shock more safely than a straight column composed of flat-slab decks.

Paper No. 1893

LINCOLN HIGHWAY FROM JERSEY CITY TO ELIZABETH, NEW JERSEY

By SIGVALD JOHANNESSON,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. FRED LAVIS, THEODORE BELZNER, AND J. B. FRENCH.

SYNOPSIS

In order to take care of the vehicular traffic concentrating at the west end of the Holland Tunnel, between Jersey City, N. J., and New York, N. Y., the New Jersey State Highway Commission began in 1924 the construction of a "super-highway," leading from the tunnel through Jersey City, Kearny, Newark, and Elizabeth, to connection with existing or new State highways. The construction of this highway was completed in 1932.

As this "super-highway" necessarily had to go through built-up sections of cities, and through other sections highly developed for railroad and industrial purposes, and as it was expected to carry a large volume of traffic, it was decided at the inception of the work to build it so as to avoid grade crossings throughout the greater part of its length.

In this paper are discussed the general aspects of the design of this highway, which included embankments, viaducts, high-level bridges, and a subway, with their ramp connections to the surface streets.

GENERAL DESCRIPTION

The last link of the New Jersey State Highway, designated the Lincoln Highway, leading from the west end of the Holland Tunnel through Jersey City, Kearny, Newark, and Elizabeth, to connection with the main highways to Trenton, Philadelphia, Pa., and beyond, was completed eight years after the inception of the work, and was opened for traffic on November 24, 1932.

NOTE.—Published in November, 1933, *Proceedings*.

FIG. 2.—PROFILE FROM HOLLAND TUNNEL TO NEWARK AIRPORT

This highway, the alignment and partial profile of which are shown in Figs. 1 and 2, respectively, is about 12 miles long, and its cost has been approximately $40 000 000.

At present (1933) this highway carries traffic at the rate of 11 000 000 vehicles per year and is expected to become one of the most heavily traveled roads in the world. For the greater part of its length it goes through built-up sections of cities with heavy street traffic, or through land developed for industrial and railroad purposes, and it crosses three navigable rivers.

When the project was originally conceived it was appreciated that these conditions would affect, materially, its economics as applied to construction and use, and, for that reason, a careful study of this phase was made prior to actual design, so as to co-ordinate, as far as possible, the cost of vehicle operation with the cost of construction. This study indicated clearly, that it would be of economic advantage to design the highway throughout the greater part of its length so as to avoid grade intersections with railroads and with other highways and streets. At first, consideration was given to movable bridges for river crossings but, subsequently, it was decided for economic reasons to provide fixed bridges, high enough above the water level to clear all river traffic.

This decision established the principle, that the section from the Holland Tunnel in Jersey City to Newark Airport (a distance of 7¼ miles) should be designed so as to avoid all interference from cross-traffic. Beyond the Airport, the route passes through partly undeveloped territory with little immediate need of grade separation, and it was possible, therefore, to design the greater part of this section as a surface road.

The various political, physical, and economic considerations that led to the final location of the highway are described in a previous paper[2] and will not be touched upon herein except to add, that no attempt was made to subordinate the alignment to possible variations in the sub-surface conditions for the purpose of making a saving in cost of construction. This was partly due to the probability that such savings in the cost of foundation construction, as might be attained by a change of alignment, would be small; but for the most part it was due to the fact that any such change would have increased the cost of vehicle operation out of proportion to the possible saving in construction cost.

No attempt was made to distort the alignment for the purpose of improving the angle of a crossing over highways, railroads, and rivers, because any saving in construction cost would have been overbalanced greatly by the consequent additional cost of vehicle operation. In fact, the highway crosses the Hackensack River at an angle of about 50°, and the Elizabeth River, with an S-turn, is crossed three times by the viaduct carrying the highway.

To avoid grade crossings with other traffic arteries, the highway in general has been built above them at such elevations as were necessary to provide the proper under-clearance for the type of traffic crossed. For highways and streets, the standard minimum clearance was 14 ft and for railways, 23 ft.

---

[2] "Highways as Elements of Transportation," by Fred Lavis, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1020.

At the crossings of the Hackensack and Passaic Rivers, which rivers carry sea-going vessels, the under-clearance height was made 135 ft at mean high water across the full width of the dredged channel; while at the crossings of the Elizabeth River, the under-clearance height was made 22 ft at mean high water. At the crossing points, the Elizabeth River is only a small stream with practically no channel depth at low water, but, nevertheless, it is classified as a navigable river.

An exception to the general method of locating the highway above the surface traffic was made in Jersey City, where it crosses a hill about 100 ft high and about ¾ mile wide. In order to avoid excessive rise and fall on the profile with the consequent additional cost of vehicle operation, the line at this place was driven through a subway below the surface streets.

As previously stated, there are no grade intersections with any kind of traffic routes between the Holland Tunnel and Newark Airport; but, with the exception of certain isolated places, beyond the Airport there are no railway crossings, and the intersecting vehicular traffic is not of sufficient importance to warrant grade separation. The greater part of the line between Newark Airport and the southern boundary of the City of Elizabeth, therefore, is designed and built as a surface road.

In due time, however, it is probable that the vehicular traffic will develop sufficiently to justify a grade separation. For this reason a strip of land, 120 ft wide, has been acquired throughout this section. At present, the roadway occupies the central 50-ft strip of this right of way. The remainder, which is intended for sidewalks and local roadways, is separated from the highway by narrow longitudinal "islands." When the crossing traffic has developed sufficiently to warrant the change, it is contemplated to raise the grade above the cross-traffic level, leaving the local roadways at the present grade to serve the surface traffic along the line of the highway.

Physical, topographical, and economic conditions have necessitated the use of many types of structures. Generally none of these types is novel or unusual in itself, but many of the designs, which now seem entirely obvious and simple, were the final results of many studies with various plans. The work on the highway was started in 1924 and completed in 1932, and during the intervening years, design was continuously in progress on some section of the highway. In details, the design of similar structures was not always identical if they were developed at different periods, because of new ideas and additional knowledge and experience gained.

Alignment and Profile of Roadway and Ramps

At the beginning of the work the width of the roadway was established at approximately 50 ft. In the earlier designs the width actually was made 48.5 ft, but, later, the roadway was made 50 ft wide. The maximum gradient was established at 3.5%, which value was maintained throughout the work for the main roadway. At grade breaks vertical curves were introduced, which were made quite long in the earlier period; but it was found difficult at times to provide proper drainage with these long curves, and gradually it became customary to make the length 67 ft for each 1% of grade change at ridges, and from 33 to 50 ft at valleys. In special cases, where these lengths have been decreased, because of physical conditions, an easy riding surface and a sight distance of not less than 500 ft have been maintained.

It was desired from the beginning, that the radii of horizontal curves should not be less than 1 000 ft., and, generally, this minimum requirement was maintained, although in some cases it was made less. For the designs made during the more recent years, the tendency was to increase the minimum radius to 1 500 ft, and, whenever possible, the curve radii have been made from 5 000 to 10 000 ft.

Ramp connections have been provided at intervals, leading from the adjacent roadway surfaces to the new level; and usually they enter at the middle of the highway, which is widened and divided where such ramps occur. At first, the reverse curves at these wide sections were generally made with radii of 1 000 ft. In one case, where local conditions were unfavorable, the reverse curves were designed with radii of less than 500 ft, but the result was not satisfactory. Later, the radii were increased to 2 000 ft for the convex part, and 1 000 ft for the concave part, of the reverse curve, which permitted the traffic to move with greater smoothness and safety, and the additional cost of construction was generally relatively small.

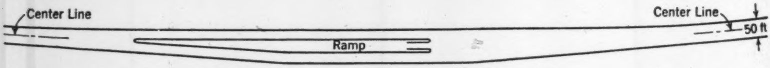

FIG. 3.—OUTLINE OF RAMP CONNECTION, KEARNY, N. J.

Wherever it was possible, it was found advantageous to place the head of a center ramp at a curve in the main line in order to avoid reverse curves. Such an arrangement is indicated in Fig. 3, which shows the outline of the ramp connection in Kearny. The curve angle of the alignment at this point is small, but it was possible, nevertheless, to construct the roadways without reverse curves.

It was necessary, of course, to introduce a vertical curve in the profile at the head of a ramp. Where the profile of the main line is descending in the same direction as the ramp, there is no difficulty, but if it is pitched in the opposite direction, it is necessary to continue the rise on the ramp for some distance. This may add materially to the length, and, consequently, to the cost of the ramp. For the sake of economy, it was found advisable in

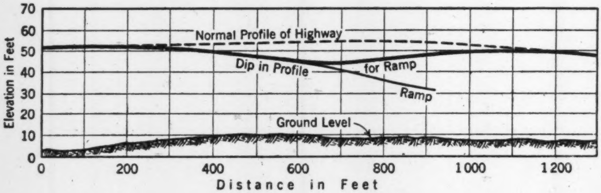

FIG. 4.—DIP IN NORMAL PROFILE TO PROVIDE FOR RAMP CONNECTION

certain cases, therefore, to dip the profile of the main highway at the head of the ramp. Such a dip was made near Newark Airport, as shown in Fig. 4, and a material saving in construction cost was gained by this expedient; but the appearance of the viaduct, as seen from the side, is not as satisfactory as might be desired, because the reason for the dip is not apparent.

Center ramps usually have been made wide enough for two lanes, one for entering, and one for leaving, traffic. The actual designed width of the ramps has been changed from time to time, but in the later designs it was 24 ft. In some cases the gradients have been made a maximum of 5.5%, in order to shorten the length of the ramp.

As it was intended that no U-turns should be made at the head of the ramps, each center ramp would serve incoming traffic in one direction, and outgoing traffic in the opposite direction only. The original plan of connections, therefore, contemplated that alternate ramps should serve the traffic in alternate directions, but in certain cases others were subsequently introduced at important street crossings.

This was done, for example, in Jersey City, where State Highway Route No. 1 leads from the George Washington Bridge south to Bayonne. When the highway was designed originally, the intention was to provide a ramp connection at this point for eastbound entrance and westbound exit. It was intended also to construct a surface highway leading west from the bottom of the ramp, so that, in fact, there would be a surface grade crossing at this point. As it was expected that the traffic would be heavy, a traffic circle was designed for the surface intersection to minimize as much as possible the inevitable delays as well as the chances of accidents. The diameter of the center line of the circular roadway was made 240 ft, which is rather small, but local conditions did not permit a larger diameter without heavy additional cost, and with a simple crossing this diameter should have been sufficient for satisfactory vehicle operation. A diagram of the traffic circle, with the originally contemplated street connections indicated in full lines, is shown in Fig. 5.

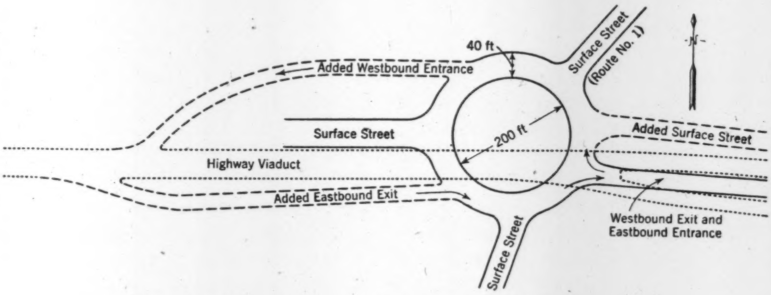

FIG. 5.—TRAFFIC CIRCLE, JERSEY CITY, NEW JERSEY

In the meantime, however, an additional street connection was deemed desirable on the east side (see dotted lines, Fig. 5), the introduction of which decreased the weaving distance necessary for proper vehicle operation, and, consequently, the efficient use of the circle. Later, it was decided further to add two side ramps from the west side of the traffic circle to the highway viaduct so as to provide a direct westbound connection with Route No. 1, in addition to the eastbound connection (see dotted lines, Fig. 5).

It is quite apparent that with these additional roadways the traffic circle cannot function as originally intended; in fact, traffic control by signal lights and traffic officers has become necessary. With this control the flow of traffic is reasonably satisfactory, but it is probable that the circle would have been made larger or that some other arrangement would have been made, if all the roadway connections had been considered at the time of the original design.

There has been some doubt as to the advisability of using center ramps rather than side ramps, mostly on account of the delay that may occur when a slow-moving truck arrives at the head of the ramp and attempts to weave through the fast-moving inner-lane traffic to the lane alongside the curb. No doubt, some delay may occur at times; but, on the other hand, the traffic probably moves more smoothly if the curb line is not interrupted, as would be necessary if side ramps were used. In addition, the cost of the work is often materially increased with side ramps, particularly where the highway profile is high above the surface level.

PILE FOUNDATIONS

As indicated in Fig. 2, the sub-surface conditions varied from place to place throughout the line of the highway. When rock or other firm materials was found near the surface level, the foundation problem usually was simple. Otherwise, it was frequently necessary to use either timber or concrete piles for the support of the foundations. Concrete piles (either pre-cast or cast in place) were used where necessary, either to carry greater loads, or to extend beyond the ground-water level.

Pre-cast piles were usually 16 in. square, with beveled corners. Cast-in-place piles were used in the foundations of the piers for the viaduct portion of the highway across the Jersey City meadows east of the Hackensack River. Where the lengths required were in excess of the maximum available for this type, composite piles were used, having a lower pre-cast section and an upper cast-in-place section.

Batter piles were required whenever there was any question as to the lateral stability of the foundations, but merely as an extra precaution because foundations of this type were used only where the ground could be expected to resist such lateral pressures as might be developed.

In one case, special arrangements were provided in the design to prevent displacement of foundations on concrete piles due to lateral pressures that might be caused by mud waves in the surrounding ground. This was in the meadow section in Jersey City, east of the Hackensack River, where the ground surface is just about the level of mean high water. The upper 10 ft or more of the meadow is soft silt, covered with vegetable growths, the roots of which form a tough fibrous mat. Below the silt are various mixtures of clay and sand, extending to rock, which is about 60 or 70 feet below the surface level.

The concrete foundations for this section were designed to extend 10 ft or more below the surface level and to be supported on concrete piles. With this arrangement, the top of the piles would generally be below the silt and the underlying material was expected to provide proper lateral support for the full length of the piles. It was thought, however, that future disturbance of the overlying silt, caused by filling in the meadows, or by other construction work in the vicinity of the highway, might possibly cause lateral mud waves, which would tend to displace the foundations. For this reason it was decided to include in the contract for the foundations a design for the two earth dikes, one at each side of the right of way of the highway, but outside the foundation sites. The design provided that strips of the vegetable mat, 18 in. wide, should be cut and removed at each side of each dike prior to the placing of the fill. This was done to prevent the fill from being suspended on the tough vegetable mat and to insure its settling through the silt, displacing and consolidating it so as to form dams, which would prevent mud waves from reaching the foundations.

As the dikes were used as roadways to provide access to the working site while the work was in progress, their construction is not believed to have added to the cost. If they had not been included in the contract, the Contractors would have had to make similar fills in order to provide access to their work, and the cost would necessarily have been included in some of the pay items under the contract. On the other hand, by including the construction of the dikes in the contract as a pay item, this necessary work was under the control of the Engineer, and the fill was placed in such a manner that it served a useful purpose, not only during the construction period, but also in the permanent structure.

Caisson Foundations

Where soft ground without material lateral stability was encountered, caisson foundations were used instead of piles, as, for example, at the foot of the steep east slope of the hill in Jersey City. Except for some surface fill, the borings at this place indicated that the sub-surface material was soft silt to within 8 or 10 ft of the top of the underlying rock, which was about 70 ft below the surface level. The viaduct structure at this point was to be about 80 ft above the surface level, and rather long spans were necessary on account of the track arrangement of the railroad yard, over which the viaduct was to be built. Taking all these matters into consideration, caisson foundations were deemed advisable.

The foundations were designed as cylindrical concrete piers, some of which were 8 ft and some 10.5 ft in diameter, and individual piers were used for each viaduct column to be supported. The caissons were designed as hollow concrete cylinders with an outside diameter equal to that of the finished pier and having a minimum wall thickness of 2 ft and a minimum specified reinforcement. After the caissons had come to a proper bearing, the construction was completed by filling them with concrete so that the finished structure was in effect a solid concrete cylinder.

A more extensive use of caisson foundations was made in the construction of the highway viaduct between and adjacent to the Hackensack and Passaic Rivers. The sub-surface strata, as indicated by borings, are shown in Fig. 2. It will be seen that the ground surface throughout this section is at or near the level of the water of the rivers and that the materials overlying the rock are soft and unsuitable for foundations. The surface of the rock, which at the east side of the Hackensack River is about 80 ft below the ground surface, rises rapidly toward the river. The original rock line at certain points under the river was perhaps less than 20 ft below the water level before the channel was deepened. West of the Hackensack River there is a rapid drop of the rock level which, near the west shore, is more than 90 ft below the water level. This somewhat peculiar formation appears to be due to a subterranean rock ridge, running in a north and west direction and intersecting the river at the location of the highway. The rock surface continues to drop until, at one point about midway between the Hackensack and Passaic Rivers, the level is about 140 ft below the ground (see Fig. 2). From this point the rock begins to rise again, so that at the crossing of the Passaic River the depth is about 60 ft, and beyond this river the elevation is from 50 to 60 ft below the surface.

Owing to the sub-surface conditions it was deemed necessary to use caisson foundations throughout the section from the east side of the Hackensack River to the west side of the Passaic River, and the design for the foundations was prepared accordingly. The drawings, however, did not show the details of the design of the caissons, but only the outlines of the finished work required, namely, concrete piers of certain horizontal cross-sections and extending from a given elevation near the ground surface to such a depth as would be necessary to attain proper bearing on sound rock. The reason for not showing the details was that, after all, it is the finished product that is desired, and as long as the work is finished in a safe and suitable manner, the method is generally of minor importance. In this way the individual contractor was also given an opportunity to design and construct the caissons according to such methods as his experience dictated might be most suitable and economical. The specifications provided, however, that,

> "Detail drawings and descriptions of the caissons and of the methods and details of construction, which the contractor proposes to use, shall be submitted to the engineer for his approval before the proposed work is commenced."

The caisson work for this section was divided into two contracts and the two contractors submitted different designs for the caisson construction according to their individual preferences. One of them proposed a complete wooden caisson, with the idea of placing the caisson concrete during the sinking operation, and leaving the wooden sheathing permanently in place. The other preferred to construct section after section of a concrete caisson, removing the wooden forms before sinking. Both designs were acceptable to the Engineer, and in both cases the work was done satisfactorily.

For this work, as well as for all other caisson work, the specifications stipulated that compressed air should be used when the cutting-edge of the caissons had reached a level a few feet above the rock surface, and that the caissons should be sealed to rock under compressed air. When the design was being prepared, consideration was given to the fact that, for some of the deeper caissons, the air pressure needed to seal the caissons might be greater than that permitted by law, if the ground should be found to be of an open character. An examination of the boring samples had indicated, however, that the material to be penetrated would be of a stiff, clayey, and impermeable character when exposed to the air pressure. It was believed, therefore, that if the work were done properly, the necessary air pressure would be materially less than the theoretical hydrostatic head indicated by the depth and that it would be within the legal limit. This belief was found to be correct, because the maximum air pressure used at any time during the construction of the caissons was 48 lb per sq in., and in the greater number of cases it was considerably less. The method of construction was to sink the caissons by open dredging until the cutting-edge was near the rock surface. The wells were then roofed over, and the remainder of the excavation was done under compressed air.

Owing to the depth to which the caissons were to be sunk, as well as to the height of the superstructure and to the character of the material to be penetrated, all the caisson foundations between the east side of the Hackensack River and the west side of the Passaic River were designed so as to provide a single pier for each viaduct bent. For the greater number of the piers the over-all horizontal dimensions were 25 ft wide by 60 ft long, while the piers for the main spans across the two rivers were 30 ft wide by 87 ft long.

On the west side of the Passaic River the conditions were somewhat different, as the average depth to rock was only about 60 ft, and the material overlying the rock was of such a character that it might be expected to afford some lateral stability. For these reasons each bent foundation was designed as two separate caissons, connected by means of a heavy concrete tie just below the surface level. The average size of these caissons was 14 ft wide by 16 ft long.

As the sub-surface conditions, as disclosed by the borings, indicated that either piling or caisson foundations might be used for this section, alternative designs were prepared and advertised for bids, one design involving caisson construction and the other concrete piling. The low bids received for the two plans were within 2% of the same amount, the bid for the caisson construction being the lower.

SUBWAY STRUCTURE

As previously stated, the part of the highway that crosses the hill in Jersey City is built as a subway under the level of the existing surface streets (see Fig. 6). It was located north of, and quite close to, both the old Erie Railroad Tunnel, and the more recent cut made by the Erie Railroad Company for its passenger trains (see Figs. 1 and 2). In fact, this location was selected largely in deference to the public opinion of the City of Jersey City, which considered the Erie Cut as a scar across the face of the city. It was desired, if another cut were to be made across the hill, that this be adjacent and parallel to that already made, and the location was determined accordingly.

Borings made previous to the design of this subway indicated that the ground immediately underlying the surface consisted of clay and sandy clay; below this there was rock. As an average, a little more than one-half the depth of the subway excavation was indicated to be in soft ground, and the remainder in rock. The design provided for a concrete wall at the north side of the structure, the upper part of which was designed as a retaining wall for the soft ground, and the lower part as a facing wall for rock.

SECTION LOOKING WEST

FIG. 6.—CROSS-SECTION OF SUBWAY, JERSEY CITY, NEW JERSEY

In order to provide proper ventilation, the excavation was sloped away from the highway at the south, but as it was desired to carry a surface road over the subway, concrete columns were provided at intervals on this side to support the roof of the subway. To provide additional ventilation facilities the roof was designed so as to cover only a part of the full width of the highway. All the steel work of the subway roof was designed to be covered with concrete, and reinforced concrete balustrades were provided around the ventilation opening at the north side of the structure, as well as along the south edge of the upper roadway.

In addition to the surface roadway constructed above the highway, another surface roadway was built north of, and immediately adjacent to, the subway. This roadway is used for westbound traffic while that built above the subway is for eastbound traffic, and together the two roadways form a wide, well paved, and much needed boulevard connecting the east and west parts of the city.

EMBANKMENTS

Earth embankments were used for the highway structure either where the roadway elevation is slightly above the surface level (as, for example, west of Newark Airport, where the elevation is only a few feet above the level of the meadow crossed), or where the physical conditions warranted embankments rather than viaduct structures. A condition like this occurred in Newark, where for a distance of about 1½ miles the highway is parallel, and immediately adjacent, to an existing railroad embankment.

In order to avoid settlement the sequence of the construction work was usually arranged in such a manner that any embankment fill would be completed a year in advance of the pavement placed on it. Nevertheless, some settlement almost invariably occurs after the pavement is built, but usually this is not of any serious importance, except immediately adjacent to an abutment where an abrupt change of surface elevation will occur. To compensate for this change of elevation, a reinforced concrete slab was introduced at the abutment during the earlier part of the work, which was capable of bridging a distance of about 20 ft. The design of this slab provided that one end of it would be supported on the abutment and the other on the earth embankment, the theory being that the end on the earth embankment might settle, but the concrete slab would form a runway to the higher elevation of the abutment, which would cause no inconvenience to traffic.

This arrangement in some cases did not prove satisfactory, although it would function as contemplated. The difficulty was that the settlement would cause changes in the roadway profile, which were too great to maintain comfortable riding conditions. The fact is that fairly small settlements are sufficient to produce excessive distortion of the profile in the short length available.

In later designs no attempt was made to introduce this concrete slab, but instead, the permanent pavement was omitted for a distance of about 50 ft immediately behind the abutment, and a temporary bituminous surface was used in its place.

VIADUCTS

Although concrete viaducts were used in a few cases, where the span lengths were moderate, the greater part of the viaduct structures was built of steel, preferably steel plate girders. The largest girder was 144 ft long, 11 ft 4½ in. deep, and weighed 60 tons.

Expansion was provided for mostly by means of double columns at the expansion joints; in fact, no sliding joints were used, throughout the length of the highway, where it was possible to avoid them. There were two reasons for attempting to avoid sliding joints, the first being that they are subject to wear and consequent expensive maintenance. Where it was necessary to use them, bronze sliding plates were provided so as to reduce wear and corrosion as much as possible. The other reason was that the steel structures as a rule were covered with a concrete protection, and it was somewhat difficult under these circumstances to arrange a sliding joint which would have no water-pockets and which could be readily maintained.

The policy has been to cover steel structures with concrete or "gunite" in order to decrease the cost of maintenance. There were exceptions to this rule, however; for example, where through truss construction was used, the steel below the level of the deck was covered, while the part above was left uncovered and was painted. The principal exception, however, was the high-level and long-span viaduct between Jersey City and Newark. For this structure the additional steel required for carrying the weight of the protection would have increased the cost so materially that it did not appear to be warranted economically.

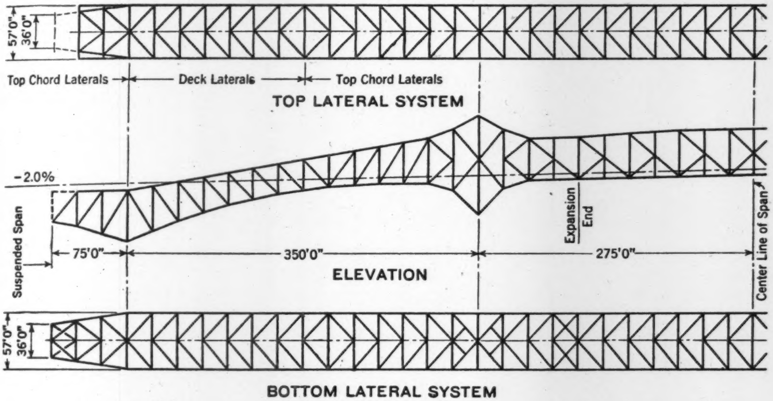
Generally speaking, concrete covering was used on columns, brackets, fascia girders, and other places exposed to view, while "gunite" was used in less exposed places. The reason therefor was that, in the earlier stages of the work, the latter was difficult to obtain with sufficiently pleasing outlines to permit its use where exposed to view. In later years, however, the art of placing has improved considerably, and at the present time this type of covering can be obtained with sharp, straight lines and even surfaces.

Members that were to be encased in "gunite," were designed with cross-sections to which the covering could be readily and economically applied, and the results indicated that material savings in cost could be made by suitable design of the members to be covered.

The thickness was generally specified as 1½ in., but this thickness can probably be materially decreased without impairing the value of the covering, and with considerable decrease in the cost, not only on account of the smaller amount of material used, but also on account of the smaller tonnage of steel required to carry the extra weight of this type of covering. Sufficient evidence has not as yet been gathered, however, to warrant a decrease materially below the standard thickness of 1½ in.

The high-level viaduct structure between Jersey City and Newark, for which the span lengths varied from about 200 to 550 ft, was designed as a deck-truss structure, except at the river crossings where through-truss construction was used. The structure throughout is a series of cantilever spans with intervening suspended spans. The deck structure consists (*a*) of cross-girders set on the top chords of the main trusses at their panel points, which are normally 25 ft apart; (*b*) of stringers framed into the cross-girders about 8 ft apart; and (*c*) of secondary cross-beams supported on the stringers. This arrangement was made to permit the main reinforcement to be placed lengthwise of the structure rather than transversely. The secondary cross-beams were spaced at varying distances apart ranging, in a 25-ft panel, from 3 ft 6½ in. at the ends to 4 ft 8½ in. at the center of the panel, so as to equalize the moments in the reinforced concrete roadway slab, which rests directly on the secondary cross-beams.

In order to get the necessary under-clearance across the dredged channels of the two rivers crossed, without undue rise and fall of the highway profile, the channel spans were designed as through trusses and, for the purpose of obtaining harmonious lines, the flanking spans were carried gradually from the higher level of the through trusses to the lower level of the deck trusses, as shown in Fig. 7. As the through trusses are 57 ft, center to center, and the deck trusses are 36 ft, center to center, it was necessary to make a horizontal break in the truss line of the flanking spans at the point where they reach the level of the deck trusses. This break was quite simple in design, and is not noticeable when the structure is seen at a distance; but from a point on the ground near the side of the viaduct, looking lengthwise to the point where the break occurs, it appears as if the curved lower chord is out of alignment. This condition was appreciated in making the design, but the only way that it might have been avoided was by tapering the trusses horizontally throughout the entire length of the flanking spans, which would have added materially to the cost of construction.



TOP LATERAL SYSTEM

ELEVATION

BOTTOM LATERAL SYSTEM

FIG. 7.—THROUGH TRUSS SYSTEM, FOR RIVER CROSSING

The trusses are supported on concrete piers by shoes of heavy steel castings with forged steel pins. On alternate piers the shoes are set on rollers to allow for changes in length due to changes in temperature.

The suspended spans are fastened at one end to the supporting cantilever arm by a hinged connection in the top chord. Actually, a simple riveted connection was used, because it was found that the deflection angle of the cantilever arm was practically the same as that of the suspended span. In other words, there is a point of contraflexure at the point of connection. The expansion end of the suspended span was supported by a vertical strut with pin connections at both ends. The reason for using a strut rather than a hanger was principally to maintain the same arrangement of diagonals throughout. If a hanger had been used, it would have been necessary to reverse the direction of the diagonal at this point.

The steel superstructure was designed to be supported on concrete piers. Each truss was supported on a separate shaft and, as there were normally two trusses to be supported, each pier bent had two pier shafts. At the location of the center ramps, however, where the structure was widened and was supported on three or four trusses, the number of pier shafts was increased accordingly. The shafts were designed with vertical outlines throughout their height, except near the bottom where they were flared out so as to form a base. Where the height was such as to require it, the shafts were connected with a horizontal strut, and, at greater heights, a truss was used instead of the strut. Both the truss and the strut were designed as steel members encased in concrete, but in order to conceal the steel outlines for the sake of appearance, the concrete covering was made so heavy that when finished, they had the appearance of masonry rather than of steel covered with concrete. Fig. 8 shows one of these pier bents.

All viaduct structures were designed for an H-20 loading. For the high-level viaduct between Jersey City and Newark the specifications used were those of the American Association of State Highway Officials for Steel Bridges, which were published about the time this work was begun. The specifications used prior to that time were those of the American Railway Engineering Association.

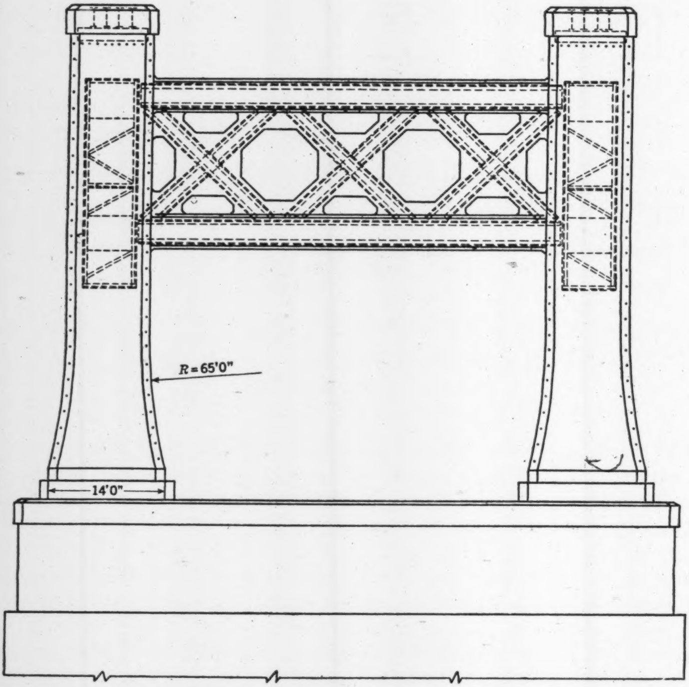


FIG. 8.—CROSS-SECTION OF PIER BENT, FOR STEEL SUPERSTRUCTURE

EXPANSION JOINTS

For the high-level steel viaduct structure just described, the expansion joints in the main structure are normally about 600 ft apart, requiring provisions to be made at the joint for a movement of 6 in., or more. The type of expansion joints designed for the roadway slab is shown in Fig. 9, Type 1. It consists of two sets of steel castings provided with a series of parallel fingers, each about $1\frac{3}{4}$ in. wide, and deep enough to carry the load that may come upon them. One set of these "finger castings" is placed at the one side of the expansion joint and the other set at the other side so that the fingers intermesh and provide a continuous surface at any position the structure may take due to expansion or contraction. The finger castings, which extend all the way across the roadway, were designed to be made in sections from 4 to 6 ft in length, and the openings between the teeth were about $\frac{1}{4}$ in. wider than the teeth so as to insure free movement of the joint. Similar castings were designed and used for the joints in the curb and sidewalk.

For viaduct structures of shorter span lengths, and where it was desired to provide tight joints, several types of expansion joints were used, but were changed in subsequent designs because the earlier designs did not prove to be as satisfactory as desired. The earliest type (Fig. 9, Type 2) was designed for the surface roadway over the subway in Jersey City. This type was found to be unsatisfactory for several reasons: First, the rivets in the checker-plate would wear loose, causing the plate to rattle in an undesirable manner, whenever a vehicle passed over it; and, furthermore, in certain cases, the entire expansion construction at one side of the joint would wear loose. This was due to the asphalt roadway surface wearing down adjacent to the concrete behind the steel expansion joint. The result was a constant pounding of the concrete by wheels striking against the exposed edge and forcing it against the steel of the expansion joint, which would gradually pulverize and destroy the concrete. Finally, the gutter between the twin girders would fill up with dust and dirt, and difficulty was experienced in removing this accumulation. It was possible for a man to enter the space between the two girders for the purpose of cleaning, but he could not make a visual inspection of it; all he could do was to feel his way along.

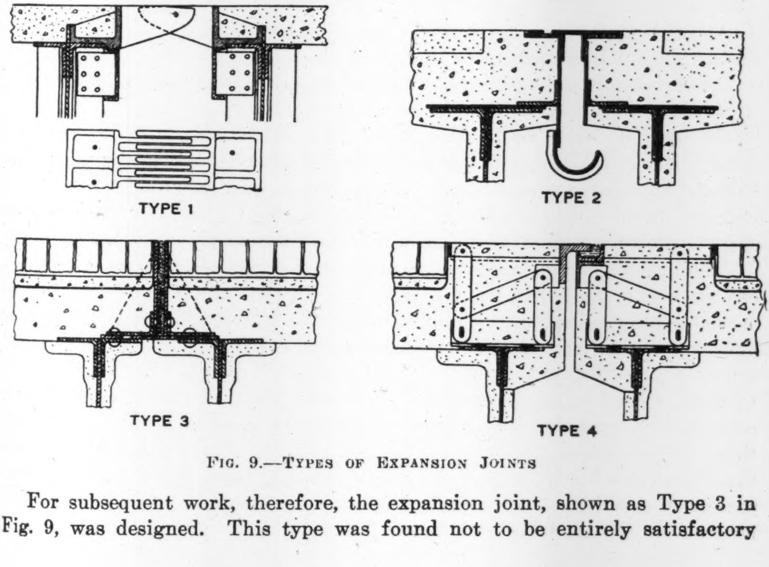

Fig. 9.—Types of Expansion Joints

For subsequent work, therefore, the expansion joint, shown as Type 3 in Fig. 9, was designed. This type was found not to be entirely satisfactory either, partly because of the difficulties of making an adequate enclosure at the ends of the joint, and partly because of the large volume changes that would occur in the space filled with mastic whenever the joint opened or closed due to temperature changes. If the joint opened, the mastic would drop below the roadway level, and if it closed, large quantities of the mastic would be squeezed out. Furthermore, it was difficult to prevent the comparatively large mass of mastic from seeking a level surface, with the result that it flowed out above the roadway surface near the curb lines and dropped below at the crown of the roadway.

The expansion joint shown as Type 4 in Fig. 9, was developed finally. It consists essentially of a small steel channel set at one side of the joint with the flanges turned up. One flange extends to the surface of the roadway and the other is cut down so as to permit the horizontal flange of a heavy steel angle, attached to the other side of the joint, to slide over it with its top surface at the roadway level. The channel is filled with mastic. The advantage is that only a small volume of mastic is needed to fill the joint, and the greater part of this is unaffected by the changes of volumes caused by temperature changes.

In order to anchor this joint to the structure, and to reinforce the roadway surface at the joint, flat steel bars, the top edges of which conformed to the roadway surface, were welded to the channel and angle. Light frameworks of flat bars were provided as shown, which not only were used for anchorage, but were also used to secure the expansion joint in place before the concrete was poured. This expansion joint has been in service for several years and has been found satisfactory.

Roadway Surfaces

At the beginning of the work the policy was established that the roadway surface should be paved with granite blocks, and this policy was followed for several years; but it was modified subsequently, and several other types of pavement were used on the highway. Surface roadways paved with granite blocks were designed to be laid on a concrete foundation. In the early designs, the foundation, due to the expected heavy truck loads, was made 10 in. thick, with top and bottom reinforcement. In later designs, this was changed to a concrete slab, 8 in. thick, without reinforcement, as this appeared to be sufficient where the sub-surface was firm.

The granite blocks, which have an average depth of 5 in., were set on a cement mortar cushion with a mastic filler in the joints. The surface was parabolic in cross-section, with a 6-in. crown for a 50-ft roadway. The mastic filler was not entirely satisfactory in all cases, because in hot weather it had a tendency to flow and cover the stone blocks, and eventually found its way to the low level of the roadway at the curb. For this reason later designs provided for a cement-mortar filler, except at intervals of about 30 ft, where three or four cross-joints, as well as the adjacent longitudinal joints, were filled with mastic. This type of construction has been used for only a comparatively short time, so that nothing definite can be said about it; thus far, however, it appears to be satisfactory.

In certain places where the highway occupies previously existing streets, the roadway was paved with a bituminous concrete surface on a concrete foundation. This was in deference to the wishes of authorities in the local municipalities; but it has a tendency to become wavy under the heavy traffic. It has the advantage, of course, that whenever openings must be made in it for construction or repairs of sub-surface utilities, it can be replaced without leaving an appreciable mark on the surface. On the other hand, as the work has been designed so as to keep sub-surface utilities outside the area of the paved highway, as far as possible, there should be little if any reason for making openings in the pavement.

A bituminous concrete pavement on a macadam foundation was found suitable as a temporary expedient when placed on fill that has not been entirely compacted. Of course, it does not remain smooth under heavy traffic, but it appears to stand up for a few years without undue maintenance. In some parts of the earlier work attempts were made to use surface-treated macadam for such temporary pavements, but it would not stand up under the heavy traffic.

A concrete pavement was adopted for the section adjacent to Newark Airport. The slab was made 10 in. thick, with top and bottom reinforcement. This heavy construction was used because there was some doubt whether the fill on which it was to be constructed, had finished settling. At other places, where the sub-surface conditions were more favorable, concrete pavements were designed with a thickness of 8 in. and a single top reinforcement. They were built with a V-crown and with a side slope of 1½ in. in 10 ft. There has been a tendency to decrease the slope to about 1 in. in 10 ft.

Where granite block pavement was used on viaduct structures, the concrete floor-slab was water-proofed and the water-proofing was protected with a layer of mortar or concrete. The pavement was placed on this protective course in a manner similar to that used on surface roads.

An asphalt block pavement was adopted on a part of the highway viaduct in Jersey City, largely for the purpose of comparing this type with others. In this case, the concrete floor-slab was water-proofed in a manner similar to that specified for granite block pavements.

For the high-level viaduct between Jersey City and Newark, considerable study was given to the selection of the most suitable type of pavement. Granite block pavement was not favored on account of its heavy weight, and, for a time, it was not considered advisable to use a type of pavement for which the wearing surface was an integral part of the carrying slab. For that reason serious consideration was given to paving the roadway with some asphaltic surface, on top of the concrete floor-slab. In the meantime, several of the bridges built by the Port of New York Authority and other important bridges had been provided with a concrete surface integral with the floor-slab, and the results appeared to be quite satisfactory. Based on this evidence, as well as on that furnished by the many concrete roadway surfaces in the State of New Jersey and elsewhere, it was decided finally to use a concrete roadway surface integral with the concrete floor-slab.

While this study of pavement type was under way, the design and fabrication of the steel structure had progressed so far that it became necessary to establish a definite slab thickness, before the exact type of floor-slab had been decided upon, and, for that reason, a thickness of 8½ in, was adopted as being that which might be used for a standard reinforced concrete slab.

Following this an intensive study was made of the various types of slabs that might be used, and several types were found suitable. The choice, therefore, depended on which would prove to be the most economical, and, for that reason, designs for four alternative types were prepared and submitted for bids.

Type 1 (Fig. 10), which was chosen eventually, is a concrete slab, 8½ in. thick, reinforced with fabricated trusses, composed of round bars welded together. Essentially, it consists of a top and a bottom chord of round bars with a web member made of a bar bent so as to form the diagonals of the truss, the various pieces being connected by pressure welding. In some cases the trusses are fabribated with single bars for top and bottom chords and with the web member placed between the two chords, while in other cases each of the chord members consists of two bars welded to the sides of the web member at its panel points.

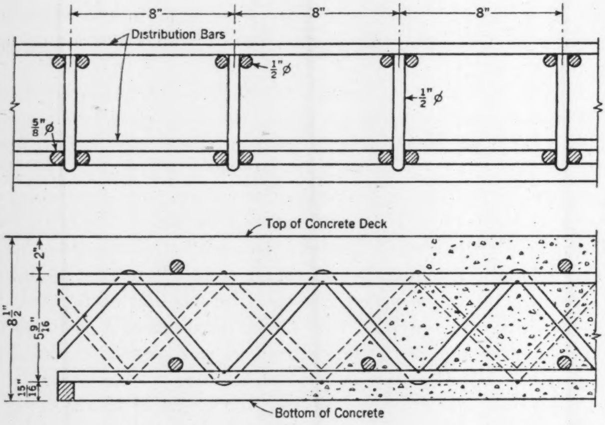

FIG. 10.—CROSS-SECTIONS OF TYPES OF FLOOR-SLABS FOR ROADWAY SURFACES

Type 2 was a series of inverted 5-in. T-beams, or half 10-in. H-beams, set closely together and tack welded so as to form a solid steel surface at the bottom of the slab, and filled with concrete to a height of 2 in. above the top of the T-beams. This type of slab reinforcement is usually fabricated in depths ranging from 2½ to 3½ in. The 5-in. depth was required because it was thought that while the slab of a lesser depth might be designed to carry the required load, it was not entirely certain that the concrete in it would not be crushed, in time, by constant use.

Type 3 was a solid-bottom plate with ribs at intervals and a steel grating attached to them with its top surface at a height of 5 in. from the bottom of the plate; concrete was placed on top of the plate to a depth of 2 in. above the steel. Type 4 was a solid-bottom plate with welded trusses, 5 in. deep, attached as ribs, and concrete was placed to a depth of 2 in. above the top of the ribs.

In all four cases the reinforcement also involved transverse top bars secured in place in various ways and, in addition, transverse bottom bars were required for Type 1. Each type was carefully investigated and found to be suitable for the purpose. For Types 2, 3, and 4, however (which had an over-all depth of 7 in.), it was necessary to introduce fillers, 1½ in. deep, between the steel support and the floor-slab, in order to make them conform to the depth of slab for which the structure had been designed. This, naturally, added to the cost of these three types although, on the other hand, the volume of concrete required was less.

The trusses in Type 1 were designed to be spaced on 8-in. centers and to be 5 in. deep over all. The two top bars and the web member were ½ in., and the two bottom bars, ⅝ in., in diameter. Rectangular spacing bars, as shown, were welded to the cross-beams on which the trusses were supported, and round top and bottom distribution bars, extending the full width of the roadway, were provided, as shown. In order to facilitate the work of erection and to insure exact spacing of the reinforcement, it was required that the trusses should be assembled in mats prior to erection by welding them together by the spacing and distribution bars. The length of the mats was required to conform to the distance between the primary floor-beams, which distance normally was 25 ft. The width was not specified, but left to the option of the Contractor, subject to the approval of the Engineer. The width of the mats actually furnished by the Contractor was normally 10 ft, but it is probable that the erection would have been easier if the width had been about one-half that actually used. The reinforcement trusses were arranged to be placed longitudinally on the structure, because better wheel-load distribution could be obtained in this manner than with a transverse arrangement of the trusses.

The concrete for the slab was required to have a crushing strength of not less than 4 000 lb per sq. in., when 28 days old. Actually, the concrete furnished had an average strength of about 4 800 lb. In computing the strength of the slab, the upper 2 in. of the concrete was not taken into account. When the time comes that it may be necessary to renew the wearing surface of the roadway it will thus be possible to remove this top layer without affecting the carrying capacity of the slab, and in this way a new wearing surface can be placed. It was thought that this new surface might be either concrete, or some type of asphaltic surface—or possibly some entirely new type of surface pavement which has not as yet been developed.

CURBS, SIDEWALKS, AND RAILINGS

No provisions have been made on any of the viaduct structures for sidewalks for pedestrians. Provisions have been made, however, for footwalks about 2 ft wide on both sides of the roadway, to be used in connection with the policing and maintenance of the highway and for emergency purposes. Except on the high-level viaduct the curb height of these footwalks is normally 8 in. above the roadway.

The general details of the footwalk as used on all steel structures, (except on the high-level viaduct between Jersey City and Newark) are shown in Fig. 11. In the earlier designs no provisions were made for any support of the curb angle during construction, but it was found that the contractors had some difficulties in aligning the curb angles properly and in securing them during the pouring of the concrete. In later designs, therefore, steel supports were provided, as shown in Fig. 11, which furnished a direct connection between the curb angle and the steel structure. These supports materially facilitated the proper erection of the curb angles.

FIG. 11.—DETAILS OF FOOTWALK USED ON STEEL STRUCTURES.

For further facility of erection the design provided for the placing of a sheet-metal form reaching from below the curb angle to the top of the concrete roadway slab. In conjunction with the curb angle, this metal form usually made it possible to pour the concrete of the roadway and footwalk slab without additional form work, and further provided a means of flashing the roadway water-proofing against the face of the curb.

The railings on all viaducts were made of concrete as shown in Fig. 11. On account of the narrow footwalk, it was considered essential to provide a railing strong enough to withstand the impact of any vehicle that might accidentally mount the curb and strike against it. Therefore, it was made quite substantial, and every one of the vertical posts was securely anchored against overturning.

On the high-level viaduct it was appreciated that special precautions should be taken, not only to prevent vehicles from falling from the viaduct, but also to allay the fear of such nervous drivers as are not able to look down from great heights without a qualm. These considerations were particularly important on this structure because, due to the narrow footwalk, the roadway is quite close to the side of the structure.

For these reasons, the curb height was made 16 in. above the roadway surface, so as to make it practically impossible for a vehicle to mount the footwalk. Behind the curb and forming the footwalk a horizontal plate girder was attached to the main steel structure at each panel point of the supporting trusses and covered on top with concrete. The vertical face of the curb consisted of a steel plate attached to the flange of the horizontal girder, and this plate extended to within 5 in. of the roadway surface, leaving an opening to permit drainage over its edge.

The top of the railing was made 4 ft 5 in. above the footwalk level, or 5 ft 5 in. above the roadway level at the curb. With this height it is not possible for a driver of a passenger car to look over the railing to the meadows below and, if he is properly attending to his driving, he cannot look through the railing between the posts; in fact, the railing appears to him as a solid wall. On the other hand, if the car is moving at a reasonably fast rate of speed, the passengers in the car, who are able to look squarely at the railing, will be able to look through the railing as if there were no posts at all.

DRAINAGE

The profile of the highway has generally been laid on a minimum gradient of 0.5%, so as to provide for proper drainage of the roadway. In undeveloped territory the cross-section was designed so as to permit the water to flow over the sides and, when necessary, side ditches were provided to carry the water to existing drainage channels. In due time, however, it may be necessary to provide curbs, and storm sewers must be built at that time. Preliminary plans of the future sewer were prepared, therefore, and the cross-drains necessary according to these plans were constructed prior to the permanent paving of the roadways.

Where the highway was constructed on embankment with curbed roadways, a complete drainage system was provided and connected either to the municipal sewer systems or to specially constructed drainage systems. Frequently, in the earlier designs, a 12-in. pipe was used, but experience indicated that this size was rather too small, and during the later years the minimum diameter was increased to 18 in.

The catch-basin heads, used on curbed surface roads, have a curb inlet and a grating that is slightly dished for the purpose of collecting the water more effectively. This is the standard design of the Highway Department, but it might be better to make the gratings flat, because drivers of cars have the tendency to avoid driving over the dished gratings, with the result that 2 or 3 ft of the width of the roadway is wasted. On a viaduct, catch-basins of a similar type, but without curb inlet, were generally used.

The basins are connected with 8-in. cast-iron pipes attached to the columns of the structure, which carry the drainage to the sub-surface sewer system.

In order to carry these pipes from the catch-basin down the structure and past the column base it was frequently necessary to introduce several bends or other fittings in the run. As each fitting appears to be a potential location for stoppage of the flow of drainage water, and as each additional fitting rapidly increases the difficulty of cleaning the drain, the writer has considered in future work, where conditions will permit such an arrangement, to place the catch-basin some distance away from the column bent and to carry the pipe vertically down to the ground level. Of course, this would necessitate a special support for the pipe, but it would facilitate the maintenance of the drains materially.

In the subway, the drainage was extended to two longitudinal drains built under the sidewalks as shown in Fig. 6. These drains divert the water to the ends of the subway, where it emerges in the open on the slopes of the hill through which the subway section was built, and from these points the drainage water flows through pipes to the existing sewer systems.

ORGANIZATION

The work of which the design has been described, was carried out under the direction of the New Jersey State Highway Commission and the State Highway Engineer. W. G. Sloan, M. Am. Soc. C. E., was the State Highway Engineer from the inception of the work until 1929, when he was succeeded by J. L. Bauer, M. Am. Soc. C. E. Fred Lavis, M. Am. Soc. C. E., was in charge of the work from the beginning until 1928, when he was succeeded by H. W. Hudson, M. Am. Soc. C. E. The writer was Designing Engineer from the inception of the work to its completion.

DISCUSSION

FRED LAVIS,[3] M. AM. SOC. C. E. (by letter).—So thoroughly has the author covered his subject that there is very little opportunity for comment or discussion. Nevertheless, emphasis may be placed on certain phases of the work, particularly in regard to those which affect engineers and engineering.

The author states that eight years elapsed from the "inception" of the work until its completion. These eight years of active work, however, were preceded by almost two years of preliminary studies[4] by an Advisory Board, under the Chairmanship of William G. Sloan, M. Am. Soc. C. E., the Highway Commission, and the State Legislature, and it seems worth while to emphasize the fact of this lapse of time and also of the almost incessant negotiations with all kinds of people and entities whose interests were affected throughout almost the entire period. The burden of these negotiations fell very largely on the Engineering Department of the State Highway Commission and on the counties and municipalities affected. The point to be emphasized is the importance of recognizing this as a part of engineering work and that this latter is by no means confined to computing the size of an I-beam or the proper mixture of concrete.

In the valuations of public utilities and other enterprises, due credit and allowance are seldom given for the time involved and the necessary costs of these factors; that is, first, the item of "Interest during Construction" and, second, the "Costs of Engineering."

It should be made quite clear, also, that there are two elements, or two major types, of design in a project of this nature: (1) The design of the route; and, (2) the design of the structure which carries the route. In both these designs the element of engineering expense is greatly increased by the need of meeting the numerous and varying demands of the many interested parties. It should not be thought that this engineering work and these demands are unnecessary or unavoidable, but their cost and the time necessary to meet them should be recognized as an important element in a project of this nature.

The engineers in charge of this work visualized its general nature, importance, and effect from the very beginning, as is witnessed by the report of the Advisory Board; but naturally these factors were not so clear to the public and other interested entities. An infinitude of details also developed as soon as actual surveys and designs were started, and their effect on the studies continued throughout the course of the work.

The writer has previously mentioned[5] the various routes through Jersey City of which more or less detailed studies were made. This was also true of the route through Elizabeth. In the matter of structures, a number of schemes, including a viaduct of reinforced concrete arches of varying length of span was worked out for the meadows crossing where now the high viaduct has been built. Fairly detailed studies were made for lift spans for the river crossings, one of which would have been, if built, the heaviest lift span in existence, and these are only instances of the many phases of the studies.

[4] Rept. of Advisory Board to the New Jersey State Highway Comm., August 8, 1923.

[5] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1020.

It is generally true, as the author points out, that there is nothing particularly novel or unusual in any of the types of structures finally adopted; but the fact should not be lost sight of that the project as a whole was new and unusual and that it required not only great patience and not a little ingenuity in the negotiations. All these things required the expenditure of much time and considerable money.

It has been the writer's experience, and that of many engineers, that all this work of preparing sketches, plans, detailed studies, innumerable estimates of costs, etc., for various schemes eventually to be discarded, is apt to be entirely forgotten after the structure is completed; or, it is assumed that the engineers should have brought forth, full fledged, the final design at the beginning.

Even in private enterprises, where there may be less diversity of opinion, this is not possible or practical. It is much less so in public enterprises where State, county, and municipal officials, Chambers of Commerce, other public bodies, and the public itself, all have ideas, often many different ideas, to all of which some attention must be paid. It is quite difficult to obtain recognition by public officials of this phase of engineering, and the work involved in the development of these projects, and it seems important, therefore, to record this and to give due recognition to the fact that the State Highway Commission of New Jersey and the State Highway Engineer never failed to give those in charge of the project complete support and full recognition of the work required, and which was accomplished, in working out the problems of this important enterprise.

THEODORE BELZNER,[6] AFFILIATE, AM. SOC. C. E. (by letter).—The author has covered his subject so thoroughly that discussion is limited to a few remarks on the subject of expansion joints.

The writer has had occasion to observe the behavior of the expansion joints shown in Fig. 9, and of many other types, all of them giving similar results, under heavy vehicular traffic.

Of them all, the writer believes firmly that Type 4, Fig. 9, is not only an ideal, efficient, and economical one from a maintenance point of view, but that it is the most serviceable type for heavy vehicular traffic on viaduct structures.

J. B. FRENCH,[7] M. AM. SOC. C. E. (by letter).—The clearness and value of a paper on such an extensive and varied piece of construction are largely dependent on the good judgment with which the descriptive and illustrative material is selected to emphasize the salient and most important features without the inclusion of too much subordinate detail; and this paper deserves high praise on this score.

[7] Cons. Engr., New York, N. Y.

Due to the almost unique importance of this "super-highway" as a trunk line of intense motor-vehicle traffic between New York City and the South and West, structural details, otherwise worth description, are quite overshadowed by questions of alignment, grades, roadway widths, and wearing surfaces, and all those details which have the most direct effect in facilitating the safe, fast, and uninterrupted flow of traffic on the elevated structure itself and which, at the same time, cause the least possible interference with the street, railroad, and water-borne traffic below.

These considerations, of course, enhance, rather than reduce, the importance of adequate foundations, solid and enduring types of construction, and the reduction of maintenance operations (particularly those that are likely to interrupt traffic) to the lowest practicable limits, and the paper gives ample evidence that all these matters have had competent and thorough-going attention.

In the viaduct structures, the use of heavy reinforced concrete floor, curb, and railing construction, the encasing in concrete of all structural steelwork below the roadway level (except in the case of the long-span trusses), the careful attention given to the collection of the drainage on the roadways, and the carefully designed expansion joints to insure smooth riding at all temperatures—all these appear admirably designed to meet the requirements imposed and to satisfy the standards of up-to-date practice.

In noting the omission of concrete covering and the painting of the steelwork above the roadway level and in the long-span trusses, the author justifies the procedure by stating that "the additional steel required for carrying the weight of the protection would have increased the cost so materially that it did not appear to be warranted economically;" and the question naturally arises whether, after making the painting of steelwork on a fairly large scale a necessary maintenance operation, it would not have been consistent to apply the same reasoning further, and thereby to have reduced proportionately the cost of both the superstructure and the foundations.

It also seems pertinent to point out, without criticism of the construction described in this paper, that recent advancement in the design and construction of open-grid metal flooring; in the use of light-weight non-corrosive metal alloys in floor construction; and the more extensive and successful use of welding processes, will, it is to be hoped, make practicable much lighter and less expensive floor, curb, sidewalk, and railing construction without involving increased maintenance cost.

Another economy that would obviously follow the adoption of open flooring would result from allowing rain and snow to go through the floor, like a sieve, in practically no more concentrated form than if the floor were not there, thereby eliminating the costly necessity of keeping acres of roadway surface water-tight and of providing a complicated and expensive system of catch-basins and water pipes, over at least large parts of viaducts where the use of the land or water below needs no special protection from the weather.

PRACTICAL RIVER LABORATORY HYDRAULICS

By HERBERT D. VOGEL[1], ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. LORENZ G. STRAUB, PAUL W. THOMPSON, RALPH W. POWELL, K. D. NICHOLS, FRANK W. EDWARDS, I. H. PATTY, CHARLES S. BENNETT, KENNETH C. REYNOLDS, V. V. TCHIKOFF, SAMUEL SHULITS, CHARLES D. CURRAN, J. B. EGIAZAROFF, AND HERBERT D. VOGEL.

SYNOPSIS

The science of laboratory hydraulics as applied to determinations of problems relating to the control of rivers is of only recent origin, although hydraulic experiments of other kinds have been common for many years. Since the beginning of the Twentieth Century, however, considerable progress has been made, and while much still remains to be learned of limiting laws and conditions, it appears, nevertheless, that the time has come to take stock of the practical information available.

It is the purpose of this paper to summarize, as briefly as possible, existing data and to describe proven methods applicable to the solution of river hydraulics problems in the laboratory. By so doing, it should serve as a basis of procedure for the laboratory technician and as a guide to the field engineer who wishes to know what specific types of problems may be reasonably subjected to laboratory treatment.

INTRODUCTION

The utilization of models as a means for the determination of full-scale performances was conceived nearly 250 years ago when Sir Isaac Newton in his monumental treatise, the "Principia," stated in a single paragraph the Principle of Similitude. For more than 175 years this idea lay dormant; then it was seized upon by Froude, an English Naval Engineer, who applied it to studies aimed to ascertain the best design for a ship's hull. Numerous

NOTE.—Published in November, 1933, *Proceedings*.

[1] Lieut., Corps of Engrs., U. S. A.; The Command and Gen. Staff School, Fort Leavenworth, Kans. (Formerly Director, U. S. Waterways Experiment Station, Vicksburg, Miss.)

models were constructed by Froude, and in a narrow, water-filled tank they were towed at varying velocities, while accurate measurements were made with a view to determining the tractive resistances encountered. These experiments with moving objects in still water quickly suggested the possibility of investigating, through the use of small-scale replicas, the effects of flowing water on stationary objects, and, similarly, the effects of engineering structures on the regimen of rivers.

In 1875, the first true river models were constructed in France by Fargue, who attempted to determine effects resulting in prototypes a hundred times as large as the miniatures with which he dealt. His models were of the Garonne River and his problem was to determine methods of improving the channel of that stream for navigation. Ten years after the experiments by Fargue, Professor Osborne Reynolds, of the University of Manchester, Manchester, England, invoked the Principle of Similitude by utilizing scale models in the investigations of flow in a tidal estuary of the River Mersey, at Liverpool. About a year later (1886), Sir William Vernon-Harcourt applied these principles in experiments for the improvement of navigation near the mouth of the River Seine in France, but his investigations, like those of his predecessors, were conducted haphazardly, without suitable equipment and without a thorough understanding of the basic principles of model research.

A renaissance era in the science of river research was initiated by Professor Hubert Engels, of the Technical University at Dresden, Germany, at the beginning of the Twentieth Century as the result of a visit to America a few years earlier. Professor Engels began his investigational work in 1891, but at that time possessed no laboratory and no organized staff for research. In the University of Michigan, at Ann Arbor, Mich., he found an embryo hydraulic laboratory with demonstration equipment then used for classroom instruction, which so inspired him that he returned to his own University with definite plans in mind for a permanent and well-ordered hydraulic research institution. His first laboratory was a modest affair installed in the basement of the University in 1898. Here, he gradually increased his range of experiments and a few years later rebuilt his laboratory in larger form. The utility of the methods which he introduced quickly attracted the attention of other German engineering colleges, where new and larger laboratories were built—guided often by the friendly personal counsel of Professor Engels.

In 1903 there appeared on the horizon a new personality destined to influence largely the development of hydraulic laboratory methods and the promulgation of the laboratory idea. This was Dr. G. de Thierry, who, in that year, received his appointment as Professor of Canal and Harbor Engineering and of Hydraulics at the Technical University in Berlin, Germany. Professor de Thierry founded an efficient student laboratory at his institution of learning and, assisted by Professor Ludin, of the same University, did much toward promoting the development of the Experiment Institute for Hydraulics and Naval Architecture in Berlin. This Institute built in 1902 and 1903 by the Prussian Government, carries definitely associated with it the name of Hans Detlef Krey, who, until his death in 1928, stood pre-eminent in the field of practical hydrodynamics. Under the supervision of Professor de Thierry and the sponsorship of the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., the monumental treatise, "Wasserbaulaboratorien Europas," came into being in 1926 as a summary by leading directors of the accomplishments of their respective laboratories. The same book translated into English and published in 1929 under the title, "Hydraulic Laboratory Practice," stands to-day as a leading reference in the subject of hydraulic research. Because of the comprehensive manner in which this work has treated the subject it is deemed unnecessary to elaborate here on the details of the many laboratories now existent in the world as offspring of the parent institution founded by Professor Engels. Suffice it to say that the idea has been received with considerable favor by engineers and that the mathematical doctrine stated somewhat obscurely by Newton, in a single paragraph, has been expanded and elaborated to cover a wide range of problems, from turbine design to the improvement of harbors. Researches carried on by means of the principle relate to: (*a*) The improvement of both the efficiency and capacity of hydraulic turbines; (*b*) the finding of remedies for the evils of cavitation in turbines; (*c*) improvements in efficiency and capacity of centrifugal pumps and propeller pumps; (*d*) the improvement of the designs of spillways for water-power dams; and (*e*) the designing of great sluice-ways so as to present a minimum loss of head. Another important problem is that of finding the best means of dissipating energy of flood waters flowing over a high dam where it is tending to cause damaging scour in the river bed below the dam.

The scope of hydraulic laboratory practice has been extended since about 1918 to include studies of bed movement in rivers, and methods of changing or influencing such movement; to investigations aimed at the determination of effects of cut-offs in large alluvial rivers; to experiments dealing with means of preventing damage to railway embankments during overflow by flood waters; and to hundreds of similar studies and investigations. In spite of this rapid expansion of the utility of the hydraulic laboratory, it appears probable that its greatest service to hydraulic science remains yet unperformed. The practical field engineer has had a new and most important tool placed at his disposal, but until he has made further advances toward mastering the technique of this science and adapting it to his purposes, it will not fulfill its full potential value. For this reason it is of the utmost importance that field forces be encouraged to maintain constant contact with tests in progress at the laboratory and that they be trained to observe, for themselves, the model phenomena and their interpretation in terms of Nature. Such observations may be of much greater benefit than a formal written report of the tests.

HYDRAULIC SIMILITUDE

General.—If two geometric figures are drawn so that all corresponding lines are of the same ratio and their corresponding angles are of equal degree, it will be found that their areas bear a fixed relationship, one to the other, that may be expressed by the square of the basic linear ratio. The two figures are then said to be similar, and from the one may be determined all the properties of the other. As defined by the dictionary, for a geometric sense, similitude is "the relation of identity between two figures irrespective of magnitude."

From an hydraulic standpoint, strict geometric similarity may often be subordinated to the necessity of preserving other, more important, relationships, and hydraulic similitude has been defined as referring to those "conditions which must be observed in experiments with a model in order to reproduce faithfully the phenomena occurring in full-scale performance." Where then, in such cases, a sacrifice of true geometric similarity becomes necessary it is on the basis of preserving dynamic or kinematic similarity as a means toward obtaining hydraulic similitude.

True geometric similarity implies undistorted linear relationships; that is, it requires that all corresponding linear dimensions in the full-scale and model must be in the same ratio. More generally speaking, however, it may be said that a kind of form similarity exists even in cases where the model is distorted, provided the distortion is a result of some definite and consistent plan.

Dynamic similarity requires that at corresponding times in full-scale and model the accelerations of corresponding mass elements must be in constant ratio to each other, and must be directed in the same relative directions. Since it is physically impossible to modify the effect of gravity in a model, the same reduction of accelerations, according to a fixed ratio, will fail to satisfy completely the foregoing requirements of dynamic similarity, but from the relationship existing between force and the product of mass and acceleration, it is evident that with corresponding forces bearing a constant ratio to each other, such similarity may be attained by making corresponding accelerations equal in model and prototype. Briefly stated, therefore, dynamic similarity is governed by the requirement that at corresponding times any two corresponding forces in full-scale and model must be in the same ratio, and to obtain this condition the conditions for mechanical and kinematic similarity must also be satisfied. The first of these requires corresponding weights in the two systems to possess a definite fixed ratio one to the other; the latter demands that the full-scale and model must be geometrically similar in all respects, at corresponding times; or, in the case of hydraulic models, the elements of flow must simulate corresponding elements in Nature with respect to both direction and time.[3] Difficulties naturally arise in the interpretation of results obtained from model studies because it is almost impossible to simulate all conditions and properties of Nature. Theoretically, this might be done in certain special cases if it were possible to control independently, and at will, all the properties of the materials in the model as well as the forces involved. These properties include the density, viscosity, and surface tension of the fluid used in the model; and the size, shape, cohesion, and density of the solid materials. The external forces include gravity, friction, and barometric pressure.

---

[3] See "Die Grundlagen der Aehnlichkeitsmechanik und ihre Verwertung bei Modellversuchen, unter besonderer Berücksichtigung· Schiffbau technischer Anwendungen," von M. Weber, Charlottenburg, Germany, 1918. For a slightly different conception refer to "Strömungslehre der Rohre und Offene Gerinne," von Schiller und Eisner, Leipzig, 1932.

Scale Relationships and Nomenclature.—Although a number of papers have been presented on the subject of similitude, it is extremely difficult in many cases to follow the reasoning involved, due to complex systems of nomenclature. These systems are obviously the result of haphazard growth rather than predetermined plan, and English, German, and Greek letters will be found indiscriminately mixed.

At the United States Waterways Experiment Station, at Vicksburg, Miss., capital letters with the subscripts, m and n, are taken to indicate corresponding quantities in the model and in Nature. The ratio of these quantities expressed in the order, model to Nature, is denoted by the same letter, uncapitalized. Thus, the length scale is, $l = \frac{L_m}{L_n}$, and is always a fraction except in the case of the slope scale, which is an integral. This is in accordance with conventional designations and the usual understanding of scale values pertinent to other sciences. The scale of a map, for example, is conventionally expressed as 1:25 000 rather than 25 000 which, by itself, constitutes only a meaningless number. The following letters are taken to represent commonly used hydraulic elements:

A = area of cross-section.
B = a distribution factor pertaining to relative fineness of sand.
C = a roughness coefficient (see, also, N).
D = depth, or head; also, diameter.
E = diameter of sand grains.
F = tractive force per unit area.
G = acceleration of gravity.
H = head (see, also, D).
J = weight of fluid per unit of volume.
K = a constant for practical purposes $\left(\text{in Equation (4), } K = \frac{Q}{L D^{\frac{3}{2}}}\right)$.
L = length, or breadth.
M = modulus of viscosity.
N = coefficient of roughness.
P = wetted perimeter.
Q = discharge.
R = hydraulic radius.
$\mathbf{R}$ = Reynolds' number.
S = slope.
T = time.
V = velocity.
Z = turbulence criterion.
α = a basic scale ratio.
$\boldsymbol{a}$ = a scale ratio of areas, $\frac{A_m}{A}$.

d = a scale ratio of depth, $\frac{D_m}{D_n}$.

e = a scale ratio of sand-grain diameters, $\frac{E_m}{E_n}$.

j = the scale ratio, $\frac{J_m}{J_n}$.

j_1 = unit weight of bed material; j_2 = unit weight of water.

l = a scale ratio of length, $\frac{L_m}{L_n}$.

m = a subscript denoting a model characteristic.

n = a scale ratio of roughness coefficient; also, a subscript denoting a prototype characteristic (n, for Nature).

p = a scale ratio of the wetted perimeters, $\frac{P_m}{P_n}$; also, density.

q = a scale ratio of discharge, $\frac{Q_m}{Q_n}$.

r = a scale ratio of hydraulic radius, $\frac{a}{p}$.

s = a scale ratio of slope, $\frac{S_m}{S_n}$.

t = a scale ratio of times, $\frac{T_m}{T_n}$.

u = viscosity coefficient.

v = a scale ratio of velocity, $\frac{V_m}{V_n}$.

This system is designed to apply particularly to practical hydraulic research and is not essential to the case of ideal similarity, such as will now be discussed.

Similarity of perfect fluids requires only a consideration of the force of gravity and, therefore, all others, such as friction and viscosity, may be neglected. When this is true, the involved quantities may be expressed as simple functions of the basic scale ratio, which will be denoted by α. The following list is based on such a conception:

Quantities	Scale values
Angular accelerations	$\alpha^{-1.0}$
Revolutions per unit of time	$\alpha^{-0.5}$
Accelerations, constants	$\alpha^{0.0}$
Velocity and time	$\alpha^{0.5}$
Linear dimensions	$\alpha^{1.0}$
Discharge per unit time per unit width	$\alpha^{1.5}$
Areas	$\alpha^{2.0}$
Discharge per unit time	$\alpha^{2.5}$
Volumes, masses, forces, weights	$\alpha^{3.0}$
Power, momentum, impulse	$\alpha^{3.5}$
Work, energy, moments	$\alpha^{4.0}$

The values in this tabulation are directly obtainable from the formula for velocity produced in a freely falling body by the influence of gravity, ($V = \sqrt{2GH}$). Beginning with this relationship:

$$\frac{V_m}{V_n} = \frac{\sqrt{2GH_m}}{\sqrt{2GH_n}} = \frac{\sqrt{2GD_m}}{\sqrt{2GD_n}} = \frac{\sqrt{D_m}}{\sqrt{D_n}} \quad \ldots\ldots\ldots\ldots \quad (1)$$

Whence,

$$v = \sqrt{d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (2)$$

or, expressed in words, the velocity scale is equal to the square root of the vertical scale. This relationship, together with that for the time scale, $t = \sqrt{d}$, is known as Froude's law and is the basic equation for the determination of velocity scales in hydraulics and other sciences, in which gravity is the controlling influence. It should be noted, however, that Equation (2) is for the effects of gravity only and is not applicable to conditions involving frictional or other coefficients. From it is derived the discharge scale:

$$q = l\, d^{\frac{3}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (3)$$

obtained by multiplying scale values for area and velocity.

In case the model is designed to show the effects of discharge over dikes, dams, or other structures functioning primarily by gravity, it is obvious that only the relationship expressed by Equation (3), is directly applicable to an expression of the natural phenomenon involved. In the case of a weir this relationship may be determined in another way, by applying the principles of similitude to standard weir formulas of the form,

$$Q = K L D^{\frac{3}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (4)$$

Factor K in this case disappearing as a constant in the resulting formula for similitude. For practical purposes, K may be assumed. Actually, experiments indicate that K is a function of D to a certain extent. Here is a first indication of the complexities that may be encountered in attempting to simulate, completely, the effects of both main forces (gravity and friction) in connection with any hydraulic model study. Fortunately, however (and generally), in practice, one of the forces may be eliminated from consideration, as in the present instance. In so far as K is not a constant, but presents frictional characteristics varying with D, a slight error will be introduced by Equation (4), which was derived solely from a gravitational relationship.

The validity of the Froudian relationship, even in cases where the frictional variances may be fairly large, is indicated by the results of experiments with full-scale and small-scale railroad embankments at the U. S. Waterways Experiment Station. These tests were conducted to determine the erosive action and general destructive effects of flood waters and to devise methods of protecting the embankment, economically, against such effects; but since several models were used they served nearly equally well to show existing scale relationships. Table 1 of readings at corresponding times, illustrates the observed similarity.

TABLE 1.—Scale Relationships Between Model and Full-Scale Embankments

Item No. (1)	Description (2)	Full-scale embankment (3)	1:5-scale embankment (4)	1:5-model results transferred to full scale (5)
	Gauge Reading 30 Ft (Distance in Full Scale) from Center Line of Track:			
1....	(a) Up stream....................	3.0	0.60	3.0
2....		3.2	0.63	3.2
3....	(b) Down stream..................	2.4	0.48	2.4
4....		2.8	0.59	3.0
5....	Velocity, in feet per second...........	5.4	2.6	5.8
6....		5.2	2.4	5.4

Open-Channel Models, Undistorted.—As previously stated, fulfillment of the conditions establishing perfect similarity is seldom had in connection with problems pertinent to flowing water, and except where gravity might be assumed to act alone, as in the case of flow over dams, weirs, etc., modifications must be made according to the nature of the predominant forces.

Where a movement of water occurs in relatively shallow channels, as is frequently the case in Nature, the factor of bed roughness assumes such proportions as to make friction practically a controlling consideration, and no longer can the relations, previously cited, be adhered to unless secondary factors are introduced for their modification. Rather than attempt this, however, it is often better to determine scale values from well-known hydraulic formulas, such as those developed by Kutter and Ganguillet, Bazin, and Manning. Making use of the formula of the latter:

$$Q = A\,V = \left(\frac{1.486\,A}{N}\right) R^{\frac{2}{3}}\ S^{\frac{1}{2}}$$

whence,

$$q = \frac{Q_m}{Q_n} = \frac{A_m}{A_n}\left(\frac{N_n}{N_m}\right)\left(\frac{(R^{\frac{2}{3}}{}_m\ S^{\frac{1}{2}}{}_m)}{R^{\frac{2}{3}}{}_n\ S^{\frac{1}{2}}{}_n}\right) = \frac{a\,r^{\frac{2}{3}}\ s^{\frac{1}{2}}}{n} = \frac{a^{\frac{5}{3}}\ s^{\frac{1}{2}}}{n\ p^{\frac{2}{3}}}$$

By correcting this relationship for frictional variations in channels of varying shapes, the same is then directly applicable to problems involving distorted scales.

If no distortion is involved, horizontal and vertical scales will be equal, and the formula for discharge will be reduced to $q = \frac{l^{\frac{10}{3}}}{n\,p^{\frac{2}{3}}}$, or, assuming the hydraulic radius equal to the mean depth,

$$q = \frac{l^{\frac{8}{3}}}{n} \quad \text{.............................(5)}$$

Since the velocity scale, $(v) = \frac{q}{a} = \frac{q}{l^2}$,

$$v = \frac{l^{\frac{2}{3}}}{n} \quad \text{.............................(6)}$$

Other functions of the model may be determined in the same manner on a basis of the Manning formula or, if desired, from the Chezy or other relationships.

Although many European experimenters have expressed themselves unmistakably as opposed to the use of distorted models, nevertheless it is impossible in many cases to adhere to true similarity of reproduction on a small scale. As a matter of fact, there is scarcely a conceivable problem with respect to the Mississippi, or any other alluvial river, for which a solution can be obtained without resort to distortion because, where depths bear small ratios to widths, a reduction of linear elements by the same scale results in shallows in the model that are similar in their functioning (through the phenomena of surface tension and adhesion) to nothing that exists in Nature. Moreover, the velocity as deduced by Froude's law may be so small as to cause stream-line flow in the model, whereas flow in Nature is almost invariably turbulent. In turbulent flow the surface slope of the fluid (and, therefore, the friction head) increases in proportion to the square of the mean velocity, while in stream-line flow it increases only as the first power of the velocity. It is plain, therefore, that the characteristics of flow will be entirely different under the two conditions, and it becomes necessary to provide, in each case, that natural phenomena are accurately simulated.

Much has been said about geometric distortion in models and little about the distortion of other properties which occurs when the scale is reduced even if the model is not distorted geometrically. In reality, every model is distorted in some respects. The investigator must not be misled into overlooking, complacently, the less obvious distortions of properties and forces while he concentrates on avoiding geometrical distortion. The question is not whether distorted models will be used; it is rather, how can the distortion that is certain to occur in every model be made least harmful?

Referring once more to the Manning formula a relationship for similarity of discharge may be derived for distorted models in the same way as previously indicated. By dropping constants and substituting scale values for the hydraulic radius, *R*, slope, *S*, area, *A*, and the coefficient, *N*, there is evolved, as an expression of the discharge scale:

$$q = \frac{r^{\frac{2}{3}}\ s^{\frac{1}{2}}\ a}{n} \quad \dots\dots\dots\dots\dots\dots\dots\dots (7)$$

If the model has been built according to principles of simple distortion—that is, with no artificial adjustment of slope—and if the cross-sections are flat enough to permit substitution of mean depth, *d*, for *r*, it is found that,

$$q = \frac{l^{\frac{1}{2}}\ d^{\frac{13}{6}}}{n} \text{ (approximately)} \dots\dots\dots\dots (8)$$

Where an additional slope is given to the model to facilitate bed-load movement, the equation becomes:

$$q = \frac{l d^{\frac{5}{3}}\ s^{\frac{1}{2}}}{n} \quad \dots\dots\dots\dots\dots\dots\dots\dots (9)$$

These relationships are of value mainly as means of determining before the construction of the model, the quantity of water it will be necessary to supply. In an active laboratory with many models in operation it is frequently necessary to conserve the water or to regulate its distribution so that each model will be adequately served. It is essential, therefore, to know in advance approximately what discharge will be required. After the model has been put into operation, exact scales for discharge, velocity, and time may be determined experimentally in a manner to be described subsequently. To use Equation (8), however, even as a basis for estimates and design, an approximate evaluation must be made of the ratio, n, which is never accurately determinable. Fortunately, it has been found by experiment that for small-scale models (those in which $l < \frac{1}{1\,000}$), built with cement mortar, and for models of intermediate scale (those in which $\frac{1}{1\,000} < l < \frac{1}{500}$), built with a sand bed, the value of n is nearly unity. Since this n is the ratio between N of the natural river and the N of the model, there would appear at first to be an anomaly, because standard tables place the value of N in a reasonably good stretch of river at about 0.030 and at about one-half that in a concrete flume. The controlling factors of slope and hydraulic radius must be taken into consideration, however, and even casual thought will reveal that in a model river of small cross-section much resistance will be encountered even when the surface is relatively smooth.

Under the assumption that n may be taken as equal to unity, the following formula is obtained for discharge in the model of a river:

$$q = l^{\frac{1}{2}}\, d^{\frac{13}{6}} \qquad \text{(10)}$$

The applicability of Equation (10) as a means of determining the required discharge in a model is shown in Table 2, which gives data in round numbers on experiments conducted at the U. S. Waterways Experiment Station. A further interesting proof of the formula is found in its application to the results of European experiments. In the case of models built to a slope scale that does not result from normal distortion, the formula must be applied in the form, $q = l\, d^{\frac{5}{3}}\, s^{\frac{1}{2}}$. Testing it for the Elbe River model of the Preussische Versuchsanstalt, where $l = 1:200$, $d = 1:40$, and $s = 8:1$, q is found to equal 1: 33 000. The value of q as determined by Professor Krey's experiments was 1: 30 000.[8]

The discharge scales given in the last line of Table 2 were determined for each model by varying the flow over the weir and adjusting the tail-gate until the flow line measured in Nature had been definitely reproduced. The ratio between the measured discharge of the model and the corresponding measured discharge in Nature was taken as the true scale for discharge. As shown by Table 2, these values are in close agreement with the theoretical determinations for channel flow, but are considerably at variance with the determinations by the gravity formula.

---

[8] Unpublished report of the Preussische Versuchsanstalt für Wasserbau und Schiffbau, Berlin, 1928.

The velocity scale is obtained as previously indicated, of course, by dividing the scale for discharge by the scale for area, whence:

$$v = l^{-\frac{1}{2}} d^{\frac{7}{6}} \qquad \text{(11)}$$

TABLE 2.—COMPARISON OF THEORETICAL AND ACTUAL DISCHARGE (Data Obtained from Tests Conducted at the U. S. Waterways Experiment Station)

Scale ratios	SMALL-SCALE, CONCRETE SURFACE				SAND BED	
	A	*B*	*C*	*D*	*E*	*F*
$l =$	1:4 800	1:4 800	1:2 400	1:1 200	1:720	1:720
$d =$	1:360	1:200	1:120	1:48	1:72	1:72
$q = l^{\frac{1}{2}} d^{\frac{13}{6}}$	1:24 000 000	1:6 700 000	1:1 567 000	1:152 000	1:284 000	1:284 000
$q = l d^{\frac{3}{2}}$	1:32 800 000	1:13 600 000	1:3 155 000	1:399 000	1:440 000	1:440 000
Measured q =	1:21 000 000	1:7 200 000	1:1 570 000	1:150 000	1:300 000	1:280 000

The time scale as referred to hydraulic discharge is determined from the relationship: $\text{Discharge} = \dfrac{\text{Volume}}{\text{Unit time}}$. Whence, the time scale equals the volume scale divided by the discharge scale, or,

$$t = \frac{l^2 d}{q} \qquad \text{(12)}$$

This relationship is particularly applicable to reservoir problems, or to flood-control problems where the time element is important, such as in the filling of back-water basins and other areas of storage. It is not applicable to problems of channel contraction, sedimentation, or similar investigations involving rates of bed development. Such rates must be determined by actual tests conducted in Nature and in the laboratory. There is no known "short-cut" to such determinations, and formulas taking into account the transporting power of flowing water and the resistance to motion of grain particles in suspension or otherwise, are almost invariably misleading.

SIMILITUDE AS APPLIED TO BED MOVEMENT IN OPEN-CHANNEL MODELS

General.—In the preceding pages it has been shown that problems encountered in a river hydraulics laboratory fall naturally into two general groups. In the case of spillways, submerged dikes, or weirs, for which it is desired to determine coefficients of discharge, head over the structure, or other similar data, gravity may be considered as the controlling force; but in the case of open-channel models, bed and wall friction becomes of increasing importance. A compromise is frequently necessary in instances where dikes must be considered as a means of channel improvement, and seldom is it possible to apply any one set of laws indiscriminately to such a problem. Where the investigation is designed for the determination of back-water limits, or the drawdown resulting from the removal of some obstacle resisting the flow of the stream, it may be that a fixed-bed model will suffice, but all too frequently it is necessary to build the replica with a bed of movable material that will be acted upon by various existent currents. Experiments with movable-bed models being of the most difficult type to perform, it follows that investigations designed to determine effects of dikes on river beds must be approached with caution and understanding.

In choosing a sand for the bed of the model it must be conceded that close adherence to principles of geometric similitude is entirely impossible because, assuming the model to be built to a scale of 1:500, the same particles of Nature would be so reduced in size as to present a microscopic appearance. The impalpable powder could not be used in the model under any operating condition because, due to its extreme fineness, it might either float, be transported in suspension as sedimentary matter, or become compacted so as to resist, completely, the tractive power of the model stream. Fine, uniform sands have been used throughout many experiments, but a cardinal objection is that riffles of the bed invariably form. These riffles, of course, bear a certain similarity to the sand waves of Nature, but their height may be so grossly exaggerated as to detract from the accuracy of the model results. In practice, the difficulty may be partly rectified by smoothing out, in the model, the ranges on which soundings are taken.

Certain limiting conditions must always be considered whenever it is planned to experiment with a movable-bed model. It is obviously impossible to simulate entirely all physical properties of a natural stream. Distortion of linear dimensions is sometimes necessary to produce measurable depths and proper turbulence. Excessive distortion may result, in certain types of models, in an extreme and undesirable dissimilarity of flow phenomena. In addition to the factors that influence bed development (such as discharge, slope, etc.), there is also to be considered the guiding of the transported bed load. Preservation of geometric similarity, on the other hand, is practically impossible for the reasons given, namely, that a scale reproduction of the transported bed material would result in a fine material, subject to excessive riffling should any movement whatever occur. Just as it is often necessary to depart from conditions of true geometric similarity in the design of the model in order to keep it within workable limits and, at the same time, to obtain measurable depths and the proper character of flow, it is also necessary to exaggerate the size of sand grains, and, concurrently, it is frequently advisable to exaggerate the model slope in order to obtain similarity of the bed-load movement.

In departing from the laws of geometric similarity by distorting the model and utilizing a coarser grained bed material, thought must be given to those natural laws that are regarded as *a priori* principles of stream-bed development; that is, the plan of the stream must be unchanged from that of Nature and all curvatures must be reproduced in their exact relationships. If the radii of curvature of the channel are altered from one point of inflection to the next so that they are smallest at the vertex of the curve and then increase gradually (from the vertex to each point of inflection) to infinity again at the points of inflection, then the pools will be deepest in the vertex of the curve and will gradually decrease in depth as the inflection points are approached. In the same way, it is essential that the length of the curve be made to correspond to the inherent nature of the stream, by matching the deflection points with those of a well-developed reach of the natural river investigated.

The result of a well-guided curvature is generally to produce a satisfactory channel in which the thalweg passes through the middle of the cross-sections at points of inflection and crosses in an easy curve to the outside of the next bend. The close relationship between radii of curvature and pool depths must be kept in mind whenever experiments with models are undertaken because, since the purpose of such experiments is to determine methods for procuring a good, navigable channel, the flow must be made to follow smoothly from one bend to the next and thus secure navigable depths at all points.

As it is scarcely possible in theory to predetermine how deep the pools in a natural stream will become as a result of contractions, or whether dredging may be required, so also is it difficult to predict with assurance what depths may be anticipated unless the entire investigation is subjected to model study. Where a depth scale is chosen, as, for example, 1:50, there is no reason to expect that the same scale will be exactly applicable to the bed formations. By trial and accident this may be true, but in many cases compensatory factors must be determined and applied if the results are to be susceptible of quantitative as well as qualitative interpretation. The method most generally followed is to shape the model bed flat and, running through typical hydrographs for sufficient time to produce equilibrium in the bed movement, make observations as to the development, and comparisons as to its similarity with the corresponding developments of Nature. In many cases the natural development of the model is so nearly like that of Nature, that it is difficult to distinguish between maps of the two.

When a model is constructed to very small scale (as is frequently necessary) investigators are confronted with the aforementioned difficulty that sand, sufficiently fine to simulate (in scale) materials of the natural stream, is neither obtainable nor satisfactory, due to resulting riffles. To avoid the formation of riffles, many experiments have been made in America and abroad to determine the practicability of using other materials, such as ground lignite, saw-dust from pressure-creosoted timber, crushed coal, and other likely substances. A more satisfactory procedure has been found, however, in the use of coarser sand and increased tractive forces through greater slopes. In doing this the velocity of flow, of course, must not be made to exceed the upper limit for turbulence, above which shooting flow will be produced. This type of flow will result in the formation of standing waves, which are not characteristic of the type of flow ordinarily encountered in rivers.

If the water depth in the model is represented by D_m, the sand-grain diameter by E_m, and the roughness factor by C_m, then according to Professor

Krey, the limiting values for slope are: $\frac{E_m}{8\,D_m} < S_m < \frac{G}{C^2_m}$. Assuming the average value of C to be 80, then $S < \frac{1}{200}$. This value of 0.005 for the slope is much too great, wherefore, with the small values for D_m and E_m, riffles must undoubtedly appear when S_m is taken approximately equal to $\frac{G}{C^2_m}$; but, if a coarse sand (with a small value of C_m) is used, the obstacle will be largely eliminated. It appears, and is, possible, therefore, to choose E_m and S_m so that, instead of riffles, true sand banks will develop. In this same connection Armin Schoklitsch[4] states that the model sand should be compounded of various grain sizes. Natural sand banks are characterized by a diversity of grain sizes and, therefore, are firmer, for the reason that the spaces between the coarse and fine sand grains are in part filled and cemented with fine sedimentary material. To insure streaming (non-shooting) flow, S_m must be less than $\frac{G}{C^2_m}$, as is discussed in a subsequent paragraph.

Experiments Involving Movable Beds.—Material particles on the bed surface of a stream are acted upon by a number of conflicting forces, including those developed by the flowing water and those of a re-active nature arising from mass resistance and friction. Turbulence of the water may result in the exertion of component forces in several directions and may even produce an actual lifting of any reasonably light particle. This is the phenomenon known as transportation by suspension and is worthy of considerable study in connection with problems of sedimentation and kindred effects. From the standpoint of the practical river engineer, however, the phenomenon meriting most serious consideration is that of the movement of material particles along the stream bottom by hydraulic traction because, if the tractive force is sufficient in any case to overcome the inertia of a particle and its frictional resistance, movement in a down-stream direction will occur. When all bed particles, including the largest and heaviest, have been put into motion, general movement is said to have taken place, and, corollary to this, the critical tractive force for any particular bed load is defined as that force which will produce general movement of the material. ("Geschiebe" is a concise and descriptive German word used to designate bed material. Literally, it means, "that which is shoved.")

The tractive force of flowing water is nothing more than the component in the direction of movement of the weight of the water. Application of the laws of mechanics shows that this tractive force, per unit of area on the river bottom, is expressed by:

$$F = J \times D \times S \text{ ....} (13)$$

in which, F is the tractive force per unit area; J is the weight of water per unit volume; S is the slope (non-dimensional); and D is the depth. Tractive force, then, is a function only of slope and depth. This is a very important consideration and should be kept in mind.

---

[4] "Geschiebebewegung in Flüssen und an Stauwerken," von Dr. Techn. Armin Schoklitsch Wien, 1926.

Suppose that it is desired to design a model involving a movable bed. The usual considerations of space, water supply, etc., have caused the adoption of definite horizontal and vertical scale ratios, assumed for the sake of argument, as 1:500 and 1:125. It is requisite that the bed load in the model move in a manner similar to that in its prototype; hence, if general bed movement in Nature begins at a 30-ft stage, it should begin at a corresponding stage in the model; but at what stage does bed movement begin in Nature? It is seldom practicable to determine this by actual observation, due to the depth and turbidity of the average river. Fortunately, a solution by laboratory methods is readily found by applying the law of M. P. du Boys[5] as given previously herein, since it may be demonstrated that for any particular bed material the critical tractive force is constant; that is, if the slope is doubled, the depth may be reduced by one-half and movement will still obtain.

To return to the problem of determining where general movement occurs in Nature: Suppose a representative sample of bed material is obtained from the actual river and moulded to a constant depth in a tilting flume. Obviously, if the flume is tilted to the average slope of the natural bed, to get movement it would be necessary for water to flow over it at a depth equal to that at which movement occurs in Nature. Since this depth could not be obtained in the average laboratory flume the critical tractive force must be determined by increasing the slope in the flume until general movement begins at less depth. Then, knowing the slope in that particular reach of the river, and by substituting this in Equation (13), it is possible to determine the depth in the river at which general movement begins. Computations and procedure for the hypothetical case are, as follows:

Obtaining a large sample of bed-load material from Nature at the locality in question, where it so happens that the average slope is 0.0001, it is placed level in the flume to a depth of about 4 or 5 in., after which the flume is tilted to a slope of 20 × 0.0001, or 0.002. Then water is passed over the bed material, keeping the water-surface slope equal to the bed slope and increasing the depth until movement occurs. Assume that general movement occurs at a depth of 0.5 ft. This indicates that movement in Nature will occur at a depth of about 20 × 0.5, or 10 ft. Therefore, movement in the model must occur at a model depth of $\frac{10}{125}$, or 0.08 ft.

Next, select the sand it is desired to use for the model "geschiebe." Suppose, for example, that it is desired to use Mississippi River sand from a reach of the river near Vicksburg. In the tilting flume, it is found that for general movement a tractive force of 0.008 lb per sq ft is required with this material. It has already been stated that movement is desired in the model at a depth of 0.08 ft; hence, in Equation (13): F = critical tractive force = 0.008 lb per sq ft; J = weight of water per cubic foot = 62.5 lb; D_m = depth = 0.08 ft; and, therefore, S_m = 0.0016 ft per ft. From this it follows that proper movement in the model will result if it is given a bottom slope of 0.0016, or sixteen times that of the natural river reach. Since there is a vertical distortion of 4 to 1, the slope of the model would normally be 4 × 0.0001, or 0.0004. Thus, it appears necessary to supply the additional slope by some approved method. The final slope distortion will be, $\frac{0.0016}{0.0001} = 16$.

---

[5] *Annales des Ponts et Chaussees,* Tome XVIII, 1879.

It is to be noted here that a tacit assumption was made, to the effect that the river bed is parallel to the water surface. That assumption is no doubt true for all practical purposes considering a long reach of a river. All it implies is that the mean depth of the river is fairly constant. However, there are pools and crossings in the river, and the bottom is not parallel to the water surface, except for average conditions over a long reach. Since one cannot hope for sufficient data to design for each crossing and each shoal, the best that can be done is to take averages, and, in the general case, such procedure should result in reasonable accuracy. Consider in this connection, that the model, too, has its pools and crossings and, hence, the average condition designed for will no doubt cause movement in the model at about the same time and place as in the prototype.

To insure proper movement of the model bed material the foregoing procedure may be epitomized, as follows:

1.—Select vertical and horizontal scales so as to produce as little distortion as may be consistent with the production of measurable depths and turbulent flow.

2.—Make a flume test of the sample of bed-load material obtained from the actual locality to be represented by the model, and determine the critical tractive force necessary to insure its transportation. Should it prove impracticable to obtain the bed-load sample in quantities sufficient for testing in the flume, or in the event equipment is not available, the critical tractive force may be obtained by the use of any one of several formulas. Probably the best of these formulas is that of Kramer,[6] namely, $F = \frac{100}{6}\left(\frac{(j_1 - j_2)}{B}\right)E$, in which, j_1 is the unit weight of the bed material; j_2, the unit weight of water; E, the mean grain diameter; and B, a sand uniformity factor obtained by plotting the curve of the mechanical analysis of the bed material, separating the area under the curve into two areas—above and below the 50% line—and determining their ratio.

3.—From a consideration of the results of Step 2 and of the average slope of the natural river, determine the depth at which bed movement occurs in Nature.

---

[6] "Modellgeschiebe und Schleppkraft," von Hans Kramer, *Mitteilungen* der Preussischen Versuchsanstalt für Wasserbau und Schiffbau, Berlin, Heft 9, 1932.

4.—Determine the critical tractive force required for the bed material which will be used in the model. The method to be adopted may be either of those described in Step 2.

5.—From Step 3, plus a consideration of the vertical scale, the depth in the model at which movement is to occur, is known. From a consideration of this model depth and of the results of Step 4 determine the slope necessary for the model.

6.—Tilt the model sufficiently to obtain the slope found in Step 5.

TURBULENCE IN OPEN-CHANNEL MODELS

Requirements for Hydraulic Similitude.—In hydrodynamics many problems arise that defy purely mathematical solutions; however, hydraulic models now provide ready means for investigating such problems. The principles of hydraulic similitude insure that the results obtained from investigation by means of the model will be transferable, quantitatively or qualitatively, to the prototype.

Geometric similitude is concerned with the relations between linear dimensions of model and prototype. Chief among the factors influencing the selection of the horizontal (length and width) scale for the model are the area and shape of the prototype, laboratory space available for the model, and cost of construction. Prominent among the factors influencing the selection of the vertical (depth) scale is the range in elevations of the prototype as against the depths necessary in the model. The latter limitation leads to a consideration of dynamic similitude.

Kinematic similitude requires that every particle in model and prototype shall describe geometrically similar paths in corresponding time intervals; and, closely akin to this, dynamic similitude requires that these motions shall be produced by forces acting in a definite model-to-prototype ratio. For all practical purposes, dynamic and kinematic similitude exists when the flow of water in the model is of the same character as the flow in Nature. If laminar or stream-line flow exists in Nature, it must be reproduced in the model, whereas, if turbulent flow occurs in Nature that kind of flow must be reproduced in the model. As a matter of fact, flow in natural channels is almost invariably turbulent. There are index numbers, derived experimentally, by means of which model and prototype may be examined to find if there is dynamic similitude with respect to any particular force.

It is important to note that both gravity and friction act on flowing water, whereas, in general, dynamic similarity can exist only in respect to a single force. Evidently, this gives rise to a conflict of requirements, and perfect similarity is not to be attained. The best that can be done is to select that force which is of predominant importance, and to seek dynamic similitude with respect to that force. The modifying effect of the other force will prevent the accomplishment of absolute similitude, which in practice is not necessary. Fortunately, the effects of one or the other of the forces is usually so predominant that little error results in considering it as acting alone. Thus, in experiments in which, a high degree of turbulence results, internal friction may be neglected and the laws of gravitation considered as governing.

Reynolds' Criterion for Turbulent Flow.—The index by which turbulence may be measured, was discovered in 1883 by the great English experimenter whose name it bears. The experiments of Osborne Reynolds were confined to small, smooth pipes, but sufficient evidence was obtained to show that a rather definite transition occurs between laminar and turbulent flow. It was further proved that this transition is indicated by a definite value of the non-dimensional expression, $\frac{VD}{K}$ (since called Reynolds' number), in which, V equals velocity; D equals pipe diameter; and K, the coefficient of kinematic viscosity.

From the expression, $\mathsf{R} = \frac{VD}{K}$:

$$\mathsf{R} = \frac{VDp}{u} \quad \text{..........................} (14)$$

in which, the coefficient, K, is replaced by its equivalent value, $\frac{u}{p}$ (viscosity divided by density). Since the dimension of V (velocity) is length per unit time, or $L\,T^{-1}$; of D (diameter) is length, or L; of p (density) is weight per unit volume, or $M\,L^{-3}$; and of u (viscosity) is $M\,L^{-1}\,T^{-1}$, Reynolds' number has no dimensions; that is, $\frac{L\,T^{-1} \times L \times M\,L^{-3}}{M\,L^{-1}\,T^{-1}} = M^{\circ}L^{\circ} = 1$, and the modulus may be shown to be merely a number, or ratio.

Table 3 gives values for absolute viscosity and kinematic viscosity of water for temperatures within possible working ranges.

TABLE 3.—VISCOSITY OF WATER

Temperature, in degrees Centigrade	Absolute viscosity, u, in English units	Kinematic viscosity, $K = \frac{u}{p}$
5	0.001020	0.00001639
10	0.000880	0.00001411
15	0.000766	0.00001230*
20	0.000600	0.00001085
30	0.000538	0.00000865
40	0.000442	0.00000713
50	0.000370	0.00000599

* Value generally used in computations.

As the experiments of Reynolds were confined to small glass pipes, his determinations for the value of the viscosity modulus are not strictly applicable to open channels, but it is worth noting that in the case of pipes the modulus is equal to about 2 500. To write the expression so that it may be used in open-channel determinations, it is necessary, of course, to change pipe diameters into hydraulic radii. It should be noted that as these are both linear dimensions no change is made in the dimensions of the modulus.

From $\mathsf{R} = \frac{V D}{K} = 2\,500$, it follows that $\mathsf{R} = \frac{4\ V R}{K} = 2\ 500$; or, $M = \frac{V R}{K} = \frac{2\,500}{4} = 625$, in which, M is the viscosity modulus for open channels, corresponding to Reynolds' number for pipes.

The value for the modulus (625) as determined from the Reynolds' number, is the subject of some disagreement among modern investigators, Schoklitsch setting its value at 900, and Hopf at 320. Probably, the safest value for its higher working limit is that established by the Prussian Research Institute for Hydraulics, Marine Design, and Earth Testing, which gives 6 000, with a notation that an ample factor of safety is included. Since the range of turbulence is wide between laminar and shooting flow, it is obviously better to choose a safe value if it can be done without too greatly increasing the cost of the model. Accepting tentatively the value of the Prussian Institute: $M = \frac{V R}{0.0000125} = 6\ 000$; or, $V\ R = 0.075$, in which, R is expressed in feet, and V, in feet per second. From this it may be assumed that turbulent flow will always exist when the product of velocity and hydraulic radius (or mean depth) is greater than 0.075.

Recent experiments conducted at the U. S. Waterways Experiment Station have thrown additional light upon the conditions necessary for production of turbulent flow in a small stream or model. The tests were made with a tilting flume, lined with concrete of the same general roughness that is used in models built at the Station, and curves were determined to show the variations of velocity with depth when slope was maintained constant. A straight-line relationship was observed to the point where turbulent flow occurred, the curve beyond this point becoming representative of a second degree function. Thus, the break from straight to curved line indicated the transition from laminar to turbulent flow and served to supply a more accurate criterion for turbulence than had been available previously. By averaging the results of many tests at different slopes, the value of the product of depth and velocity was found to indicate definitely the character of flow produced and, where the value was greater than 0.02 (in English units), turbulence prevailed. Expressed mathematically the criterion for turbulent flow is:

$$Z = V\ D > 0.02 \qquad \text{(15)}$$

D being expressed in feet and V, in feet per second.

It is possible, of course, for flow in the model to pass upward through the turbulent stage and into shooting flow. This possibility must be investigated, and, since the velocity of shooting flow is the same as wave velocity, $\sqrt{G\,D}$, in which, G is the acceleration due to gravity, the necessary condition to insure non-shooting flow is that the velocity be less than $\sqrt{G\,D}$. To summarize, turbulent (streaming) flow exists in the model when $\frac{0.020}{D} < V < \sqrt{G\,D}$.

The discussion of geometric similitude has developed the fact that the depths necessary in the model govern the selection of the vertical scale. The discussion of Reynolds' criterion reveals the connection between model depths (hydraulic radii) and turbulent flow. To insure a high degree of turbulence in models of large rivers, such as the Mississippi, it is almost invariably necessary to use a scale value of depths larger than that for horizontal dimensions. This results in distortion of the model.

To summarize briefly: The horizontal dimension scale of a model is arbitrarily selected, usually with a view to making the model fit in the space available for it. The vertical scale is more intimately connected with the requirements for dynamic similitude, and must usually be made larger than the horizontal scale. On the typical river model, turbulence is to be tested by use of Reynolds' number, the viscosity modulus, M, or the turbulence criterion, Z.

To make application of the foregoing principles clearer the reader is referred to an actual example published elsewhere[7] by the U. S. Waterways Experiment Station, which demonstrates how turbulence was considered in connection with a model of the Ohio River.

PRACTICAL LABORATORY EXPEDIENTS

Necessity being the mother of invention it would seem far better to complete the work of equipping a laboratory over an extended period as demand indicated than to complete the equipment at the very beginning. Heavy, fixed equipment is expensive, difficult to manipulate, and, unless chosen with discretion by a well-informed and experienced individual, may be inapplicable to the special needs of the proposed institution. Of course, in the case of laboratories designed for instruction of University students, it is more necessary to install a certain amount of fixed equipment in the beginning, and, in general, past experience may be used as a guide to such purchases. The set-up of a practical river laboratory, on the other hand, must be so flexible as to permit it to deal with any problem falling within its general scope, and the first essential to this is adequate and unencumbered space.

Special flumes, designed to carry river models are relatively worthless for the reason that they are adaptable only to special problems. Where one model may be 12 ft wide and 100 ft long, the next required may be 40 ft wide by 60 ft long; and, obviously, the same flume would be inapplicable to both. Moreover, the reach of the river under investigation may bend back upon itself in such a way as to preclude the use of a uniformly tilting flume. For a reasonably straight reach of river the tilting flume would be desirable in dealing with models requiring a slope greater than that resulting from vertical distortion; but if the river winds materially such slope must be acquired by the placement of successive templates. Even so, it is sometimes difficult to apply slope corrections, the situation being practically impossible when the river meanders and when over-bank flow must be considered. If flood stages are to be reproduced no slope may be given the model except that normally resulting from distortions, but if less than bank-full flow is the important thing, or if the reach to be investigated is reasonably straight, practically any increase in slope may be given. Fortunately, those problems requiring experimentation with extensive models are generally concerned with hydraulics of flow instead of bed movements, and increased slopes are non-essential to their satisfactory solution. In any case a temporary wooden box of sufficient size will make a container for the model, which may be built of sand and concrete. Alternate types of containers are built of concrete or brick and mortar.

---

[7] "Model Study of Effects of Dikes on the River Bed at Walker's Bar, Ohio River," *Paper L*, U. S. Waterways Experiment Station, 1932.

The simplest method of constructing a model is to cut templates from sheet iron to conform to river and over-bank sections; level the containing box; and place the templates to grade by means of a level. The templates may then be braced and filled to within an inch of their tops with moist sand, packed in place. A coating of concrete, placed level to the tops of the templates and moulded to conform in shape with the sections, then completes the model proper, which must be equipped subsequently with an adjustable tail-gate, a measuring weir, an entrance chamber, and baffles. All these devices are extremely simple and except for the weir may be made by any good handy-man or carpenter. Practically any type of tail-gate is satisfactory to produce a back-water similar to that induced by resistance to flow of the entire river below the lowest point represented in the model. Fig. 1 is a model of a tail-gate, showing a valve outlet for fine adjustments.

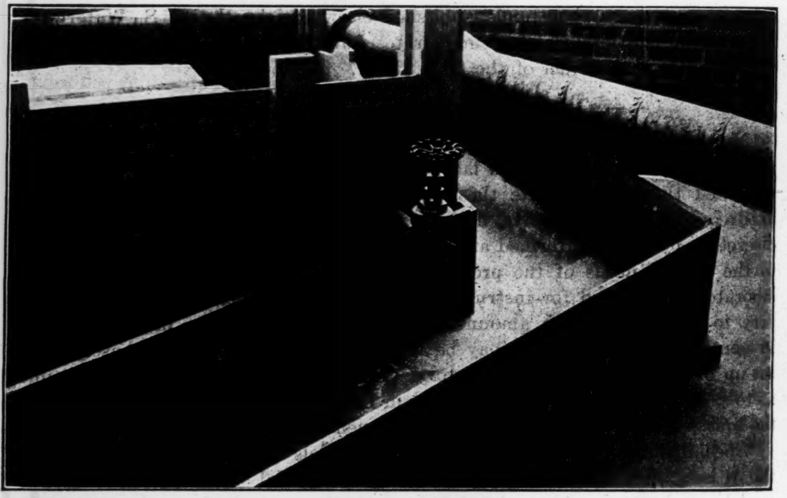

FIG. 1.—TAIL-GATE OF RACE-TRACK TOWHEAD MODEL, SHOWING VALVE OUTLET FOR FINE ADJUSTMENTS

Special flumes may be needed, of course, in a river laboratory for control tests and for tests of dams, weirs, spillways, and various measuring devices.

In this connection it is well to make the flume as long as the building will permit and of as great cross-section as is required to accommodate the maximum flow of water that can be allowed. Flumes of steel are generally more suitable than those of concrete because cracks and leakage may be developed in the latter as possible settlements in the building's foundations or as temperature changes occur. The former, moreover, may later be cut at any point should it be desired to insert plate-glass sections, or manometer connections. A smaller tilting flume may be built of wood or other material if suitably mounted on steel **I**-beams, or similarly rigid supports.

Having provided a laboratory building with expensive and unencumbered floor space upon which models may be constructed, and having designed an inlet and outlet system for the water, together with a diversion to some measurement chamber, little more need be taken into account until experiments actually have been begun. After work has started various needs will present themselves and ingenuity may be given free play in meeting requirements. If a reservoir system is used it may be unnecessary to provide pumping equipment, but nearly always it will be desirable to arrange for some pumping and circulation of water. This is particularly essential when the reservoir is supplied by run-off of rainfall from adjacent territory and droughts may occur during summer months. Whenever a pumping and circulating system is used it is necessary to provide also for: A deep (or storage) reservoir with overflow; pumps of required capacity; a constant-head reservoir; and incidental piping.

The capacity of the pumps, size of the pipe, and dimensions of the high and low reservoir are naturally determined by the character of work it is proposed to perform in the laboratory, it being unnecessary to arrange for great volumes of flow under high head if only normal river problems are anticipated. The constant-head reservoir—having as its purpose (as its name implies) the supplying of water from pumps to models under an unvarying pressure and, therefore, without fluctuations in flow—must have a length of overflow crest great enough to eliminate, entirely, such variations as will result from pump pulsations. A good value to use as a basis of design is 20 lin ft of overflow crest for each second-foot of water pumped.

In subsequent paragraphs other accessories of a modern river laboratory are described. These descriptions are general and it should be kept in mind that any other workable design may be equally good in any case. The personnel should be encouraged to think and develop new ideas as new problems present themselves. Listed briefly, the accessories are:

(*a*).—*Level Pedestal.*—Since a level must be used continually for setting templates, checking elevation of model beds, and setting gauges for zero readings, a fixed pedestal mount is extremely convenient and helpful.

(*b*).—*Profilograph.*—This is a labor-saving device for obtaining cross-sections of the model river bed after running (see Fig. 2). It consists of a carriage that travels along a rack and holds a vertically sliding shaft equipped with a pencil at its upper end. The shaft is counterweighted and placed between nearly frictionless rollers so that as a roller at its lower end is moved across the model bed the shaft, with its pencil, will rise and fall. Geared to the main carriage is a secondary carriage fastened to a vertical board on which a sheet of cross-section paper may be mounted. Movement of the main carriage results in reduced movement of the secondary carriage in relation to it, so that with the pencil moving vertically and the paper horizontally a section of bed is traced to full vertical and reduced horizontal scale. A more direct and efficient method of obtaining the same result has been recently developed, by utilizing a special sounding rod equipped with a pivoted foot and an adjustable T-head that rides on a leveled cross-beam.

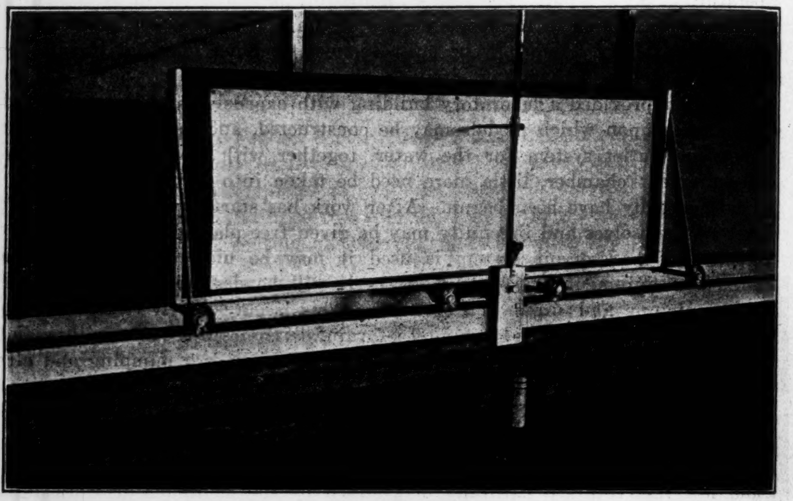

FIG. 2.—PROFILOGRAPH FOR TAKING CROSS-SECTIONS OF MODEL RIVER BEDS

(*c*).—*"Geschiebe" Meter.*—This is a simple device designed to feed bed material to the model at a fixed rate and in accordance with the movement of such material in the model. Operating on the hour-glass principle with funnels of various sizes to be used interchangeably, it is free from moving parts and is very effective. The bed material is washed into the model by a small stream of water brought in by a rubber tube.

(*d*).—*Current-Measuring Devices.*—These devices are of many types and designs, the simplest expedient for velocity determinations being the use of floats of varying weights and densities. Other devices are pendulums actuated by the velocity of flow, small propellers mounted between jeweled bearings, and Pitot tubes.

(*e*).—*Depth Meter.*—Difficulties are frequently encountered in determining depths of flow in very shallow reaches of a model, where, as in a floodway problem, many such determinations must be made. By placing round-headed gutter nails in the model so that the heads project but slightly through the concrete, a needle-gauge mounted on a U-frame may be used to determine differences between elevations of the nail-heads and the water surface. Data are obtained for each nail-head and with the depth meter measuring the distance between the head of the nail and the water surface in each case, elevations referred to a common datum are readily determinable.

(*f*).—*Traveling Crane.*—Traveling cranes of many types and purposes are made commercially and may be purchased in the open market. Purchase should not be made, however, until a definite need has been revealed, after which the choice of type will be obvious.

(*g*).—*Multiple-Gauge Rack and Wells.*—This is a simple device to make one hook-gauge serve the purpose of several (see Fig. 3). It consists of a single gauge mounted rigidly to a carrier which slides along a carefully machined steel bar. The bar being leveled in place with leveling screws, one zero is obtained for the gauge and applied to all readings obtained.

(*h*).—*Dye Injector.*—A long thin nozzle through which dye may be introduced under pressure to the model is often advantageous in making observations as to the character of flow obtaining in various reaches.

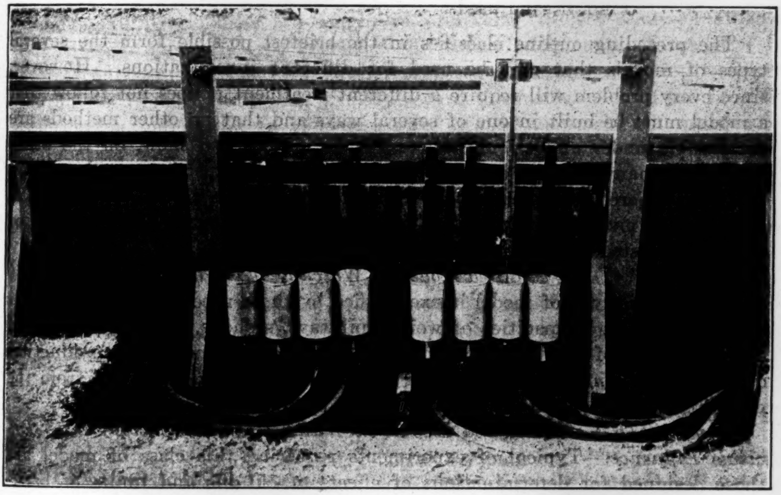

FIG. 3.—GAUGE RACK WITH MULTIPLE-WELL ARRANGEMENT.

(*i*).—*Racks and Baffles.*—These may be of many types and their design in any case should be the result of trial, experience, and experiment. Wooden gratings, crushed rock, coarse gravel, baffle-plates, wire screening, and swinging boards may all be used as the case demands.

(*j*).—*Valve Outlet at Tail-Gate of Model.*—This arrangement, shown in Fig. 1, is often advantageous in controlling the flow from the model. After a rough setting of the gate, fine adjustments of flow are possible by regulating the value.

TYPICAL EXPERIMENTS ENCOUNTERED IN A RIVERS AND HARBORS LABORATORY

Classification of Model Types

Fluvial models may be classified according to the character of their beds and according to the nature of their predominant forces, thus:

1.—Fixed Bed Models.—

(*A*) Those for which a consideration of gravitational force is paramount, and to which Froude's law must be applied, either: (*a*) Strictly; or (*b*), where channel friction is of decisive influence, by application of a factor to adjust the velocity and discharge scales.

(*B*) Those for which a consideration of internal friction is paramount and to which Reynolds' law must be applied.

2.—Movable Bed Models.—

Same as Item 1(*A*) and Item 1(*B*). For this type of model, consideration must also be given to a development of tractive force comparable to that existing in Nature according to the kind of sand used.

The preceding outline classifies in the briefest possible form the several types of models that may be used for different investigations. However, since every problem will require a different treatment it does not follow that a model must be built in one of several ways and that no other methods are permissible under any circumstances. It is intended to show, on the other hand, that many possible combinations of conditions must be considered and that while there are typical model forms, these must be varied sufficiently in each case to meet the peculiarities of the problem. Several general types of models suggested by the outline will now be discussed.

Type 1(A(a)).—Fixed Bed Models to Which Froude's Law Must Be Strictly Applied.—This type of model is exemplified by those used for determinations of: (1) Discharge capacities of weirs, spillways, siphons, etc.; (2) effects of sills on aprons of overflow structures; (3) factors influencing the production of an hydraulic jump; and (4) other hydraulic phenomena resulting from the gravitational fall of water when friction may be largely neglected.

Type 1(A(b)).—Fixed Bed Models in Which Channel Friction Is of Decisive Influence.—Typical of experiments requiring this class of model are those designed for determinations of effects of cut-offs and limits of back-water. These problems, being practically independent of channel changes, may be solved satisfactorily with a fixed bed in which experimental runs may be repeated time after time for the assurance of accuracy. When it is desired to obtain effects of silting or erosion, critical parts of the model may be built in of sedimentary materials. The problem of back-water or its corollary is frequently offered to a laboratory for solution, and it will be worth while for the reader to study two brief reports of the U. S. Waterways Experiment Station on this subject.[8]

---

[8] "Experiment to Determine the Limit of Backwater Influence in the Illinois River," *Paper Y*, 1931, and "Experiment to Determine the Effects of Mississippi River Backwater on the Red River," *Paper 10*, 1933.

The problems described in these reports resolved themselves into simple determinations of water-surface profiles after adjustment of the models had been accomplished, and no question of bed movement was involved in the investigations. Cut-off problems and similar determinations involving the addition or subtraction of resistance to flow are pursued in an identical manner, the questions of erosion and sedimentary deposition being subordinated to questions of effects on stages within the reaches considered.

Type 2(A(a)).—Movable Bed Models in Which Gravity May be Considered the Controlling Force.—Experiments with models of this nature will generally follow the lines of those mentioned in connection with models of Type 1(*A*(*a*)), the main difference being that erosive effects must be taken into consideration. Investigations conducted by Antonin Smrček, in Brno, Czecho-Slovakia,[9] and by Theodor Rehbock, in Karlsruhe, Germany,[10] to determine relative scour below spillway aprons, involved typical models of this classification.

Type 2(A(b)).—Movable Bed Models with Channel Friction the Controlling Force.—Models built for the determination of design of contraction works of permeable type are illustrative of this classification. In the general case, where qualitative effects are sought in preference to less easily obtainable quantitative data this type of model will suffice adequately. Thus, if it is desired only to choose between several proposed plans of contraction works, a movable bed model, built with primary regard to consideration of the force of traction, is indicated. In this case rates of bed movement in model and Nature are observed, and corresponding bed changes under the various imposed conditions are compared.

In practical experimentation there occur instances in which the foregoing classifications cannot be applied rigidly. Most common is the case of flow over a regulating work, where the question arises as to whether the channel friction is of appreciable influence. For a method by which compatibility between the laws may be attained in a model, the reader is referred to a discussion by Lieut. John Paul Dean, U. S. Corps of Engineers, and the writer.[11]

The types of study indicated under 1(*A*(*b*)) and 2(*A*(*b*)) of the preceding classification are those in which the forces of internal friction of the fluid are predominant. Typical of such studies is the problem of the resistance to motion of a deeply submerged body, such as a submarine. The laws governing this type of experimentation are not compatible with those governing the cases heretofore discussed unless fluid different from that of the prototype is used in the model. Fortunately, in the field of practical river hydraulics, the forces of internal friction of the liquid are relatively small and may be neglected without appreciable error resulting. It may be noted that the more turbulent the regimen of a stream becomes the more nearly negligible are the forces of internal friction.

PROBLEMS SUSCEPTIBLE TO LABORATORY TREATMENT

Experience indicates that the following general types of problems may be prosecuted successfully in river hydraulics laboratories: (1) Effects of dikes or other contractive works on the river bed; (2) effects of cut-offs of river bends; (3) back-water influences; (4) effects of channel dredging; (5) relationship existing between mean discharge and river sections; (6) discharge over navigation dams and spillways; (7) design of locks and dams; (8) determinations of velocities and current directions in rivers after placement of corrective works; (9) flow through siphons, siphon spillways, etc.; (10) effect of baffle-piers on spillway aprons; (11) loss through trash-racks and screens; (12) effect of storage basins on flood flow; (13) progression of flood waves; (14) flow through diversion floodways; (15) effect of bends in a river; (16) harbor entrance problems; (17) resistance of, and flow around, cylinders and bridge piers in streams; (18) effects of flow over highways and railroad embankments; (19) experiments to determine effects of obstructions placed in a stream (submerged sills, etc.); (20) flow of water through sluices of various kinds; (21) towing experiments and experiments on bodies falling in water; (22) experiments relating to transportation of sedimentary and bed materials; (23) design of stilling-pools; (24) movement of sedimentary material and its distribution at river divisions; and (25) seepage in earth embankments and levees.

Types of investigations of the future are difficult to predict, but the definite tendency is toward more and more work with models of the movable bed type. In this field the surface has been scratched by experiments similar to that performed to obtain a solution of the difficulties encountered at Island No. 35, Mississippi River, but infinitely more remains to be accomplished. However, that may be, it still seems assured that much work will remain at all times for every hydraulic laboratory in the land.

ACKNOWLEDGMENTS

It is desired to express appreciation to H. W. King, M. Am. Soc. C. E., and C. O. Wisler, Assoc. M. Am. Soc. C. E., for carefully reviewing this paper in an earlier form, and to acknowledge gratefully the loyal assistance and co-operation rendered by the Staff of the U. S. Waterways Experiment Station in developing new methods of laboratory technique described in the preceding pages.

DISCUSSION

LORENZ G. STRAUB,[12] ASSOC. M. AM. SOC. C. E. (by letter).—The treatment given by Lieut. Vogel to practical river laboratory hydraulics is timely and especially interesting because of the author's connection with the development of the U. S. Waterways Laboratory. He points out in a clear manner the value of the laboratory in solving a variety of river-improvement problems.

The writer has used a nomenclature similar to that proposed by Lieut. Vogel and finds it especially convenient. Most nomenclatures used heretofore in presenting the principles of mechanical similitude are complicated with numerous Greek and German letters which have no apparent relation to each other, entirely different symbols being used for homologous items in the prototype and model. Such a set of symbols makes it difficult to follow the literature which has been presented on this subject particularly because each writer uses his own set of letters. In keeping with the general scheme proposed by the author it might be well to use the symbol, l, for the basic scale ratio instead of a. The writer prefers the inverse of the ratio used by the author; that is, the ratio of the length, time period, velocity, etc., in the prototype to that in the model; this provides integers instead of fractions for the ratios and seems somewhat more convenient in application when dealing with a series of models of different size.

Frequently, it is not understood that although the usual mechanics are practically unlimited in applicability in so far as pure dynamic occurrences are concerned, the applicability of the mechanics of similitude has certain limitations. Not all motion occurrences can be imitated by means of a model, and therefore, not all dynamic problems met with in practice can be solved by means of the mechanics of similitude. In fact, relatively few motion occurrences can be imitated accurately by means of a model. Obviously, therefore, the first step in the design of a model for the solution of a practical hydraulics problem necessitates a study of whether or not the problem can be treated at all by the method of similitude.

An analysis must be made to determine what physical forces cause the occurrence. The nature of these forces fixes the "model law" under which the model must operate, if it is to be similar to the occurrence in the prototype. The physical forces in the sense here used are those that cause acceleration of the particles forming the system concerned. Some of the more important are as follows: The earth's gravitational forces, frictional forces between liquid particles, capillary forces, elastic forces, normal and tangential forces (in solid bodies), and many others. Each one of these forces defines a model law; that is, the relation between the length ratio and time ratio for the prototype and model.

The most important physical forces that cause fluid motion are the earth's gravitational forces, friction between fluid particles, and capillary forces. It is seldom that any one of these is the sole cause of the occurrence. Consequently, perfect similitude is almost never obtainable; the motion of particles in the hydraulic model is almost never perfectly similar to that in the prototype. The solution of design problems by means of models, therefore, resolves itself largely into determining the limitations of the applicability of various models.

---

[12] Associate Prof. of Hydraulics, and Head, Hydraulics Div., Experimental Eng. Laboratories, Univ. of Minnesota, Minneapolis, Minn.

The degree of similarity obtainable between the model and the prototype depends upon the nature of individual circumstances. If the movements in the prototype and model are influenced by the action of only one type of physical force, the model occurrences may be made to take place in a mechanically similar fashion to the prototype occurrences. The model law that must be followed in order to obtain mechanical similitude may be determined from various equations. The most natural procedure seems to be to determine the relation of the basic ratios,[13] l, t, and f, in a manner somewhat as follows. The ratio of the inertia or mass accelerating forces may be represented by:

$$f = \frac{M_m\ B_m}{M_n\ B_n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which, M_m and M_n represent the masses of homologous volumes in the model and prototype, respectively, and B_m and B_n represent the corresponding accelerations of these masses. (The writer prefers the inverse of the ratios herein presented; the ratios are set up to correspond to the author's paper for the sake of uniformity.) Inasmuch as, for geometric similarity, the masses vary as the cube of the linear dimension, the ratio, $\frac{M_m}{M_n}$, is equal to $\frac{\Gamma_m}{\Gamma_n}\ l^3$; also, since $B = \frac{d^2 X}{dT^2}$, the ratio, $\frac{B_m}{B_n} = \frac{l}{t^2}$. Therefore, in terms of the scale ratios, the ratio of the mass accelerating forces may be represented by,

$$f = \frac{\Gamma_m}{\Gamma_n}\ l^3\ \frac{l}{t^2}\ \frac{\Gamma_m}{\Gamma_n}\ \frac{l^4}{t^2} = \phi_1\ (l, t) \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

For similarity, the ratio of the inertia forces must be equal to the ratio of the physical forces producing the occurrence; hence,

$$f = \frac{F_m}{F_n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

in which, F_m and F_n are the physical forces (such as the force of gravity) acting upon homologous masses in the model and prototype, respectively. This equation may be written in the form:

$$f = \frac{F_m}{F_n} = \phi_2\ (l, t) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

The value of the force ratio, f, may be eliminated from Equations (17) and (19), thus obtaining the "model law" in question in the basic form,

$$t = \Omega\ (l) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

---

[13] See "Nomenclature," pp. 122–123.

Here, an arbitrarily chosen length ratio, l (ratio of length between model and prototype), fixes the time ratio, t (ratio of time required for an occurrence to take place in the model to the time required for a corresponding occurrence to take place in the prototype). It will be observed that an infinite number of models (of different scales) are possible for this case in which only one physical force comes into consideration. It will also be noted, from Equation (17), that the model law is influenced by the ratio of the densities of the mediums used, respectively, for the model and prototype. Equation (20) is of general form for all model laws, provided only one physical force comes into consideration.

Consideration will not be given at this time to various model laws which might be derived from the foregoing equations; suffice it to use the force of gravity as the physical force causing the occurrence in order to exemplify the method of analysis. Equation (17) will be written in the form,

$$f = \frac{M_m B_m}{M_n B_n} = \frac{\Gamma_m}{\Gamma_n} \frac{l^4}{t^2} \qquad \ldots\ldots\ldots\ldots (21)$$

and Equation (19) in the form,

$$f = \frac{F_{gm}}{F_{gn}} = \frac{W_m v_m}{W_n v_n} = \frac{W_m}{W_n} l^3 \qquad \ldots\ldots\ldots\ldots (22)$$

in which, W_m and W_n are the unit weights of the mediums of the model and prototype. These unit weights may be represented by $W_m = \Gamma_m G_m$ and $W_n = \Gamma_n G_n$, in which, G_m and G_n are the homologous accelerations of gravity in the similar occurrences. The expressions, v_m and v_n, are homologous volumes. Of course, normally, G_m and G_n are equal, the value being 32.09 at the equator, 32.17 at the 45° parallel, and 32.25 at the poles.

By equating the two expressions for f given in Equations (21) and (22), and solving for the ratio of time periods:

$$t = \sqrt{l \frac{\Gamma_m \div W_m}{\Gamma_n \div W_n}} \qquad \ldots\ldots\ldots\ldots (23)$$

so that the model law (relation of time ratio to length ratio), if the force of gravity is the only physical force influencing the occurrence, is given by,

$$t = \sqrt{l \frac{G_n}{G_m}} \qquad \ldots\ldots\ldots\ldots (24)$$

This relation is referred to as the Froude model law. If G is the same for both prototype and model, Equation (24) takes the form,

$$t = \sqrt{l} \qquad \ldots\ldots\ldots\ldots (25)$$

A similar method of analysis might be used in determining the model law for other physical forces. Once having the model law one can readily determine the relation of homologous discharges, homologous velocities, homologous accelerations, etc., of the prototype and model.

However, as pointed out by Lieut. Vogel, ordinarily perfect similarity is not obtainable; this is due to the fact that more than one physical force influences the motion occurrences. It will be assumed, for example, that two physical forces effect the flow conditions, possibly the force of gravity and frictional forces between liquid particles. Three equations are then obtained between the force ratio, time ratio, and length ratio, as follows:

Ratio of inertia forces:

$$f = \phi_1 \, (l, t) \quad \text{.......................(26)}$$

Ratio of gravity forces:

$$f = \phi_2 \, (l, t) \quad \text{.......................(27)}$$

Ratio of frictional forces:

$$f = \phi_3 \, (l, t) \quad \text{.......................(28)}$$

Since there are three equations with three unknowns (the ratios, *l*, *t*, and *f*), none of the unknowns may be chosen arbitrarily as in the simple case of only one type of force influencing the occurrence; each unknown has a definite value. Therefore, when once the medium of the model is fixed, there is only one size model that will provide perfect mechanical similarity. If the medium in both prototype and model is the same (for example, if it is water in both cases) then the model must be of the same size as the prototype for perfect similarity.

Since perfect similarity in models is seldom if ever obtainable in the development of practical hydraulic designs, recourse must be had to certain approximations. This is particularly true in the case of working models of rivers and harbors. For these, in the apt words of the author, "the question is not whether distorted models will be used; it is rather how can the distortion that is certain to occur in every model be made least harmful?" What are the advantages and shortcomings of different types of distortion?

In river models, similarity based upon the empirical Manning formula apparently gives better agreement with experimental results than either Reynolds' model law or Froude's model law. In this case the predominant forces influencing the occurrence are fluid friction and the force of gravity. However, similarity cannot be completely satisfied, ordinarily, for either of these forces if the most workable model is to be obtained. Usually, in well-designed river models, Reynolds' number is smaller than in the prototype. In some laboratories, the practice has been to design such models to satisfy Froude's number as far as velocities are concerned and to limit the scale ratio in such a manner that turbulent flow will occur in the model; also, in the case of movable bed models, the scale ratio has been limited so that sediment transportation will occur. Table 2 indicates that Manning's formula gives a better value for the velocity and discharge than Froude's number.

The necessity of geometrical distortion becomes particularly evident when designing models of large alluvial rivers having relatively fine bed materials. In many cases it will be found necessary to make a model of a size covering several acres if recourse is not taken to some kind of geometrical distortion. The large size often imposed in order to obtain a geometrical non-distorted workable model would result in excessive cost of construction of the model and very cumbersome operation.

For broad river channels the hydraulic radius, for all practical purposes, is proportional to the mean depth of the channel; in the case of a model in which the vertical scale is different from the horizontal scale, therefore, the hydraulic radius will here be assumed equal to the mean depth. Using the author's nomenclature and Manning's formula as a basis, for a vertically distorted model the velocity ratio becomes:

$$v = \frac{d^{\frac{2}{3}}\, s^{\frac{1}{2}}}{n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

If the amount of distortion is represented by $k = \frac{d}{l}$, it will be found that the velocity in the distorted model may be represented by:

$$v = \frac{1}{n}\, d^{\frac{2}{3}} \left(\frac{d}{l}\right)^{\frac{1}{2}} = \frac{1}{n}\, k^{\frac{7}{6}}\, l^{\frac{2}{3}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

Thus, the velocity increases as the seven-sixth power of the distortion. This condition is particularly desirable inasmuch as the velocity in small scale models frequently becomes too low.

Vertical distortion also results in a definite increase in the tractive force of the stream in moving sediment along the bottom of the model river. Assuming the ratio of the tractive forces of the model and prototype to be represented by f, the ratio may be expressed by the linear ratios, by:

$$f = d\, s = d\, \frac{d}{l} = k^2\, l \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

showing that the tractive force increases as the square of the vertical distortion. In a similar fashion, it may be shown that the ratio of the Reynolds' numbers for the model and prototype is represented by:

$$\frac{\mathsf{R}_m}{\mathsf{R}_n} = k^{\frac{13}{6}}\, l^{\frac{5}{3}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

Reynolds' number thus increasing as the thirteen-sixth power of the distortion for a given horizontal scale ratio. This is a particularly desirable condition because the Reynolds' number of the model is ordinarily lower than that of the prototype in the case of river models. Distortion thus results in a degree of turbulence more nearly that of the prototype. These advantages of vertical distortion may be summarized as follows:

1.—The velocity in the model is increased by distortion, thus resulting in more suitable Reynolds' numbers and making possible more precise measurements in consequence of the increased discharge.

2.—Tractive forces (and consequent suitability of models for use in experiments involving movable beds) are increased markedly.

3.—Great economies arise in the cost of construction and operation of the model because the necessary horizontal scale may thereby be greatly reduced.

Counterbalancing these advantages are a number of disadvantages, particularly where the amount of distortion attempted is very large. For various reasons accurate similarity of the bed elevations in the distorted model as compared to the prototype are not possible. This is particularly true where the erosion in the prototype causes the bottom to stand at approximately the natural under-water angle of repose of the sedimentary material. For example, in Fig. 4 let the shaded area represent the idealized scour that occurs in the non-distorted model. In the distorted model the corresponding scour should be represented by the triangle, *ABC*; but, since it is not possible for the slope to be greater than is allowed by the natural angle of repose, the scoured pool would take the form represented by the triangle, *DEC,* if the scoured depth is to correspond to the depth ratio. It is conceivable, therefore, that where the vertical distortion is great, considerable deviation between the results of an undistorted model and the conditions in the prototype might obtain. A similar analysis could be made in the case of sedimentation; in fact, it might be shown that the model could indicate erosion where sedimentation would occur in the prototype.

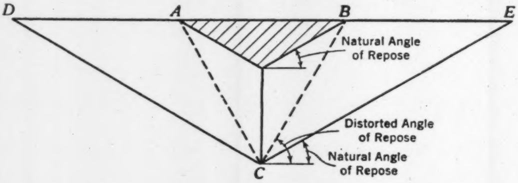

FIG. 4.—ANALYSIS OF EROSION CONDITIONS IN VERTICALLY DISTORTED MODELS

Other conditions brought about as a result of distortion which might be harmful are the formation of fixed eddies (frequently referred to as "rollers"). Distortion may result in the elimination of these fixed eddies in some localities and the introduction of some in other localities, inasmuch as there are limits to the amount that a "roller" may be distorted without breaking it into counteracting "rollers."

The foregoing are some of the shortcomings that cannot be eliminated, nor can their effect be determined accurately without comparative experiments in the individual cases concerned. The observer must be constantly alert to avoid making erroneous deductions as a result of his experiments on models constructed to vertically distorted scales.

It has sometimes been suggested that the proper type of distortion consists in merely increasing the slope of the model—that is, by tilting the model to a slope steeper than that of the prototype while the horizontal length ratio and vertical length ratio remain equal. Such an arrangement has certain advantages in that it brings about the desired greater velocities and greater transporting force (although not to as marked a degree as vertical distortion) and greatly eliminates the disadvantage of producing "rollers" where they should not occur. On the other hand, in the case of a broad river model, inasmuch as the flow takes place in a serpentine rather than in a rectilinear direction, the model would have to be warped in order to obtain uniform distortion in slope.

In connection with experiments concerning the regimen of the Upper Rhine River, Dr. Theodore Rehbock, of Karlsruhe, Germany, found that certain advantages were obtained by using a sedimentary material composed of volcanic ash. The specific gravity of this material was considerably less than ordinary sand, being about 1.6. In this material no difficulty was encountered with riffle formation; bars formed in the model river channel in a manner quite similar to that actually occurring in the Rhine River.

Paul W. Thompson,[14] Jun. Am. Soc. C. E. (by letter).—The study of problems in open-channel regulation by use of small-scale models has received great impetus in the United States during recent years. This impetus is due in no small part to the wisdom and generosity of the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., who provided for the Fellowships which have resulted in making available in this country the best of foreign hydraulic laboratory practice. Another powerful factor has been the increased use by the Engineer Department of the Federal Government of the small-scale model as an aid in the solution of certain problems arising in the administration of the rivers and harbors of the country. The U. S. Waterways Experiment Station at Vicksburg, Miss., where most of the model studies for the Engineer Department are made, has been, for the past few years, among the most active laboratories in the world. It is encouraging to note that many of the principles followed and developed at that Station have been made available through the medium of this paper, which is a valuable addition to the literature of experimental hydraulics.

The author's remarks on the effects and importance of turbulence in open-channel models will serve to clarify this little understood subject. Turbulence is that fortunate condition of flow which justifies the assumptions that: (*a*) The forces of internal friction in the fluid are negligible; and (*b*) the force of gravity is predominant. The consistency of these two assumptions with the requirements of the law of Reeche-Froude (generally called the law of Froude) will be observed at once. The observation is substantiated by consideration of the facts that: (1) In turbulent flow, velocity is a function of the square root of the depth; while, similarly, (2) under the law of Froude, the velocity scale is a function of the square root of the depth scale.

The evaluation of a turbulence index as given by Equation (15) is a noteworthy addition to the list of practical aids to the experimentalist. The value of $Z = 0.02$, should be considered as an absolute permissible minimum. In most of the open-channel models at the U. S. Waterways Experiment Station the product of the actual mean velocity by the actual mean depth has proved to be several times this value. Turbulence is a comparative phenomenon—that is, there are degrees of turbulence. Thus, in a regimen in which the value of Z is, say, 0.06, the effects of the forces of internal friction will be more nearly negligible than in a regimen in which Z has a value less than 0.6. Short of going into "shooting flow," the experimentalist will seek as high a degree of turbulence as possible, since he will try to render the effects of internal friction as nearly negligible as possible.

---

[14] Second Lieut., Corps of Engrs., U. S. Army; Military Asst., Dist. Engr., Omaha, Nebr. (Asst. to Director, U. S. Waterways Experiment Station, June, 1932, until November, 1933.)

Lieut. Vogel has touched on most of the practical difficulties that confront the small-scale model experimentalist. Perhaps the most important of these difficulties concerns the adjustment, and the need for the adjustment, of the roughness of the model. The writer, who has been privileged to co-labor with Lieut. Vogel on much of the work at the U. S. Waterways Experiment Station, believes that a few more words may be justified in regard to this matter of model roughness.

The basic decision that the experimentalist must make in planning his model study concerns the forces with respect to which he is to seek similitude. The author has discussed the reasoning which, in the case of open-channel models, usually results in the decision to seek similitude with respect to the force of gravity. This decision having been made, the question of model roughness immediately assumes important proportions.

The decision to seek similitude with respect to the force of gravity presumes, in effect, that water is a perfect fluid. The result is the law of Reeche-Froude; namely,

$$t = \sqrt{d} \quad \text{.........................(33)}$$

From this law follows immediately the relations expressed by Equations (2) and (3) of the paper. Consider, now, the difficulties that arise in an attempt to realize the fundamental relationships expressed by Equations (2), (3), and (33).

Assume that flow in an open channel in Nature is in accordance with the Chezy law:

$$V_n = C_n \sqrt{D_n \, S_n} \quad \text{.......................(34)}$$

and that flow in a model of that channel also accords with that law, as follows:

$$V_m = C_m \sqrt{D_m \, S_m} \quad \text{.....................(35)}$$

It immediately follows, using the nomenclature of the author, that,

$$v = c \sqrt{ds} \quad \text{.........................(36)}$$

Thus, if the fundamental relationship of Equation (2) (Froude's law) is to obtain, it is necessary that,

$$c \sqrt{s} = 1 \quad \text{.........................(37)}$$

The experimentalist will endeavor to maintain an "undistorted' slope; that is, he will endeavor to keep s equal to unity. This is true because of the impossibility of analyzing completely all the effects due to any form of distortion. However, if s is to equal unity, then according to Equation (37), c must equal unity. Since c is simply the quotient of the C for the model (C_m) divided by the C for Nature (C_n), this is tantamount to stating that,

$$C_m = C_n \quad \text{..........................(38)}$$

Consider now the position of the experimentalist who is designing an open-channel model, and who is aiming for similitude with respect to the force of gravity. He knows that the accuracy of his results will be a function of the degree to which he can satisfy the law of Equation (38). The degree of his success in satisfying this law must rest on: (*a*) The accuracy to which the value of C_n may be determined; and (*b*) the degree of control, or manipulation, that may be exercised on C_m. The experimentalist will proceed to study all the data available concerning the laws of flow in the prototype, and he will thus arrive at his "best value" for C_n. He will then consult his own records, and the records of others, in an endeavor to determine just how he may insure a value of C_m which approaches the "best value" for C_n. Thus, as an idealized illustration, suppose that the experimentalist has determined that $C_n = 40$. From his own files and from the files of others, he finds records of models, similar to the one he contemplates, as follows: (*a*) For Model *A*, made of rough mortar, $C_m = 30$; (*b*) for Model *B*, made of glazed plaster of Paris, $C_m = 46$; and (*c*) for Model *C*, made of smooth mortar, $C_m = 41$. Obviously, the experimentalist decides to construct his model of smooth cement mortar, since, in the light of past experiences, it offers the best chance of satisfying the law of Equation (38).

Actually, the problems will never be so simple of solution as indicated in the illustration. First, the "best value" for C_n often is not a very good value. Indeed, in many instances—especially those in which proposed construction will exert great influence on the value of C_n—the "best value," in reality, may be the "best estimate." Second, such records of model roughness coefficients as are now available are scarcely ever extensive enough to justify absolute dependence on them; in fact, in many instances, such records as are available form little more than general indications or guides. In such instances, the experimentalist must keep before him the factors that influence the value of *C*. Thus, taking the Manning relationship (because it is used by the author), the experimentalist considers that $C \propto \frac{D^{\frac{1}{6}}}{N}$. Herein are indicated the effects of the reduced linear dimensions of the model. Thus, *N* is a value that increases with increasing roughness; but *D* is a value that decreases as the linear scale ratio, model to Nature, decreases. It can thus be seen that, if Equation (38) is to be satisfied, the model, as it is made progressively smaller, must be made correspondingly smoother.

After his model is built, the experimentalist will proceed to "adjust" it; that is, he will run many tests, under various conditions, and obtain, thereby, actual values for C_m. He will be able, by smoothing or roughening the model, to manipulate his values within reasonable limits. He will continue his "adjustments" until he is satisfied that the requirements of Equation (38) are as well fulfilled as is practicable.

This discussion has concerned itself with the problem of satisfying Froude's law in the case of an "undistorted" model; but, as pointed out and explained by the author, most of the problems arising from the great alluvial rivers of this country require models in which the horizontal linear scale ratio is considerably smaller than the corresponding ratio for vertical dimensions. In building such models, it is customary (although not essential) to make the slope of the model greater than the slope of the prototype by the value, $\frac{d}{l}$. In other words, usually, $s = \frac{d}{l}$. The significance of such a condition, as effecting the subject under discussion, is apparent from a consideration of Equation (37). Thus, consider the values given for Model F, in Table 2: $l = \frac{1}{720}$; and, $d = \frac{1}{72}$. For Model F, $s = 10$; hence, in this particular case, if the law of Froude were to be satisfied, $c = \frac{1}{\sqrt{10}}$ or,

$$C_m = \frac{1}{\sqrt{10}} C_n \text{ ....} (39)$$

Considering that the value of C decreases as roughness increases, Equation (39) serves to explain an apparent anomaly. Thus, the fact that the dimensions of individual roughnesses cannot be reduced to the same extent as other dimensions, would justify the expectation that small-scale models, in general, would be too rough. However, in the case of distortion of scales, the slope factor enters, as illustrated in Equation (39), and often operates to make the model too smooth. A case in point is Model F, already noted. Table 2 shows that the actual discharge scale of the model was $\frac{1}{280\,000}$, while, according to the Froude law, it should have been $\frac{1}{440\,000}$. Obviously, the model was too smooth; that is, C_m was too large.

The author presents, as Equation (10), an expression for discharge scale obtained by the simple process of applying the Manning formula to the discharges of model and Nature, respectively, and dividing the former result by the latter. Implicit in his operations are the assumptions of $n = 1$, and $s = \frac{d}{l}$. Obviously, if the Froudian law is to hold, peculiar and definite relationship must exist between the d and the l of Equation (10). This relationship may be easily determined by writing the Froudian expression for discharge scale, Equation (3), and solving it simultaneously with Equation (10). This operation was reported in another connection,[15] wherein it was found that, if $d = l^{\frac{3}{4}}$, there is no conflict between Equation (10) and the Froude law. This requirement has been called the "law of compatibility." Making the same assumptions that the author makes in deriving Equation (10), ($n = 1, s = \frac{d}{l}$), and inserting the Manning expression for C in Equation (37), it follows as before that $C = l^{\frac{3}{4}}$. Thus, the law of compatibility is an adaptation, under certain given conditions, of the general requirement, $c \sqrt{s} = 1$.

---

[15] *Civil Engineering*, August, 1932, p. 467.

In this connection it can be noted that a judicious manipulation of the slope ratio, s, might serve as a means of obtaining satisfaction of Equation (38). This notation is entirely correct, but it should be observed that such manipulation introduces the indeterminate effects of a distortion in the model results. Furthermore, it should be observed that the slope ratio must be determined before the model is built, and may not be altered after construction. Since it is impossible to foresee exactly the effects of reduced dimensions, altered slopes, etc., it follows that manipulation of the slope ratio alone will not insure satisfaction of the law. Resort must still be had to the methods already described.

It must not be concluded that failure to obtain exact satisfaction of the law of Equation (38) invalidates the model results. Such failure, of course, does affect the results, and must be taken into careful consideration when data from the model study are analyzed and interpreted. A small-scale model represents at best a series of compromises—a structure in which theoretical considerations have conflicted, at many points, with practical possibilities. The word, model, is itself almost too exact an appellation to apply to the small-scale replica of a natural stream. More strictly appropriate would be some title, such as "approximate reproduction."

The writer is a firm believer in the advisability of the use of small-scale models in the solution of open-channel problems where large sums of money are involved. His belief, indeed, is so firm that he does not deem it necessary to overstate the case in favor of the use of models by a single iota. The open-channel laboratory can stand on its own feet, and is more and more able, as time goes on, to point to the record books for its justification. With all its limitations, the small-scale model is still a valuable tool for the river hydraulician who understands its use.

RALPH W. POWELL,[16] M. AM. SOC. C. E. (by letter).—The great increase during the last few years in the use of models for the solution of various problems connected with rivers, makes this paper very timely, and the author deserves the thanks of the profession for making the results of his experience available.

There are only a few minor criticisms. Where so many quantities are involved there seems a distinct advantage in making use of the Greek alphabet, especially where such use is already familiar. It would seem better not to break with such established usage as ρ for density, μ for coefficient of viscosity, and ν for coefficient of kinematic viscosity. It must be discouraging to those who are working for uniformity in the use of symbols to see one of the best established ones —g for the acceleration of gravity— replaced by G. Furthermore, M is called "the viscosity modulus for open channels." It would seem that "critical value of Reynolds' number for open channels" would better express the idea. However, the writer has endeavored to abide by the author's nomenclature in what follows.

The statement preceding Equation (10), that small-scale models of cement mortar and intermediate-scale models of sand, have about the same coefficient of roughness as the natural river, is interesting. Certainly Kutter and Ganguillet, Bazin, and Manning meant the coefficient of roughness in their formulas to depend only on the material, and to be independent of the size of the channel cross-section; but it is also probably true that none of the formulas actually holds over a wide range of sizes. The increasing use of small-scale models gives the question an importance it had not had before, and creates an urgent demand for a new and better formula for channel flow. As a preliminary step in that direction, the writer offers the following theoretical considerations.

---

[16] Associate Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

Suppose that the average velocity over the cross-section of the channel is V, and that it depends on the following seven factors only: S, the surface slope; D, the mean depth = cross-sectional area divided by surface width; W, the surface width; G, the acceleration of gravity; p, the density of the liquid; u, the coefficient of viscosity of the liquid; and, E, a measure of the roughness, such as the average diameter of the sand grains, the average height of the projections which produce the roughness of a cement model, or some such quantity. Then, the formula desired will be of the form:

$$f\ (V, S, D, W, G, p, u, E) = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (40)$$

By a method developed independently by D. Riabouchinsky[17] and by Edgar Buckingham,[18] this can be replaced by the equation:

$$\phi\ (\pi_1, \pi_2, \pi_3, \pi_4, \pi_5) = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (41)$$

in which all of the π's are dimensionless, and, $\pi_1 = V^{x1}\ D^{y1}\ u^{z1}\ G^{-1}$; $\pi_2 = V^{x2}\ D^{y2}\ u^{z2}\ p$; $\pi_3 = \frac{E}{D}$; $\pi_4 = \frac{W}{D}$; and, $\pi_5 = S$.

The dimensions of the quantities in Equation (40) are:

$$\begin{array}{ll} [V] = [L\ T^{-1}] & [G] = [L\ T^{-2}] \\ [S] = [L^0]\ \text{(dimensionless)} & [p] = [M\ L^{-3}] \\ [D] = [L] & [u] = [M\ L^{-1}\ T^{-1}] \\ [W] = [L] & [E] = [L] \end{array}$$

The values of the x's, y's, and z's are found by applying the principle of dimensional homogeneity to the expressions for the π's; π_1 gives,

$$[\pi_1] = 0 = [L\ T^{-1}]^{x1}\ [L]^{y1}\ [M\ L^{-1}\ T^{-1}]^{z1}\ [L\ T^{-2}]^{-1} \quad \ldots\ldots\ldots\ldots (42)$$

Equating the exponents of M:

$$z_1 = 0$$

---

[17] "Methode des Variables de Dimensions Zero," par D. Riabouchinsky, *L'Aerophile*, September 1, 1911.

[18] "On Physically Similar Systems," by Edgar Buckingham, *Physical Review*, Vol. 4, pp. 345–376 (1914); also, "Model Experiments and the Forms of Empirical Equations," *Transactions*, Am. Soc. Mech. Engrs., Vol. 37, pp. 263–296 (June, 1915); and "Notes on the Method of Dimensions," *Philosophical Magazine*, 6th Ser., Vol. 42 (November, 1921), pp. 696–719.

Equating the exponents of T:

$$-x_1 - z_1 + 2 = 0$$

therefore, $x_1 = 2$.

Equating the exponents of L:

$$x_1 + y_1 - z_1 - 1 = 0$$

therefore, $y_1 = -1$, and $\pi_1 = \frac{V^2}{D\,G}$. This is "Froude's number" and is usually represented by the symbol, F.

The expression for π_2 gives:

$$[\pi_2] = 0\,[L\,T^{-1}]^{x_2}\,[L]^{y_2}\,[M\,L^{-1}\,T^{-1}]^{z_2}\,[M\,L^{-3}] \quad \text{.............} (43)$$

Equating the exponents of M,

$$z_2 + 1 = 0$$

therefore, $z_2 = -1$.

Equating the exponents of T,

$$-x_2 - z_2 = 0$$

therefore, $x_2 = 1$.

Equating the exponents of L,

$$x_2 + y_2 - z_2 - 3 = 0$$

therefore, $y_2 = 1$ and $\pi_2 = \frac{V\,D\,p}{u}$. This is Reynolds' number, R. If, similarly, $\pi_3 = \frac{E}{D}$ is represented by E, and $\pi_4 = \frac{W}{D}$ by W, Equation (41) becomes $\phi\,(\mathsf{F}, \mathsf{R}, \mathsf{E}, \mathsf{W}, S) = 0$, or,

$$S = \Phi\,(\mathsf{F}, \mathsf{R}, \mathsf{E}, \mathsf{W}) \quad \text{....................} (44)$$

By experiment it is known that F is by far the most important of the four factors, and that as far as it is concerned the function is of the simplest sort; therefore,

$$S = k\,\mathsf{F} = \frac{k\,V^2}{G\,D} \quad \text{......................} (45)$$

in which $k = \theta\,(\mathsf{R}, \mathsf{E}, \mathsf{W})$. The classical formulas are in terms of R, the hydraulic radius, instead of D, the mean depth, but in this discussion the writer follows the author in using them more or less synonymously. Then, the Chezy formula is Equation (45), with $\frac{G}{k} = C^2$. Bazin's formula, $C = \cfrac{87}{0.552 + \cfrac{m}{\sqrt{R}}}$, would reduce to:

$$k = \frac{G\,(0.305 + \frac{1.104\,m}{\sqrt{R}} + \frac{m^2}{R}}{7\,569} \quad \text{.................} (46)$$

which is obviously not dimensionally homogeneous and, therefore, cannot be the ideal formula that is being sought. The same applies to Kutter's formula. Manning's formula may be put in the form, $S = \frac{N^2 V^2}{2.208 R^{\frac{4}{3}}}$, which is Equation (45), if $R = D$ and $k = \frac{N^2 G}{2.208 D^{\frac{1}{3}}}$. This shows that the dimensions of Manning's N are $[T L^{-\frac{1}{3}}]$ and that his formula cannot be expected to give the same value of N for the same surface in different sizes. The Williams and Hazen formula, $V = 1.318\, c\, R^{0.63} S^{0.54}$, reduces to Equation (45) if $R = D$ and $k = \frac{G}{1.737\, c^2 D^{0.26} S^{0.05}}$. This makes the dimensions of the Williams and Hazen $c = [T^{-1} L^{0.37}]$, so that it would be expected to vary with the size slightly more than Manning's N.

Until the true form of the Φ-function in Equation (44) is known the simplest assumption to make is that it is of the form, $S = k\, \mathsf{F}\, \mathsf{R}^{-x}\, \mathsf{E}^{y}\, \mathsf{W}^{z}$, which reduces to:

$$S = \frac{k\, K^x E^y W^z V^{2-x}}{G\, D^{1+x+y+z}} \quad \dots\dots\dots\dots (46)$$

in which, K is the coefficient of kinematic viscosity $= \frac{u}{p}$ and k is an absolute dimensionless constant. From the analogy with pipes it is quite certain that x is between 0.00 and 0.10; but a great amount of careful research would be required to get a more accurate value and to find y and z. Furthermore, it might be found that no equation of the form of Equation (46) would accurately represent the facts, because x is probably not a constant for all roughnesses, and probably the velocity distribution, as determined by bends in the channel, etc., is quite important; and it has not been brought into the formula at all.

If, however, it is assumed that at least Equation (46) will approximately represent the facts, the requirement for similarity between model and prototype would be:

$$\frac{S_m}{S_n} = \frac{d}{l} = \frac{K^x{}_m\, E^y{}_m\, W^z{}_m\, V_m^{2-x}\, D_n{}^{1+x+y+z}}{K^x{}_n\, E^y{}_n\, W^z{}_n\, V_n{}^{2-x}\, D_m{}^{1+x+y+z}} \quad \dots\dots\dots\dots (47)$$

If $K_m = K_n$, $\frac{d}{l} = \frac{e^y\, l^z\, v^{2-x}}{d^{1+x+y+z}}$, or,

$$v^{2-x} = \frac{d^{2+x+y+z}}{l^{1+z}\, e^y} \quad \dots\dots\dots\dots (48)$$

For a non-distorted model, in which $l = d$,

$$v^{2-x} = \frac{d^{1+x+y}}{e^y} \quad \dots\dots\dots\dots (49)$$

Multiplying by the area scale, $a = l\ d$, to get discharge, q for the distorted model is expressed by,

$$q^{2-x} = \frac{d^{4+y+z}\ l^{1-x-z}}{e^{y}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (50)$$

and for no distortion,

$$q^{2-x} = \frac{d^{5-x+y}}{e^{y}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (51)$$

Assuming that $x = 0.04$, Equation (50) becomes,

$$q^{1.96} = \frac{d^{4+y+z}\ l^{0.96-z}}{e^{y}}$$

or,

$$q = \frac{d^{0.51(4+y+z)}\ l^{0.51(0.96-z)}}{e^{0.51\,y}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (52)$$

Then n in the author's Equation (8) will be:

$$n = l^{0.010+0.51z}\ d^{0.127-0.51\,(y+z)}\ e^{0.51y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (53)$$

The values of n as computed from Table 2 are:

Test	Value of n	Test	Value of n
A	0.875	D	0.987
B	1.075	E	1.056
C	1.002	F	0.986

Using the values of n, l, and d for Tests A, B, C, and D, and solving by the method of least squares for the most probable values of y, z, and e, gives $y = 0.40$, $z = -\ 0.85$, and $e = 1:2\,800$; and $n = l^{-0.424}\ d^{0.357}\ e^{0.304}$. Then, Tests E and F give $e = 1:374$ and $1:523$, respectively. Taking the average as 1:450, it can be said that these tests indicate that the sand was about 6.25 times as coarse as the equivalent size of the cement surface, and that the natural river was 450 times as coarse as the sand. Undoubtedly, these values are incorrect, but they are near enough within the range of probability to indicate that this method of attack, supported by extensive tests on channels of different scales and distortions, and definite roughnesses, might lead to a satisfactory formula for the flow in open channels, and, therefore, to a true law of model similarity.

K. D. NICHOLS,[19] JUN. AM. SOC. C. E. (by letter).—Although this is a valuable contribution to the science of experimental hydraulics and covers the entire field relating to the solution of river hydraulic problems in the laboratory in an excellent manner, there are many points that should be explained more completely.

A pertinent case relates to the selection of a suitable sand for use in a movable bed model. Under the heading "Experiment Involving Movable Beds," Lieut. Vogel has epitomized in six steps the procedure to be followed in order to insure proper movement of the model bed material. This procedure insures movement of sand in the model. However, it gives no index of the amount of movement to be expected. An improved method is to select a sand that, in addition to fulfilling all the requirements as listed by Lieut. Vogel, will also give adequate movement. This selection must be based on flume tests to determine the rate of movement for any given tractive force.

---

[19] Lieut., Corps of Engrs., U. S. Army, Berlin Germany (Formerly Asst. Director, U. S. Waterways Experiment Station, Vicksburg, Miss.)

Fig. 5 and Table 4 illustrate the mechanical sieve analyses of four sands that have been tested in a tilting flume at the U. S. Waterways Experiment Station. The theoretical critical tractive force has also been determined by formula for each sand and is listed. On the basis of the theoretical critical tractive force necessary to insure movement Sand *A*, with the least tractive force required for general movement, is the best sand, followed in order by Sands *B*, *C*, and *D*.

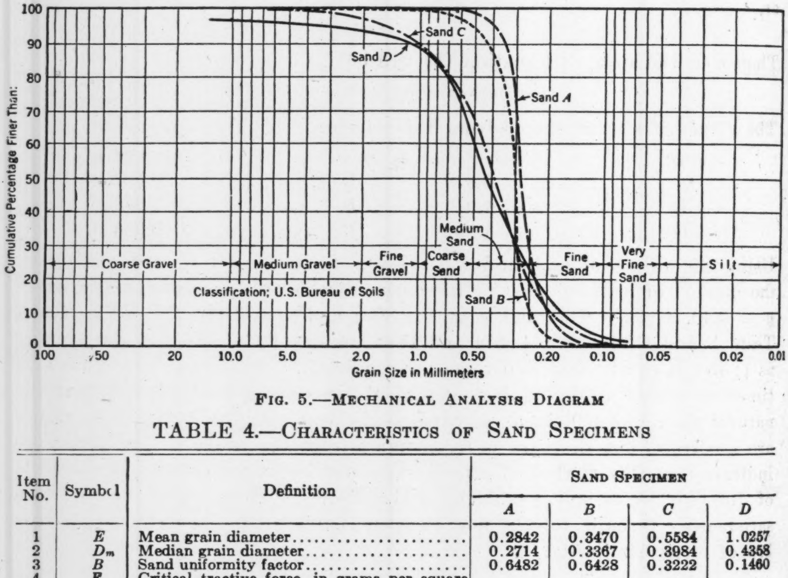

FIG. 5.—MECHANICAL ANALYSIS DIAGRAM

TABLE 4.—CHARACTERISTICS OF SAND SPECIMENS

Item No.	Symbol	Definition	Sand Specimen			
			A	*B*	*C*	*D*
1	E	Mean grain diameter	0.2842	0.3470	0.5584	1.0257
2	D_m	Median grain diameter	0.2714	0.3367	0.3984	0.4358
3	B	Sand uniformity factor	0.6482	0.6428	0.3222	0.1460
4	F	Critical tractive force, in grams per square meter	11.91	14.84	46.80	193.19
5	j_1	Specific gravity of bed material	2.63	2.65	2.62	2.65

Fig. 6 illustrates the results of tests made in a tilting flume to determine the rates of movement for the four sands. The tests indicate that Sand *C* has a much higher rate of movement for any given tractive force than either Sand *A* or Sand *B*. Sand *D*, while having in general a more rapid rate of movement than Sand *C*, requires a higher tractive force for the beginning of general movement.

One of the chief advantages of using a more rapidly moving sand is the saving in time required for the operation of a river model. Consider, for example, a model of a reach in the Mississippi River with scales, as follows: $l = \frac{1}{1\,000}$, $d = \frac{1}{125}$, and $s = 17.4$. The use of Sand *C* in lieu of Sand *A* reduces considerably the time of operation of the model to represent a given time in the prototype. Table 5 compares the rates of movement of Sands *A* and *C* to be expected at different stages. The values in Column (2) are the products of the measured slope and the mean depth in the model and the values in Columns (3) and (4) are read from Fig. 6.

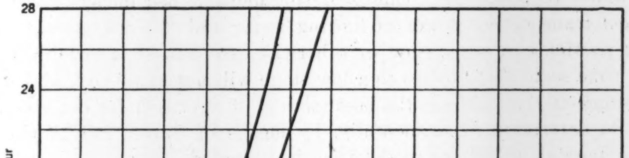

FIG. 6.—RELATION OF RATE OF SAND MOVEMENT TO PRODUCT OF SLOPE AND DEPTH

TABLE 5.—RATE OF MOVEMENT OF BED LOAD MATERIAL FOR DEPTHS AND SLOPES ENCOUNTERED IN A TYPICAL MISSISSIPPI RIVER MODEL

Stage (1)	$D \times S$ (2)	RATE OF MOVEMENT, IN POUNDS PER HOUR PER FOOT OF WIDTH: Sand *A* (3)	Sand *C* (4)	Ratio of movement, $C \div A$ (5)
0	0.000252	0.2	8.5	42.5 : 1
5	0.000308	0.6	12.0	20.0 : 1
10	0.000360	1.1	16.9	15.4 : 1
15	0.000412	1.8	23.5	13.1 : 1
20	0.000458	2.5	28.5	11.4 : 1
25	0.000504	3.3	....	......
35	0.000596	7.2	....	......

It should be noted that the ratio of the rate of movement of Sand *C* to Sand *A* is not a constant for different stages. For a 5-ft stage twenty times as much sand moves if Sand *C* rather than Sand *A* is used, whereas for a 15-ft stage the ratio of the rates of movement is only 13.1 : 1. Similarly, for other sands, the ratio of rates of movement varies according to some as yet unknown law. This variance for any two sands emphasizes Lieut. Vogel's statement that formulas representing a time scale for movable bed models based on the theoretical transporting power of flowing water and the resistance to motion of grain particles in suspension or otherwise, are almost invariably misleading. A time scale that applies to a low stage will not apply to a higher stage.

This suggests that perhaps the best method of approach for deriving a time scale is to determine experimentally, by means of flume tests, a time scale for each stage at which the model is to be operated.

TABLE 6

$$\left(l = \frac{1}{1\,000}; d = \frac{1}{125}; s = 17.4.\right)$$

Stage, in feet (1)	$D \times S$, in Nature (2)	$D \times S$, in model (3)	RATE OF MOVEMENT, IN POUNDS PER HOUR PER FOOT, OF WIDTH		q (sand) (6)	t (sand) (7)
			Nature sand (4)	Model sand (*C*) (5)		
0.....	0.00181	0.000252	900	8.5	$\frac{1}{106\,500}$	$\frac{1}{1\,170}$
5.....	0.00222	0.000308	2 200	12.0	$\frac{1}{182\,000}$	$\frac{1}{690}$
10.....	0.00259	0.000360	4 150	16.9	$\frac{1}{244\,000}$	$\frac{1}{510}$
15.....	0.00296	0.000412	7 500	23.5	$\frac{1}{323\,000}$	$\frac{1}{390}$

The computations compiled in Table 6 are obtained, as follows (data are for river model with scales of $l = \frac{1}{1\,000}$, $d = \frac{1}{125}$, and $s = 17.4$):

1.—Compute the product of depth times slope in the prototype for various stages, for example, at 5-ft increments (Column (2), Table 6).

2.—Compute the product of depth times slope for corresponding stages in the model (Column (3), Table 6).

3.—Determine by flume test the rate of movement of the prototype sand for values of $D \times S$ computed in Step 1 (Column (4), Table 6).

4.—Determine by flume test the rate of movement of the model sand for values of $D \times S$ computed in Step 2 (Column (5), Table 6).

5.—Determine the discharge scale value for bed-load movement (Column (6), Table 6), by the formula,

$$q \text{ (sand)} = \frac{\text{Pounds of model sand per foot of width per hour}}{\text{Pounds of Nature sand per foot of width per hour}} \times l$$

6.—Compute the time scale for each stage, by the formula:

$$\text{Time scale, } t \text{ (sand)} = \frac{\text{Volume scale}}{\text{Discharge scale}}$$

For example (see Column (7), Table 6), for the 5-ft stage,

$$t\text{ (sand)} = \frac{l^2\,d}{q\text{ (sand)}} = \frac{\dfrac{1}{125\,000\,000}}{\dfrac{1}{182\,000}} = \frac{1}{690}$$

Table 6 illustrates the variation in time scale for various stages, for a typical movable bed model. It should be noted that the values in Column (4), Table 6, have been obtained by extrapolation of existing data for a Mississippi sand and probably are only approximately correct. However, it is possible to determine the proper data experimentally and more work should be done along this line as soon as possible. These values should be obtained by flume tests for the particular sand in the prototype.

Having obtained, experimentally, the time scale for the various stages at which the model is to be operated, a model operating chart representing a cycle of one year is computed on the basis of allowing a time interval for each stage equal to the product obtained by multiplying the time scale by the time duration of that stage in the prototype during a typical or average year.

The procedure described herein is only one of various methods of attacking this difficult problem.

FRANK W. EDWARDS,[20] JUN. AM. SOC. C. E. (by letter).—As the possibilities offered by model studies have gradually become apparent to engineers in the United States, the application of the principle of hydraulic similitude has attracted more attention. A number of papers have been written on the subject, some of which have been highly theoretical. These have their place in engineering literature, of course, but it has seemed that the purely theoretical papers should be supplemented with practical suggestions for actual model design, operation, and interpretation. The author has furnished the needed supplement in his practical paper, the purpose of which, as set forth in its "Synopsis," has been fulfilled.

It is the purpose of this discussion to bring out a few points that may be of interest to engineers engaged in model study. The following points are discussed: First, the author's Equation (10); second, the possibility of selecting the horizontal and vertical scales, for a proposed model, in such a manner that the discharge ratio, q, will more nearly satisfy both the gravity and friction formulas; and third, the feasibility of controlling, within limits, the roughness factor in the model.

In Table 2 of the author's paper, Equation (10) has been compared with the actual discharge ratio, as determined experimentally in several models. The relatively close agreement between the ratio, as determined by the formula and by experimentation, is rather surprising. This formula is restricted in three ways: (*a*) The roughness factors in the model and its prototype must be equal; (*b*) the slope of the model must not be distorted artificially (that is, the slope in the model should equal the slope in Nature multiplied by the scale distortion); and (*c*) the cross-sections of both the model and its prototype must be such that the hydraulic radius can be replaced by the mean depth without causing appreciable error. It is possible to meet the requirements imposed by the first two restrictions, but the third offers difficulties. In the majority of cases the substitution of d, the scale ratio for the depth, for r, the scale ratio for the hydraulic radius, would introduce a considerable error. In a cross-section of a river which is wide in comparison with its depth, the hydraulic radius may be replaced by the mean depth. The resulting error will be negligible. When this same section is reproduced in a model having a distorted scale, the depth, which is greatly exaggerated, is no longer insignificant when compared with the width. In some cases, when a large distortion is used in a model, the mean depth in the model cross-section might equal twice the value of the hydraulic radius for the same section. This reasoning suggests that, in the majority of cases, the actual ratio, r, as determined from cross-sections in the model and in Nature, should be used in the formula for interpreting certain results of model operation. The formula would then be written,

---

[20] Asst. Engr., U. S. Corps of Engrs., Zanesville, Ohio.

$$q = l^{\frac{1}{2}}\, d^{\frac{3}{2}}\, r^{\frac{2}{3}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (54)$$

It should be noted, also, that using the ratio, r, introduces more difficulties. This ratio will not be the same for all stages of the river. For the lower river stages, R_m, the hydraulic radius in the model, would approach D_m, the mean depth in the model; but, more often than not, the high stages are the subject of experimental investigation. For certain types of problems, the scale ratios should be chosen to keep the variation of the ratio, r, within definite limits for all the river stages to be simulated in the model.

As to the second point: When a model study involves, at the same time, flow through an open channel and flow over a structure, such as a spillway or submerged wing-dam, both gravity and friction should be considered. The author's Equation (3) follows from Froude's law, and Equation (10) from the Manning formula. In a specific problem, the correct ratio for r could be used in the formula instead of replacing r with d. To satisfy both laws, $l\, d^{\frac{3}{2}} = l^{\frac{1}{2}}\, d^{\frac{13}{6}}$, and,

$$d = l^{\frac{3}{4}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (55)$$

This means, according to the Manning formula, that the depth scale must equal the length scale raised to the three-fourths power, if both the gravity and friction formulas are to be satisfied.

Using a similar procedure with the Kutter formula as a basis, it is learned that the value of the exponent for l varies for each specific problem. For ordinary models, having scale ratios within the limits indicated by the author's paper for a roughness factor ratio of unity, the Kutter formula gives the following results when equated to the gravity formula: $l^{0.86} > d > l^{0.75}$. The correct exponent is determined by the specific problem.

It is interesting to compare the results obtained from the Manning and Kutter formulas with those obtained from a formula derived by Richard

Winkel, of the Technical University at Danzig. He suggests that the coefficient in the Chezy formula varies with the characteristic value, $VR\rho$ (modified Reynold's number).[10] With this as a basis, he obtained,

$$q = l\, d^{\frac{12}{7}}\, s^{\frac{4}{7}} \quad \text{..........................(56)}$$

in which, s = the slope ratio, model to Nature. For no artificial distortion of the slope,

$$q = l^{\frac{3}{7}}\, d^{\frac{16}{7}} \quad \text{..........................(57)}$$

Then, using the foregoing procedure, to satisfy the gravity and friction formulas,

$$d = l^{0.728} \quad \text{..........................(58)}$$

This equation gives an exponent for l that is smaller than that obtained with the Manning formula, but is within the limits indicated by the Kutter formula.

To illustrate the formulas just derived, assume a proposed model study that involves both gravity and friction. For this problem let $D_n = 40$ ft, $S_n = 0.0001$, and $N_n = 0.030$. Suppose a horizontal scale of $\frac{1}{500}$ appears suitable. According to the Manning formula, $d = l^{0.75} = \frac{1}{106}$; according to the Kutter formula, $d = l^{0.69} = \frac{1}{73}$; and according to the Winkel formula, $d = l^{0.728} = \frac{1}{92}$. Experimental data alone can provide evidence for determining which formula is the most satisfactory.

The third point to be discussed herein is the control of the roughness factor of the model. When it is assumed that N_m, the model roughness factor, and N_n, the prototype roughness factor, are equal, a determined effort should be made to produce this result. It is practically impossible to predict the roughness that will apply to a proposed model. This factor, which is actually affected by a number of items besides channel roughness, has a relatively high value in small-scale models. Probably the short radius of curvature and the small sections encountered in the model contribute most to the large values. When constructing a fixed bed model, the surface should be left as rough as practical until tests to determine the model roughness factor can be made. These tests can then be used as a basis for finishing the surface of the model to produce the desired roughness factor within the limits of its determination in the prototype.

Very little can be done in the case of a movable bed model. However, if more than one bed material is equally suitable for satisfactory bed-load movement, the material that provides the proper roughness should be selected. Usually, the sides of a movable bed model are made of concrete; that is, they are fixed, while the movable bed material is confined to the bottom of the channel. This fixed surface offers another opportunity for varying the roughness factor to some extent.

I. H. PATTY,[21] ESQ. (by letter).—In this excellent paper Lieut. Vogel presents Equation (12) as a time scale for models, stating that this formula is applicable to reservoir problems, or to flood-control problems where the time element is important, such as in the filling of back-water basins and other storage areas. The author further states that the formula is not applicable in problems involving bed-movement development; that no formulas have been devised which reliably indicate the relationship for such development; and that such ratios must be determined by actual tests.

During the short space of time that has elapsed since the establishment of the U. S. Waterways Experiment Station, distinct advances have been made in the technique of designing and operating hydraulic models. This is particularly true in connection with experiments on models of the movable bed type. Such models have beds moulded of sand or other transportable material and are used when it is desired to determine the effects of a stream on its bed and banks. They are useful in problems involving river regulation where it is desired to study effects of dikes, channel alignment, methods of increasing depths for navigation, effects of cut-offs, caving banks, and general channel stabilization. The technique of experimentation with these models has advanced to the stage that quantitative results are regularly attained with a fair degree of accuracy. Naturally, the value of the findings are increased enormously if the time of their accomplishment in Nature can be predicted. To make such predictions requires a scale value indicating the relationship between the time required to produce given effects in the model and corresponding effects in the prototype.

There are two methods whereby a time scale for a movable bed model may be developed. A time scale may be established when at least two surveys, taken at different times, are available of the territory represented by the model. The procedure is to determine by actual observation the length of time required for the model to reproduce known changes that have occurred in its prototype. The scale is then established as the ratio between the observed time required by the model and the prototype to effect these changes. This is the method that has been most commonly followed by experimenters in the past, and it is fairly accurate where the necessary survey data are available.

For many years attempts have been made to devise time scales by straight mathematical procedure. Such formulas usually have had factors representing the relationships for length, depth, slope, and mean grain diameter of bed materials. When applied to models for which scales have been derived experimentally, they have invariably indicated relationships so widely at variance, and so conflicting, that they have come to be considered, not only as having little value, but as being misleading.

A formula for a time scale has been derived, mathematically, and has been tested on the movable bed models built at the U. S. Waterways Experiment Station. On several of these models, experimentally derived time scales were also developed, and were found to agree with those determined by the theoretical method, indicating the latter to be both accurate and dependable.

---

[21] Asst. Engr., U. S. Waterways Experiment Station, Vicksburg, Miss.

A stream of water (either a model stream, or its prototype) performs work and loses energy as it flows down-hill, transporting its burden of sedimentary matter, and shifting the materials of its bed to change its hydrographic features. The ability of a movable bed model to simulate the hydrographic configurations of its prototype was demonstrated more than fifty years ago by Fargue, and such results are now regarded as routine technique in hydraulic laboratory practice. Scales for such characteristics in the model as length, depth, slope, velocity, discharge, etc., are derived by direct linear relationships. The time scale developed at the Vicksburg Laboratory after Lieut. Vogel's paper was written, shows the ratio between the time required for a model and its prototype to perform similar work.

Work is done by a force moving a body through any distance. The product of the numerical value of the force and the distance is a measure of the work, or it may be expressed by the equation:

$$W = F\,L \text{.........................} (59)$$

in which, W = work; F = force, and L = length traveled. Equation (59) may be adapted to express the work done by a flowing stream. It was shown by du Boys, in 1879, that the tractive force of flowing water may be expressed by the formula:

$$J\,D\,S \text{.............................} (60)$$

in which, D = depth; S = slope; and J = the weight of a unit volume of the liquid. Placing $J\,D\,S$ equal to F in Equation (59):

$$W = J\,D\,S\,L \text{.....................} (61)$$

Similarly, a work scale, W, denoting the ratio between the work done by a model and its prototype per similar unit length, can be derived if the respective values for the model are divided by those for the full scale:

$$\frac{W_m}{W_n} = \frac{J_m\,L_m\,D_m\,S_m}{J_n\,L_n\,D_n\,S_n} = l\,d\,s = w \text{..............} (62)$$

The scale, $l\,d\,s$, would also denote the ratio between the time required for the model and the prototype to perform similar work if the velocity of flow in each were the same. This is never true in river models, but if the work scale, $l\,d\,s$, is divided by the velocity scale, v, the result will be a unit-time-work scale, t_w:

$$t_w = \frac{l\,d\,s}{v} \text{........................} (63)$$

From Manning's formula the scale value for velocity in models has been found about equal to $d^{\frac{2}{3}}\,s^{\frac{1}{2}}$, the expression, $\frac{1.486}{n}$, being cancelled since it is quite nearly equal to unity. In Equation (63), let $v = d^{\frac{2}{3}} s^{\frac{1}{2}}$; then:

$$t_w = \frac{l\,d\,s}{v} = \frac{l\,d\,s}{d^{\frac{2}{3}}\,s^{\frac{1}{2}}} = l\,d^{\frac{1}{3}}\,s^{\frac{1}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (64)$$

Equation (64) is a complete expression for a unit-time-work scale, showing the ratio between the time required for a model and its prototype to perform similar work. It presumes the bed material in each to be identical, or nearly so, and when they are dissimilar a factor, *f*, denoting the relative transportability of the two materials, as determined by one of several existing formulas or by flume test, must be added and the scale computed for each of the stage heights at which the model is operated. The complete formula, then, will be:

$$t_w = f\,l\,d^{\frac{1}{3}}\,s^{\frac{1}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (65)$$

The mathematical soundness of Equation (64) may be further demonstrated by developing it from a different angle. A tractive force scale, *d s*, may be derived as follows:

$$d\,s = \frac{J_m\,D_m\,S_m}{J_n\,D_n\,S_n} \quad \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

in which, the factor, *J*, being equal to unity, cancels out. A unit-time-distance scale, t_d, showing the ratio between the distance traveled in the model and in Nature, in unit time, may be derived by dividing the length scale, *l*, by the velocity scale, *v*, or,

$$t_d = \frac{l}{v} \quad \ldots\ldots\ldots\ldots\ldots\ldots (67)$$

Then the product of the unit-time-distance scale, $\frac{l}{v}$, and the tractive force scale, *d s*, will give the unit-time-work scale, or,

$$t_w = \frac{l}{v}\;d\;s = \frac{l\,d\,s}{v} = l\,d^{\frac{1}{3}}\,s^{\frac{1}{2}} \ldots\ldots\ldots\ldots\ldots\ldots (68)$$

Most of the movable bed models constructed at the U. S. Waterways Experiment Station have horizontal scales (*l*) of between 1 : 1 000 and 1 : 500, and vertical scales (*d*) of from 1 : 150 to 1 : 100. On such models the average time of operation, indicated to simulate 1 year in Nature, is from 6 to 16 hours.

Experience gained on nearly one hundred model studies has demonstrated the reliability of the various formulas given by Lieut. Vogel in his paper. With the exception of a formula for determining the time relationship for movable bed models they comprise all the scale values commonly needed in a river hydraulics laboratory. Other methods of deriving a time scale for such models are being investigated.

CHARLES S. BENNETT,[22] M. AM. SOC. C. E. (by letter).—Engineers engaged in the field of applied hydraulics should welcome this excellent compilation of data on laboratory methods of solving numerous hydraulic problems. The use of models in the study of certain hydraulics phenomena furnishes the only practical and reliable solution to many problems confronted by designers of hydraulic structures.

---

[22] Engr., The Miami Conservancy Dist., Dayton, Ohio.

The writer wishes to call attention to the fact that expensive equipment and elaborate laboratories are not always necessary for the application of some of the studies outlined by Lieut. Vogel. It is often possible to secure valuable data on specific problems by the use of a small amount of equipment and some ingenuity.

The improved channel of the Miami River at Dayton, Ohio, is designed to carry a regulated maximum flood flow with a free-board of 3 ft on the levees flanking the channel. Several years ago it was proposed to erect several low overflow dams in this channel to provide slack water during periods of low flow, primarily to enhance the appearance of the stream and to provide facilities for boating and swimming. Before such structures could be approved it was necessary to determine what effect they might have on river stages at times of high flow. As various shapes and types of dams were under consideration it did not seem feasible or safe to rely entirely on calculations of the effects of such structures.

It was decided to construct a small model of the section of the stream involved and to measure the effects of various types of dams, using flows corresponding to great floods. The reach of river channel to be investigated was about 6 000 ft long, with an average width of about 600 ft. Space available for the model limited the scale to 1: 600 horizontal and 1: 120 vertical.

A specially constructed table top of laminated wood, about 4 by 10 ft, was mounted on trestles set up on a concrete garage floor. The table was carefully and accurately leveled and adjusted with clamps so as to maintain its level position. The model was constructed on this table, using the top surface as a datum plane. Templates made of cardboard coated with shellac and spaced 200 ft apart were used. The model was made of a concrete consisting of cement and commercial asbestos in about equal proportions. This material can be cut with a knife, nails can be driven in it, and it is relatively light in weight. Two paintings with a liquid water-proofing material made it impervious.

Water was furnished by a 2-in. direct-connected centrifugal pump, discharging into a baffled weir box in which was a 90° V-notch of steel plate. Water flowing through the channel passed out at the lower end under an adjustable tail-gate and emptied into a storage trough under the table, from which it flowed back to the pump. The maximum quantity of flow required was about 0.15 sec-ft.

Measurements of surface elevations in the channel were made with point gauges, each mounted on a beam spanning the channel. These cross-beams slid on long steel-bar beams mounted parallel to the channel on each side. The point gauges were equipped with verniers and could be read to 0.0005 ft. During tests an engineer's level was used to check all adjustable parts of the model set-up to insure accuracy.

Models of dams were cast of babbitt metal to fit the bed of the stream at pre-determined points. The various models could be interchanged as required.

The cost of this model was relatively small. The pump and motor cost $60 (second-hand) and were available for other uses. The total cost of materials was about $85. All labor was performed by regular employees who were handy with tools. Even the point gauges were "home-made," the verniers being salvaged from discarded level rods. Many valuable data were secured by the use of the model and most of the material was salvaged for subsequent experiments.

KENNETH C. REYNOLDS,[23] ASSOC. M. AM. SOC. C. E. (by letter).—The U. S. Waterways Experiment Station is carrying on excellent researches and the presentation of methods and equipment which have proved to be satisfactory at this Station, is of inestimable value to other experimenters in the field of river hydraulics.

The writer agrees as to the desirability of having uniform nomenclature although he can not agree with some notations used by the author. If some Greek letters have been frequently used for certain factors, they might well be considered as standard. Thus, ν is used by many for the kinematic coefficient of viscosity.

Immediately preceding Equation (5), consideration is given to an undistorted model, and it is shown that the ratio of discharges is, $q = \frac{a\, r^{\frac{2}{3}}\, s^{\frac{1}{2}}}{n}$. In deducing Equation (5) it is assumed that the hydraulic radius is equal to the mean depth. This assumption is unnecessary since the hydraulic radius is an area divided by a wetted perimeter or is a linear dimension for an undistorted model. The ratio of these linear dimensions is l, from which Equation (5) follows.

In the paragraph preceding Equation (10) Lieut. Vogel states that it has been found from experiments with distorted models of rivers that the ratio of the roughness coefficients for model and prototype is unity, both for models built of cement mortar, if the scale ratio of length is less than 1 to 1 000, and also, for models with a sand bed when the scale length is between 1 to 1 000 and 1 to 500. This information is of real value. In 1925, Erik G. W. Lindquist, M. Am. Soc. C. E., determined[8] this ratio of coefficients analytically for an undistorted model with non-uniform flow to be the sixth root of the scale of length.

V. V. TCHIKOFF,[24] M. AM. SOC. C. E. (by letter).—In this extremely valuable paper the author covers, quite completely, the theory and practice of river laboratory hydraulics. For a model and the prototype to be hydraulically similar it is theoretically necessary that they have geometrical, kinetic, and dynamic similitude. However, when a river model is designed, the cross-section is usually distorted and, referring to the last two mentioned conditions, the author states: "For all practical purposes, dynamic and kinematic similitude exists when the flow of water in the model is of the same character as the flow in Nature."

---

[23] Asst. Prof. of Hydraulics, Dept. of Civ. and San. Eng., Mass. Inst. Tech., Cambridge, Mass.

[24] Cons. Engr., New York, N. Y.

The question now arises as to how to judge when the flow in the model is of the same character as that in Nature. The best and, perhaps, the only practical criterion is whether the character of transportation is the same for the same silt in both channels. If the prototype and model meet these requirements, their flow will have the same character and there will be hydraulic similitude.

The study of the phenomena of silting leads to two inevitable conclusions: First, the prototype and the model must have the same kinetic flow factor; and, second, their discharges should be in proportion to the hydraulic radius, cubed. As will be shown, subsequently, the first condition provides the same turbulence of water, and the second, determines the precise distortion of the cross-section.

Kinetic Flow Factor.—This important idea was introduced by B. A. Bakhmeteff, M. Am. Soc. C. E.,[25] in connection with his "specific energy of flow" expressed by the equation:

$$\epsilon_d = D + \frac{V^2}{2\,g} = D\ (1 + \tfrac{1}{2}\ K_d) \ldots\ldots\ldots\ldots\ldots (69)$$

in which, ϵ_d is the average velocity head (energy per unit weight of liquid) referred to the bottom of the canal cross-section; and K_d is the kinetic flow factor, a dimensionless number which is equal to:

$$K_d = \frac{V^2}{g\,D} = 2\,\frac{\frac{V^2}{2\,g}}{D} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (70)$$

or twice the ratio of the kinetic energy head to the potential energy head.

From Equation (70):

$$V = \sqrt{K_d\,g\,D} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (71)$$

which is no more than the author's Equation (2), or Froude's law derived from the formula for velocity of a body falling freely under the influence of gravity. It applies also in the case of a channel of indefinite width.

Fluid friction, however, becomes of considerable importance in the usual channel and most of the formulas for uniform flow in channels and pipes are connected with the hydraulic radius. Therefore, if one refers the energy head to the hydraulic bottom instead of to the bottom of the cross-section as in Equation (70), the result is a new expression for the specific energy:

$$\epsilon_r = R + \frac{V^2}{2\,g} = R\ (1 + \tfrac{1}{2}\ K_r) \ldots\ldots\ldots\ldots\ldots (72)$$

in which,

$$K_r = \frac{V^2}{gR} = 2\,\frac{\frac{V^2}{2\,g}}{R} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (73)$$

---

[25] "Hydraulics of Open Channels," by Boris A. Bakhmeteff, p. 64.

is a factor of turbulence, or is the kinetic factor of flow; but in the more general hydraulic understanding of the liquid flow, this is twice the ratio of the velocity head to the hydraulic radius.

If a curve of ϵ_r is constructed as a function of the hydraulic radius, R, it will be similar to that of Equation (70), with D substituted for the hydraulic radius, R. The first derivative of Equation (72) will give the critical flow conditions depending on the form of the cross-section. In the case of a channel of indefinite width when $R = D$, it is not difficult to obtain the well-known equation for critical depths:

$$D_{cr} = \sqrt[3]{\frac{q^2_b}{g}} \quad \dots\dots\dots\dots\dots\dots\dots\dots (74)$$

in which, q_b equals the discharge per unit of channel width.

Similar to Equation (71) the value of V, from Equation (73), is equal to:

$$V = \sqrt{g\,K_r\,R} \dots\dots\dots\dots\dots\dots\dots\dots (75)$$

The correctness of Equation (75) and the general incorrectness of Equation (71) is proved by practical data on non-silting channels. This problem has been studied thoroughly by engineers in British India and the equation for the critical non-silting velocity,

$$V_s = b\,X^c \dots\dots\dots\dots\dots\dots\dots\dots (76)$$

passed through the evolution illustrated by Table 7.

TABLE 7.—VALUES OF NON-SILTING AND NON-SCOURING VELOCITY, V_s, BRITISH INDIA (VALUES IN EQUATION (76))

Item No.	Authority	UPPER BARI DOAB CANAL			LOWER CHENAB CANAL			MADRAS GODAVERI WESTERN DELTA CANAL

6	The writer....................	1.15	R	0.50	1.13	R	0.50	0.81	R	0.50

One of the most recent students of this problem is Gerald Lacey[28] and his formulas (see Item No. 5, Table 7) are now generally adopted. Mr. Lacey's equation completely coincides with the writer's Equation (75) developed from theoretical considerations. Item No. 6, Table 7, contains the comparable elements of the writer's formulas for the three canals mentioned, calculated on the basis of mean value of the kinetic factor. For the three canals, V_s equals

---

[28] "Stable Channels in Alluvium," by Gerald Lacey, *Minutes of Proceedings*, Inst. C. E., Vol. 229, Session 1920–30, Pt. I.

4.15%, 3.98%, and 2.04%, respectively. The writer's data yield a quantitative expression of kineticity of flow (that is, turbulence) and, of course, are directly related to the size of the silt particles. Thus, to secure hydraulic similitude, the same kinetic factor in the model and prototype is the first prerequisite.

Hydraulic Similitude.—There are many channels, however, with the same kinetic factor. It is easy to fulfill this condition in designing the model, but this is not sufficient to obtain the definite dimension of a channel. A second condition is that the discharges in the prototype and model must be in proportion to their hydraulic radius, cubed. The reason for this is again the necessity of preserving the same character of silt transportation.

The discharge of water is represented geometrically by a solid with a plan area, $A = PR$, and a height, $V = \sqrt{g\,K_r\,R}$. The relation of discharge for the same kinetic factor will be:

$$\frac{Q}{Q_1} = \frac{A\,V}{A_1\,V_1} = \frac{A\,R^{0.5}}{A_1\,R_1^{0.5}}$$

The area, A, may be represented as,

$$A = PR = y\,R^2 \qquad (77)$$

in which, $y = \frac{P}{R}$ depends on the shape of the cross-section; and the relation of the discharge will be,

$$\frac{Q}{Q_1} = \frac{y\,R^{2.5}}{y_1\,R_1^{2.5}} \qquad (78)$$

If the areas are geometrically similar, y will equal y_1 and the discharges will be in proportion to $R^{2.5}$. This condition occurs in designing non-distorted hydraulic models of channels. In this case, it is necessary to change the other hydraulic elements accordingly.

Thus, keeping the similitude of cross-sections, the relationship of the discharge will be as $R^{2.5}$, which means that the discharges represented as volumes are not geometrically similar. In order that they may be similar, even if only hydraulically, it is necessary that they be comparable in relation to the hydraulic radius cubed; thus:

$$\frac{Q}{Q_1} = \frac{R^3}{R^3_1} \qquad (79)$$

or, in view of Equation (75):

$$\frac{Q}{Q_1} = \frac{V^6}{V^6_1} \qquad (80)$$

In other words, the discharges vary as the sixth power of velocity. This may be considered as a well-established law for turbulent flow, as was pointed out by Mr. Lacey[27] in reducing the same formula, although by a different method. Comparing Equations (78) and (79), it is found that the relation of the coefficient, y, to the square root of the hydraulic radius must be a constant and,

$$\frac{y}{y_1} = \frac{R^{0.5}}{R_1^{0.5}} = \frac{V}{V_1} \qquad (81)$$

---

[27] *Minutes of Proceedings*, Inst. C. E., Vol. 229, Session 1929–30, Pt. I, p. 271.

This shows that, in order to have hydraulic similitude of discharges, it is necessary to distort the cross-section of the channel, so that the coefficient, $y = \frac{P}{R}$, varies according to the velocity. The necessity of this relationship has been shown by Dr. H. E. Hurst.[28]

The discharges for the channels of the same hydraulic similitude can be designated by,

$$Q = Y\,R^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (82)$$

in which, Y is the constant coefficient for the channels with the same kinetic factor and the same transportation characteristics.

If one constructs the relation of Q as a function of R, using the data of the three non-silting canals given by Lacey, the result is: $Q = 6.93\ R^3$ (Upper Bari Doab); $Q = 9.45\ R^3$ (Lower Chenab); and, $Q = 4.77\ R^3$ (Madras Godaveri). This is the practical confirmation of Equation (82). Coefficient Y is known in the prototype.

Thus, in order to preserve the same character of flow in the model, or the same transportation characteristics, it is necessary to fulfill both conditions, namely, the same constant kinetic factor and the relationship of discharges as R^3. This will give definite data for designing the model which will be precisely distorted.

Viscosity.—The smaller the model the more important is viscosity, the second flow factor. Entirely similar to the kinetic factor it is advisable to introduce the viscosity factor of flow which, according to Poiseulle's law, is:

$$U = \frac{Y\,V}{g\,R^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (83)$$

in which, U is the viscosity factor and Y, the coefficient of kinematic viscosity. Comparing Equations (73) and (83), it is clear that in the model it is impossible to keep both factors. The preservation of the kinetic flow factor is possible up to a certain size of model when viscosity must be considered. Reynolds' number serves as the criterion. Having two factors, kineticity and viscosity, this number is obtained by dividing one by the other:

$$\mathsf{R} = \frac{K_r}{U} = \frac{VR}{Y} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (84)$$

This is a simple and clear definition of Reynolds' number. Its numerical values are discussed by Lieut. Vogel.

Manning's Exponent.—The writer would also like to make some remarks about the variation of Manning's exponent of $\frac{1}{6}$. That this exponent is not constant, varying with the nature of the soil of the channel, is a well-established fact. This has no particular importance in the use of Manning's formula for normal practical conditions when the hydraulic radius is, say, between 0.8 ft and 10.0 ft. However, in designing the model of a river the variation of the hydraulic radius is much greater. To find the relationship of Manning's exponent to N, the coefficient of roughness, the writer constructed the value of Chezy's C as function of R for various Kutter N-values and found that the following formula represents this relation:

---

[28] *Minutes of Proceedings*, Inst. C. E., Vol. 229, Session 1929–30, Pt. I, p. 330.

$$z = 6\,N + 0.05 \qquad (85)$$

in which, z is Manning's exponent.

For Kutter's $N = 0.010$, one has $z = 0.11$ (about $\frac{1}{9}$) and for $N = 0.040$, $z = 0.29$ (about $\frac{1}{3.4}$). This shows considerable variation in comparison with the usual Manning's exponent, $z = \frac{1}{6} = 0.167$. The last value of z corresponds with $N = 0.0194$, when only Manning's exponent is correct. Therefore, in developing relations for the model while using Manning's formula, Equation (85) must be taken into consideration.

Some comparisons can be made of the author's and writer's formulas in reference to exponential dimensions. Equation (74) is similar to the author's Equation (3), both having the general exponent, 2.5. Equation (10) is based on Manning's exponent, $\frac{1}{6}$. In another paper[29] Lieut. Vogel gives the value for N for the Mississippi River as 0.037. The corresponding value of Manning's exponent from Equation (85) will be equal to 0.272 instead of 0.167. If the general exponent, 2.67, in Equation (10), is corrected, it becomes 2.77 as compared with 3.00 in the writer's Equation (82).

SAMUEL SHULITS,[30] JUN. AM. SOC. C. E. (by letter).—Equation (10) of this instructive paper is a special case of a more general law for the discharge scale of distorted models. Consider the well-known formula for the loss of head in pipes:

$$H = \lambda \, \frac{L}{D} \, \frac{V^2}{2\,G} \qquad (86)$$

in which, λ is a coefficient of friction, and the other symbols are as defined in the paper. This form of equation is highly desirable because of the non-dimensional coefficient, λ. It can, and should, be adapted for open-channel flow. This can be accomplished easily by inserting the hydraulic radius, R, for D. The fact that $D = 4\,R$ is knowingly disregarded, because it would only necessitate the inclusion of the numeral, 4. Equation (86), rewritten, then becomes:

$$V = \sqrt{\frac{2\,G}{\lambda}} \, \sqrt{RS} \qquad (87)$$

It is evident that the term, $\sqrt{\frac{2\,G}{\lambda}}$, is nothing more than the Chezy roughness coefficient, C. The relation between the non-dimensional coefficient and the Chezy number is $\lambda = \frac{2\,G}{C^2}$, in which, C has the dimension, $\frac{L^{0.5}}{T}$.

[29] "Geometric *versus* Hydraulic Similitude," by Herbert D. Vogel, Assoc. M. Am. Soc. C. E., *Civil Engineering*, August, 1932, p. 467.

[30] Asst. Engr., U. S. Bureau of Reclamation, Denver, Colo.

It is important to note that the use of the coefficient, λ, has become general practice in Europe, especially in hydraulic laboratories. If Equation (87) is used instead of the Manning formula, the discharge scale becomes:

$$q = \frac{\lambda_n^{0.50}}{\lambda_m^{0.50}} \, a \, r^{0.50} \, s^{0.50} \quad \ldots\ldots\ldots\ldots\ldots\ldots (88)$$

With the same assumptions as in the original paper, it is found, finally, that,

$$q = \frac{\lambda_n^{0.50}}{\lambda_m^{0.50}} \, l^{0.50} \, d^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (89)$$

Since $C = \frac{1.486 \, R^{\frac{1}{6}}}{N}$, the relation between λ and N is:

$$\lambda = \frac{2 \, G N^2}{(1.486)^2 R^{\frac{1}{3}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (90)$$

Substitution of Equation (90) in Equation (89) yields the author's Equation (8) which proves that the latter equation is only a special case. Had the Ganguillet and Kutter formula been used instead of the simple one of Manning, a very complex equation, indeed, would have been obtained for the discharge scale.

Lieut. Vogel's formula for the discharge scale is a valuable tool for the laboratory technician because it will enable him to estimate the scale when experience data are lacking; but it must be emphasized that the rule was derived by using the Manning flow formula, and for models and prototypes for which n is approximately equal to 1.

A more rational method now in use in many laboratories consists in collecting values of λ_m, the non-dimensional coefficient of roughness, for the various surfaces and types of models encountered in the laboratory during its operation, and plotting these values against Reynolds' number. Sometimes over-bank roughness caused by trees during floods is simulated in the model by means of pebbles. Values of λ_m computed from such models with different values of R would facilitate greatly the determination of the discharge scale for future models, since roughness coefficients for such conditions are not to be found in any engineering tables. Equation (88) or Equation (89) is used for this purpose. It is desirable, of course, that the ratio of λ_m to λ_n be as close to 1 as possible. A very instructive and useful table on scales is given by Eisner.[81]

Turbulence Criterion.—The criterion for turbulent flow, Equation (15), should be used with some care. To obviate the inconvenience of the Reynolds' number with its string of zeros, Krey[82] introduced what is known to-day as the Krey number, $V D \rho$, in which, ρ is a modified form of the kinematic viscosity, K; that is, $\rho = \frac{1.2}{10^6 K}$ in the metric system. The value of ρ is chosen so that at a mean temperature of 13.2° C, it has a value of 1; but at 5° C, it is

---

[81] "Theory of Flow in Open Channels," by F. Eisner, Leipzig, 1932.

[82] "Grenzen der Übertragbarkeit der Versuchsergebnisse und Modellähnlichkeit bei praktischen Flussbauversuchen," *Zeitschrift* für angewandte Mathematik und Mechanik, 1925, Vol. 5, No. 6, p. 484.

0.79, and at 25° C it is 1.32 sec. per sq m. Consequently, if the value of VD was determined at the higher temperature, the corresponding metric Krey number would be $1.32 \times 0.00186 = 0.00245$. With water at a temperature of 41° F (5° C), as sometimes occurs in the Denver Laboratory, VD would have to be as high as 0.00311 to yield the same Krey number. This is an increase of 67% over the value in Equation (15) (in metric units, $Z = VD > 0.00186$). The use of VD alone as a criterion probably would result in laminar or transitional flow. In models with very shallow depths of flow in warm climates, the effect of temperature may be considerable.

Bed-Load Scale.—Krey gives the following approximate relation for the bed-load scale, which will be designated by β:

$$\beta = l\, d^6\, s^6 \text{..........................} (91)$$

This relation is based on the fact that according to experimental data the bed load per unit width of channel varies directly, and approximately, as the sixth power of the tractive force, F, in Equation (13).

Charles D. Curran,[83] Assoc. M. Am. Soc. C. E. (by letter).—Doubtless, this is the most complete treatise on the subject of river laboratory hydraulics presented in recent years. It gives concisely those tenets of earlier research still followed and presents clearly the latest developments in the science as practiced to-day in the United States, and especially at the U. S. Waterways Laboratory, at Vicksburg, Miss.

Since this art is relatively young in this country those interested in it will have widely ranging opinions of what problems have been solved adequately and what problems are in urgent need of solution. It must first be remembered that the practice of river laboratory hydraulics has a dual goal; (1) The prompt, accurate, and practical solution of the problem presented; and (2) the development of more precise laws of the elements affecting both rivers and models.

The first is especially important in Federal work. A waterways engineer is confronted with a problem that calls for immediate solution. Therefore, the laboratory solving the problem must work as expeditiously as possible to give him the best answer it can in time for him to use it. The principles of reproduction are followed and a laboratory representation of the river or harbor in question is constructed. Because of the impossibility of exact undistorted reduction of every dimension and every force, a true model cannot be built and truly quantitative results cannot be obtained. The writer was pleasantly surprised to learn[84] that experiments of the U. S. Waterways Experiment Station have given accurate quantitative results in the solution of some river problems. However, he believes that, as yet, answers found must be presented by laboratory workers as qualitative and, likewise, must be accepted by field workers as qualitative. Neither must expect that laboratory experiments will show that such and such an island will be scoured away 50 ft in 2 years and 3 months if certain dikes are constructed. An experiment will show rather that with such construction the island will recede, stay fixed, or advance in a short time or a long time. The attempt to learn of conditions that will exist in the year 2000 in the Rangoon River Delta[35] is probably expecting too much from a study of a laboratory model, and surely problems being studied in a limited time should not be expected to be so precisely solved. When more laws are more exactly known and when unlimited time may be spent in model study, then perhaps one can expect answers that are quantitatively precise.

---

[83] Lieut., Corps of Engrs., U. S. Army, Brooklyn, N. Y.

[84] *Civil Engineering*, March, 1934, p. 118.

Hand in hand with the practical solution of river problems must go work on the problems of determining various hydraulic laws. Among such latter problems is that, met in movable bed models, of tractive force on the bed load. Work on this problem is being undertaken at many laboratories. Equation (13) is a simple solution of this problem. Its veracity has been proved in German experiments. However, as the author states, it is based on the assumption that the bottom slope is parallel to the surface slope. Furthermore, Lieut. Vogel states that this assumption is not absolutely accurate. Presumably this will make only a negligible difference in average reaches of river at normal stages. However, in a rising river, as a flood approaches, surface slope increases; and as the flood recedes, surface slope decreases. It is true that depth varies likewise. However, bottom slope does not necessarily remain parallel to surface slope. Does the du Boys formula (Equation (13)) then hold true? It is possible to find a stretch of river, practically unvarying in bottom slope, which, at different seasons, will have different surface slopes but equal depth.

When surface slope is parallel to bottom slope it can be seen from consideration of the Chezy formula and Equation (13) that $F \propto V^2$. Does this relationship hold true in a rising and in a falling stream?

Kennedy's[36] experiments give evidence of a kind that indicates such a variation. He stated that power of suspension varied as V^3, theoretically; yet because of bottom movement he found this suspension power varying as $V^{2.56}$. If he considered all material moved by the stream as in suspension, it may well have been that because $F \propto V^2$ the combining of bed-load material with suspended material gave him the exponent of 2.56. At present, the writer is inclined to give greatest credence to du Boys' equation. However, he is not yet willing to disregard entirely Gilbert's[37] work and other works that give tractive force varying as high as the sixth power of velocity. From Lieut. Vogel's paper it may be judged that the du Boys and Kramer formulas give sufficiently accurate results.

J. B. EGIAZAROFF,[38] ASSOC. M. AM. SOC. C. E. (by letter).—A number of very interesting and important questions are developed in this excellent paper. Its special merit lies in the fact that its author has brought to a conclusion the answer to practical questions that formerly were explained only in a general way.

[36] *Minutes of Proceedings*, Inst. C. E., Vol. 119, p. 281.

[37] *Professional Paper No. 86*, U. S. Geological Survey, 1914.

[38] Prof., Electrotechnical Inst. in Leningrad, Leningrad, Union of Socialistic Soviet Republics.

Two aspects of the problem should be emphasized: (1) The value of the criterion for turbulent flow in models; and (2) conditions to be met in devising fluvial models to accommodate a movable bed load.

(*1*) *The Value of the Criterion for Turbulent Flow.*—The author has shown that, for the Reynolds' criterion as proposed by Professor H. Krey, $V D > 0.075$, can be substituted by $V D > 0.02$, even for a smooth concrete-lined bed.

Consequently, for a model with a movable bed load (sand), this condition will give results even more favorable, on account of the greater roughness of the bed. Therefore, it becomes possible to experiment with non-distorted models which, according to Professor Krey, it was necessary, formerly, to distort.

Of great influence in the choice of the scale of a model is that part of its cross-section, that is in active motion. The entire cross-section of a river does not take part in this motion; in a part of the channel (especially in cases when water flow is retarded by a dam) the water has a mild eddying motion. The application of the Reynolds' criterion to the entire cross-section, including those parts not actively involved in the motion of the stream, seems to be incorrect.

(*2*) *Conditions to Be Met in Designing River Models.*—Of exceptional interest is the question of similitude in models designed to accommodate a movable bed. This paper and others emanating from the U. S. Waterways Laboratory, indicate clearly how to choose sand as to size and quantities, and the corresponding rate of flow for any experiment. Hans Kramer, Assoc. M. Am. Soc. C. E., particularly, has contributed valuable information in this field.[39]

One serious difficulty remains, however, the task of obtaining sufficient data as to the movement of the bed load in Nature (the prototype), so as to create the same conditions in a laboratory flume. This problem is especially serious in the forebays of hydro-electric plants where, after sedimentation, particles are put in motion, which could not be considered as present in the normal bed load of the stream.

From 1931 to 1933 experiments were performed in the Hydro-Electric Laboratory in Leningrad,[40] on three models of head-works with intakes. Observations were made of the behavior of a movable bed load in a river with a steep slope, and in a laboratory flume. All these experiments showed, that when the size of sand particles chosen for the model was limited to 0.5 mm to 2 mm and when the average effective diameter did not exceed 1.5 mm, the new bed of the river, in the forebay, assumed a slope that was practically independent of the size of the sand particles.

This new bed slope, however, was greatly influenced by the ratio of the quantity of sand to the quantity of water that passed through the model at the same time. The results thus obtained make easier the selection of model

---

[39] *Proceedings*, Am. Soc. C. E., April, 1934, p. 443.

"geschiebe" for torrential streams retarded by dams, than would be necessary for freely flowing streams, with relatively flat slopes and transporting a finer silt.

Naturally, comparisons of observations on a model and prototype are of the utmost importance. Such a comparison was made in 1933 at the Hydro-Electric Laboratory for the hydro-electric plant at Zemo-Avtchally, U.S.S.R. The scale ratio of the model (non-distorted) was 1:100. The forebay of the prototype was fully silted after two years, with little change in the succeeding three years; the material was composed of fine sand in suspension, without gravel or boulders. In the model the sedimentation was entirely the result of "geschiebe" movement. Comparisons of the silted sections of prototype and model indicated a discrepancy of 6 to 8% near the head-works and intake structure, and as much as 25 to 35% farther up stream where a sharp curvature of the channel may have influenced the result.

HERBERT D. VOGEL,[41] ASSOC. M. AM. SOC. C. E. (by letter).—Inasmuch as the main purpose in presenting a paper on practical river laboratory hydraulics was to draw out constructive thought on the subject, the many discussions which ensued have proved most gratifying. The fact that several have emanated from young men in the profession is also encouraging because, as the science itself is young, its full future development will rest upon engineers who have years of growth ahead of them. The principal point of disagreement among those offering discussions, fortunately, is one which should be easily settled by the newly appointed Special Committee of the Society on Hydraulic Research. No one individual can lay down symbols and nomenclature which will be universally acceptable, but an impartial committee, acting on the matter, should be able to arrive at a generally satisfactory terminology.

Professor Straub favors the designations used in the paper with the reservation that symbols for scale should represent whole numbers instead of proper fractions. This makes for a certain degree of simplification, but may cause confusion in the minds of those who have habitually expressed scales—as of maps—as proper fractions. The effects of distortion have been well brought out by Professor Straub and recent tests conducted at the U. S. Waterways Experiment Station have served to verify a number of his points. In the case of a model of the St. Clair River from which it was desired to obtain the hydraulic effects of submerged sills, it was found that a distortion of about 3 to 1 caused a sufficient departure from the Froudian law to give results materially different from those obtained in the case of a non-distorted model constructed subsequently. Changing the roughness of the distorted model served to bring the results into much closer agreement with those of the non-distorted model, but practicable limits of roughness could not be exceeded. Tests on the non-distorted model with discharges varying from Froudian relationships relatively the same degree as on the distorted model, were in close agreement with the results obtained on the latter, thus indicating that if Froudian relationships had been adhered to the distorted model would have given accurate results. In this case, the practicable limits of roughness having been reached, a decrease in slope throughout the model (to be obtained by progressively raising each template from head to foot of the model sufficiently to eliminate part of the increase in slope due to geometric distortion) was indicated as a necessity to comply with Froudian relationships.

---

[41] Lieut., Corps of Engrs., U. S. A.; Student, The Command and General Staff School, Fort Leavenworth, Kans.

Had the model been built for the determination of resulting bed configurations—that is, had it required a movable sand bed—an increased slope (additional to that imposed by distortion) or depth would have been necessary to develop adequate tractive force, and a greater departure from Froudian laws would have been necessary. Relatively few movable bed models comply with Froudian relationships, however, and if proper verification tests are conducted this departure is unimportant.[42] In a movable bed model the principal objection to distortion is that angles of repose of sand banks are substantially the same as in Nature, while distortion requires that they be maintained much steeper. Professor Straub has explained this point to advantage.

Lieut. Thompson has introduced a new note in striking upon the Chezy coefficient as a criterion for controlling roughness in the model. This entire subject is one upon which much future research should be centered. At present, it can only be said that the sum of knowledge relative to roughness coefficients of natural rivers or models is pitifully small and that there is no index for the actual measurement of roughness. The symbols, n, m, or C, as commonly used, are factors introduced to make the answer "come out right", and include resistance of bends, loss in eddies, effects of changes of cross-section, unknown obstructions, such as wrecks of vessels, etc.

Professor Powell voices the attitude just expressed in stating the need for a "new and better formula for channel flow". His theoretical treatment of the problem from a basis of dimensional analysis is extremely interesting, although not necessarily conducive to aid in the practical design and operation of river models. As stated in his closing paragraph, however, the method is the principal contribution that can be advanced at this time, and any really satisfactory formula must follow from extensive tests on channels of varying characteristics. The American Committee of the World Power Conference, in 1932, undertook the task of co-ordinating research activities in this field.

The efforts of Lieut. Nichols and Mr. Patty to develop a suitable and dependable time scale are wholly laudable, but in spite of all present evidence to the contrary the writer still believes that, as was previously stated (see paragraph following Equation (12)),

> "There is no known 'short-cut' to such determinations, and formulas taking into account the transporting power of flowing water and the resistance to motion of grain particles, in suspension or otherwise, are almost invariably misleading."

---

[42] See "Sand Mixtures and Sand Movement in Fluvial Models", by Hans Kramer, Assoc. M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., April, 1934, p. 443.

Recognizing that for every condition of bank alignment or curvature there will result for each stage an ultimate bed development of unchanging nature, it seems more reasonable to assume a cycle of such duration as will fit into a normal working day, and then, for each condition to be tested, to repeat the cycle a sufficient number of times to insure the attainment of stable conditions. Both Mr. Patty and Lieut. Nichols recognize this fact, and the latter has made it particularly plain by his discussion that practical difficulties exist, which make an empirical formula nearly impossible of achievement.

The discussion by Mr. Edwards points out once more the possibility of reconciling the Froudian law with established laws of friction flow in open channels. This was tried in the case of the St. Clair River experiment, previously mentioned, and again in the canal-crossing experiment at Freeport, Tex. In the latter experiment the silt-transporting capacity of the model river had to be reconciled with the natural laws of hydraulic flow as established by Froudian principles. This was accomplished by designing the model so as to obtain a discharge scale based on the Manning formula, and, subsequently, roughening the concrete bed so as to obtain a value for Manning's n which would bring the discharge scale in perfect agreement with both the Froudian law and the Manning formula. A heavily stuccoed concrete bed produced the required frictional resistance ($n = 0.022$), and no other expedients were necessary to obtain compatibility. Another method of adjustment is to change the form of the relationship, $d = l^{\frac{3}{4}}$, or to add negative supplementary tilt to the model. Much experimental work must be done before laws can be established to meet the manifold ramifications of compatibility requirements. Eventually, research will point the way to true reconciliation of the requirements of Froudian laws, turbulence, and bed-load transportation, but for the present the first thing to be recognized is that, as a rule, each model is designed for a particular purpose—that is, to procure similarity of behavior with respect to a single type of phenomenon.

Mr. Bennett's discussion serves a valuable purpose in showing how model tests may be accomplished at very low cost when limited funds are available to the experimenter. The accuracy of experimental data is generally greater for models of large scale than for those of small dimensions, but frequently a model of modest proportions will serve to supply necessary information within the range of required accuracy. It would appear foolish to forego all model testing simply because the goal of achievement has been set too high. When funds are not available for extended research and experimentation, it is still possible that a less ambitious program will yield results sufficiently accurate for practical purposes.

Professor Reynolds joins with Professor Powell in protesting departure from the use of standard Greek symbols to designate viscosity, kinematic viscosity, and density. Since these symbols are not strictly a part of scale designations, it would seem wise to follow their suggestion and adhere a while longer to the more easily recognized notations.

Mr. Tchikoff offers a number of valuable ideas, all of which are interesting and few of which are subject to serious controversy. He expands somewhat on the statement in the paper (see heading, "Turbulence in Open-Channel Models") that: "For all practical purposes dynamic and kinematic similitude exists when the flow of water in the model is of the same character as the flow in Nature." He then raises the question, "How is one to judge when the two flows are of the same character?" This is answered by the presentation of a practical criterion, based upon the Bakhmeteff theory of hydraulic flow,[25] according to which the prototype and model must have the same kinetic flow factor and the discharges must be in proportion to the cubes of the hydraulic radii. As a basis for the foregoing criterion, it can be assumed that the character of silt transportation must be the same for the same silt in both channels. Mr. Tchikoff, however, does not make clear his definition of silt, or his reason for believing it necessary to use the same material in the model as in Nature. If by "silt" bed material is meant, the factors of slope and depth will control; hence, by judicious control of the model slope and by careful selection of the model sand, similarity of action is readily procured. It is desired to emphasize here, as elsewhere, that in general a model should be designed to fulfill a single specific mission; that the controlling factors should be carefully taken into account in each case; and that if more than a singe purpose is to be fulfilled a conscious check must be made to determine whether the original model—modified perhaps—will suffice, or whether an entirely new model should be constructed.

Mr. Shulits' discussion of the friction factor and its effects is rational and interesting. The method of simulating over-bank roughness by means of pebbles, has long been in use at the U. S. Waterways Experiment Station, but in recent months (1934) wire screens have been found more satisfactory, especially when it becomes necessary to represent floods of considerable height which would overtop small stones on the over-bank. Data are gradually being accumulated in all laboratories to determine values of the non-dimensional roughness coefficient, but the combinations of surfaces and types of models are so many as to make the problem a lengthy one. In the meantime, the situation is far from hopeless if adequate data are known of the river investigated. One method is to reproduce a water-surface profile in the model corresponding to less than bank-full flow in Nature; then, by comparing discharges in model and in Nature, to determine a definite discharge scale; next, using the discharge scale thus determined, to reproduce a flood of considerable known magnitude, for which gauge readings were taken in Nature; and, finally, to adjust the over-bank roughness on the model until a water-surface profile is procured which coincides with that of the natural river. Referring to Mr. Shulits' comments relative to the effects of temperature on the turbulence criterion, it is agreed that considerable importance should be attached to this item. In the general case, however, turbulence is not an all-important factor because if bed movement is a requirement there will always be high turbulence when slopes and depths are such as to result in the production of adequate tractive force.

Lieut. Curran states a timely warning in advising against a too optimistic interpretation of model results; but, nevertheless, recent progress has been such as to make quantitative answers frequently obtainable. In cases where exact reproductions of natural developments appear impossible, corrective factors may be applied to the model results with nearly complete satisfaction.

Professor Egiazaroff points out that, assuming turbulence to result whenever the product of velocity and depth exceeds 0.02, there remains little need for distortion of models, especially in the case of a movable bed. This would be true if turbulence were the only requirement, but, if the bed is of sand, then sand movement is another matter for consideration, and distortion may be necessary for attainment of the required tractive force. The rapid development of Russian laboratories and the excellent work being performed at Leningrad, make Professor Egiazaroff's remarks of particular interest, and his citation of recent experiments gives a valuable sidelight to his discussion.

During the past summer (1934) it has been the writer's privilege to revisit leading hydraulic ("flussbau") laboratories of Germany and, mentally, to compare their present installations and methods with those of 1929. While considerable progress has been made, particularly in the field of lock models, the advancement has been not nearly as rapid, or upon as broad a front, as in the United States. Probably the most important single contribution to the science is the work of Hans Kramer, Assoc. M. Am. Soc. C. E., on the movement of bed material in fluvial models.[43] Investigations supplementary to the studies of Captain Kramer are being carried on at present by the U. S. Waterways Experiment Station and at the Berlin Laboratory of the Prussian Government (Preussische Versuchsanstalt für Wasserbau, Schiffbau, und Erdbau) by Captain Hugh J. Casey, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., but the original work by itself has opened an entirely new field for model investigations. That this is true is evidenced by the fact that nearly every laboratory in the United States has recognized the importance of tractive force studies and is carrying the work forward along individual lines.

What the future will bring forth is difficult, if not impossible, to predict, but it seems certain that American engineers are coming more and more to appreciate the advantages following from tests of river and harbor models. In nearly every section of the country where important public works are being constructed, there can now be found the proposed works in miniature and under test by competent, well-trained, hydraulic-model engineers. It is to be hoped that the growth will be steady and sure, with a background of common sense and practical applicability constantly maintained, and that, as a result, model studies will take their proper place with other forms of engineering activities, not exaggerated in importance, not regarded as a cure-all for all troubles, but respected as an auxiliary method available to the practical engineer in connection with problems not readily susceptible to a purely theoretical analysis.

MODEL OF CALDERWOOD ARCH DAM

By A. V. Karpov[1] and R. L. Templin,[2] Members, Am. Soc. C. E.

With Discussion by Messrs. A. W. Simonds, Lars R. Jorgensen, A. C. Janni, P. Wilhelm Werner, Eldred D. Smith, Elmer O. Bergman, E. Probst, and A. V. Karpov and R. L. Templin.

Synopsis

A model built in the Aluminum Research Laboratories in New Kensington, Pa., of the Calderwood Arch Dam on the Little Tennessee River, south of Knoxville, Tenn., is the subject of the paper. The writers present a discussion of the theoretical principles on which the model study is based, how these principles are incorporated in the model, and the results of a series of tests made on the model in conjunction with some of the tests made on the prototype.

Theoretical Considerations

The behavior of an arch dam is so complex that in order to make possible a model study it is essential to determine a simple relationship between the two. This relationship is included in a set of conditions that are usually designated as similarity conditions. The writers have referred elsewhere to: (*a*) The mathematical derivation of the similarity conditions and the specifications that the material for an arch dam model must meet in order to satisfy these conditions[3]; (*b*) the discussions of these similarity conditions[4]; and (*c*) the work done in developing a proper material.[5]

Note.—Published in December, 1933, *Proceedings*.

The relationship between the behavior of the prototype and its model may be given by the ratios of the deflections and the stresses. Introducing the ratio of the corresponding linear dimensions of the model and prototype as the scale of the model, R, the similarity conditions stated in Reference (*a*) show that the simplest possible relationship of deflections and stresses are: First, to have the ratio of deflections of the prototype and its model equal to the square of the inverse scale of the model, $\frac{1}{R^2}$, multiplied by the ratio of the specific gravities of the materials of the prototype and its model, $\frac{\rho_p}{\rho_m}$, multiplied by the inverse ratio of the moduli of elasticity of the prototype and its model, $\frac{E_m}{E_p}$; and, second, to have the ratio of the stresses of the prototype and its model equal to the inverse scale of the model, $\frac{1}{R}$, multiplied by the ratio of the specific gravities of the materials of the prototype and its model, $\frac{\rho_p}{\rho_m}$.

In order to have such simple relationship, the following similarity conditions stated in Reference (*a*) must be satisfied:

1.—The materials of the prototype and model must follow Hooke's law, which means that the modulus of elasticity, E, is constant in the prototype and the model. (A better expression for that condition is: The materials of the prototype and its model for their respective ranges of stress must exhibit a straight-line relationship between stress and strain.)

2.—The ratio of the specific gravities of the material of the prototype and its loading fluid, $\frac{\rho_p}{\gamma_p}$, must be equal to the same ratio of the model, $\frac{\rho_m}{\gamma_m}$.

3.—Poisson's ratios of the prototype and model materials must be equal at corresponding stresses, $\mu_p = \mu_m$.

4.—The ratio of the moduli of elasticity of the model and prototype must be equal to the scale of the model, R, multiplied by the ratio of specific gravities of the loading liquids of the model and prototype, $\frac{\gamma_m}{\gamma_p}$.

5.—The ratio between the ultimate unit tensile stresses that can be carried by the horizontal joints of the model and prototype must be equal to the linear scale of the model, R, multiplied by the ratio of the specific gravities of the loading liquids of the model and prototype, $\frac{\gamma_m}{\gamma_p}$.

6.—The ratio of the width of the vertical construction joints in the model and prototype, $\frac{b_m}{b_p}$, must be equal to the square of the scale of the model, R^2, multiplied by the ratio of the specific gravities of the loading liquids, $\frac{\gamma_m}{\gamma_p}$, and by the inverse ratio of the moduli of elasticity, $\frac{E_p}{E_m}$, of the model and prototype.

7.—The action of the indefinitely large foundation rock may be represented by a block of elastic material, of some definite dimensions, which has a fairly low modulus of elasticity, so that by supporting it on a base made of a material having a high modulus of elasticity, the conditions of an elastic foundation block supported on an unyielding non-elastic base can be represented.

8.—The ratio of the temperature difference of the model material, between the time of testing and building of the model, and of the temperature difference of the material of the prototype, between the time for which the investigations are made and the time of the building of the prototype, $\frac{T_m}{T_p}$ must be equal to the inverse ratio of the coefficients of thermal expansion of the materials of the model and the prototype, $\frac{c_p}{c_m}$, provided these coefficients are sufficiently uniform to be assumed as constant.

In applying these conditions to the correct design of a model, it is more convenient to divide them into the following classes: (I) Conditions Governing the Methods of Loading the Model; (II) Conditions Governing the Properties of the Model Material; and, (III) Conditions Governing the Method of Building the Model.

(I) Conditions Governing the Methods of Loading the Model

There are two possible ways to load the model. The first is to simulate exactly the loading conditions of the prototype and to load the model by action of gravity forces (weights) of the model material and the loading liquid. The second is to attempt to simulate the loading conditions of the prototype by loading the model with properly distributed forces. A number of methods may be devised for this purpose, such as loading the model by means of a number of weights or springs, or by placing it in a centrifuge and, by rotating it, produce the load by centrifugal forces.[6]

By the first method a comparatively simple relationship may be established between the behavior of the prototype and its model, depending on the fulfillment of Similarity Conditions 1 to 8, and only water or mercury can be considered. Since mercury is excluded on account of the specific gravity limitation, water is the only suitable liquid. Any attempt to establish exact similarity conditions for any model loaded in accordance with the second method will result in such a complicated relationship between the behavior of the prototype and its model that it probably could not be applied to the general study of the behavior of an arch dam.

(II) Conditions Governing the Properties of the Model Material

The established similarity conditions, stated in Reference (*a*), show that a simple relationship between the behavior of the prototype and its model is possible only when the ratios of the specific gravities of the loading liquid to the material in the prototype are the same as in the model. To realize the importance of this similarity condition, the principle of superposition should be applied properly to a model dam. This well-known principle may be stated as follows:

---

[6] "Use of Models for the Study of Mining Problems," by Philip B. Bucky, *Technical Publication 425*, Am. Inst. of Min. and Metallurgical Engrs.

> Any increase or decrease in the loading will cause a proportional increase or decrease of the stresses and deflections, provided the deflections are sufficiently small.

If applied properly to the model this principle would mean that if the loading is increased by a simultaneous increase of the specific gravities, both of the loading liquid and the material of the model, the deflection and stresses will change proportionally. Under such conditions the corresponding deflections and stresses of the prototype can be readily evaluated.

An improper application would be to assume that the specific gravities of the loading fluid and material of the model may be changed independently and that the stresses and deflections would still remain proportional. If the principle of superposition could be applied in such a manner, the ratio of specific gravity requirement would be of no importance, and it would be a simple matter to recompute the stresses and deflections of a model that is built with an improper ratio of specific gravities of loading liquid and material and to predict the stresses and deflections of the prototype. For several reasons, however, the inter-relation between the weights of the loading liquid and the dam material must be taken into consideration.

The first reason is that, by taking the strictly theoretical point of view, and considering the vertical stresses in a vertical element of an arch dam (that is, the so-called cantilever stresses), if the straight-line distribution of stress is assumed, the principle of superposition could be applied independently and an increase or decrease in the specific gravity of the loading liquid or the material would simply increase or decrease the stresses in the proper ratio. However, the assumption of straight-line distribution of stress does not represent the actual stress conditions. An illustration of this point may be of interest. For such illustration, it is preferable to consider a dam with a cross-section, as shown on Fig. 1, which differs somewhat from the conventional. The difference consists in introducing fillets at the sections where the faces of the dam meet the foundation by making the foundation surface a continuation of these faces. Such a shape removes the lines of discontinuity that occur in the conventional dam cross-sections at points where its faces meet the foundation, and makes it easier to visualize the stress conditions.

If an attempt is made in such a case to follow the vertical stresses along the line, *A-B,* at the foundation, they are definitely known at only two points: At *A,* the vertical stress is equal to the total water pressure, $w\ h$, and at *B* it equals zero. No methods are known by which the stresses can be evaluated between these two points, but it is clear that in order to retain static equilibrium, a distribution of vertical stress of the order illustrated on Fig. 1 is necessary, and this stress distribution may be assumed as giving a fairly correct picture without attempting to show its relative magnitude. If, now, the specific gravity of the material of the dam is reduced and that of the loading fluid remains the same, the stress shown along the line, *A-B,* will change and the maximum tension and compression will increase as indicated in Fig. 1 by dotted lines. However, the stresses at *A* and *B* will remain unchanged. In other words, there will be no proportionality of any kind in change of stress and, consequently, of deflection.

In order to retain the proportionality between stresses, and, consequently, between deflections, of the prototype and its model, it is necessary, in case of a change in the specific gravity of the material, to change it in the same ratio as the specific gravity of the loading fluid. Then the pressure of the fluid, $w_f\, h$, will change in the same proportion as the stresses, and the necessary proportionality will be retained between the stresses, and also between the deflections of the prototype and its model. The same reasoning applies to the horizontal stresses at the points at which the horizontal arches meet the abutments or the bed-rock of the canyon.

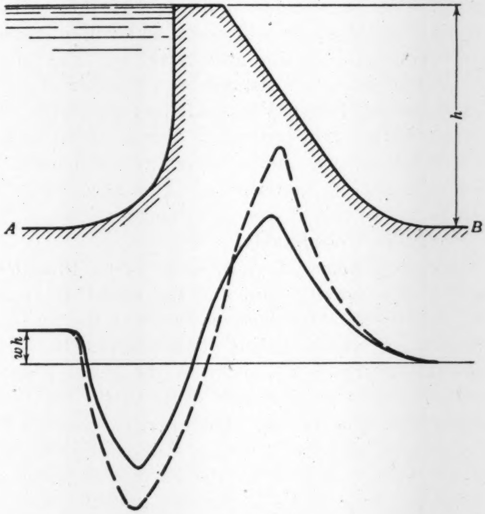

FIG. 1.—DISTRIBUTION OF VERTICAL STRESSES IN A VERTICAL ELEMENT OF A DAM

The second reason for considering the relative weights of the loading liquid and the dam material is that the effect of the ratio between the specific gravities of the material of the model and the loading fluid is important when the resistance to overturning is considered for the dam as a whole. When subjected to water load an arch dam deforms elastically and tends to tip over as a unit. This tendency is opposed mostly by the resistance of the arch abutments. The ratio of the specific gravities will influence the proportion of load carried by the arches and transmitted to the abutments.

The third reason is a more practical consideration. Even assuming a straight-line distribution of stress, it is clear that if the ratios of specific gravities of the loading liquid and the material of the dam differ considerably in the prototype and its model, a reversal of stress will occur at some points; that is, tension will appear in the model instead of compression at the corresponding point of the prototype, or *vice versa;* and, under actual conditions of stress distribution, similar to those in Fig. 1, more pronounced reversal of stress would occur. Only when the ratio of the specific gravities is the same in the prototype and in its model, will there be a complete similarity of stress distribution in sign and magnitude. If this ratio is different, a dissimilarity of sign of the stress will occur and will increase in proportion to the difference between the specific gravity ratios. The joints of the prototype practically exclude tension resistance at a number of points, but if tension appears at these points the joints will act as planes of discontinuity, changing the stress distribution radically. For a model loaded with a heavy liquid, tension will appear at a number of points and tension resistance must be introduced to save it from destruction. This necessitates the building of a model without joints, so that it can withstand tension, which again violates the similarity conditions considerably.

From the theoretical point of view, there is no fundamental difference between the model of a gravity dam and the model of an arch dam. The same similarity conditions cover both cases since the straight gravity dam is an arch dam with an infinite radius of curvature. However, in designing a model, consideration should be given to the relative importance of the various similarity conditions, which may differ in the two types of dams.

As long as the prototype is such that gravity action is subdued (as, for instance, in a very thin arch dam, with a short radius of curvature, and in which most of the load is carried by the horizontal arches), the similarity condition pertaining to the ratios of specific gravities may be of little importance. This ratio becomes more important with an increase in the thickness of the dam or in the radius of curvature, until it is of paramount importance in a straight gravity type of dam. The only conclusion that can be derived from a model of a gravity dam, in which the ratio of the specific gravity of loading liquid to the material is many times higher than in the prototype, is that every gravity dam will fail. The impossibility of arriving at correct conclusions concerning the behavior of a gravity dam based on such a model study applies also to thick arch dams.

Agreement between the calculated and measured stresses and deflections on models loaded with mercury has generally been considered sufficient proof that this particular similarity condition is of little or no importance. This statement is rather convincing, but analyzing it more carefully, it can be shown that it is probably incorrect since no attempt was made to compare directly the calculated deflections and stresses in an actual dam with the results of the model tests. Such calculations were made only for the model, which did not have vertical joints as in the prototype, and was loaded with mercury; consequently, the gravity action was considerably subdued and the arch action exaggerated.

Rubber-Litharge Compound Developed as Suitable Model Material.—The specifications covering a material suitable for the model may be derived from Similarity Conditions 1, 2, 3, and 4. Using water as the loading liquid, the specific gravity of the model material is definitely fixed (in accordance with Similarity Condition 2) as 2.4; that is, the same specific gravity as the concrete in the prototype.

Similarity Condition 4 is of quite minor importance. It is derived from the requirement of exact geometrical similarity between the prototype and its model before and after the loads are applied. If the deflections of the model are not excessive, so that the loaded model does not change its geometrical shape appreciably, these conditions can be violated with the assurance that such violation will have little influence on the behavior of the model; furthermore, increased deflections facilitate model study.

Consequently, the following specifications for the material of the model were laid down in Reference (*a*)[7]: (1) Specific gravity of 2.4; (2) uniform elastic properties without pronounced directional qualities; (3) absence of skin or internal stresses; (4) low modulus of elasticity; (5) reasonably uniform values of the modulus of elasticity under varying unit stresses; (6) low permanent set; (7) low plastic properties; (8) properties that will permit the material to be provided readily in the required irregular shapes; (9) Poisson's ratio close to 0.20; and (10) uniform coefficient of thermal expansion.

The rubber-litharge compound used in the model of Calderwood Dam meets all these specifications reasonably close except Specification (9), in which Poisson's ratio is 0.50.

The question then arises, "How will a model be influenced by this difference in Poisson's ratios?" If a gravity dam is located or constructed in such a way that the vertical joints permit enough lateral expansion to provide for lateral bulge of the material, the test results on a model built of such material will be close to actual conditions, the principal variation being the difference in deflections due to different shear moduli. If the conditions are such that they do not permit expansion of the material at the vertical joints, it is only necessary to determine the stresses in the model at a sufficient number of places, after which they can be expressed readily in terms of the prototype. In other words, for a gravity dam, the non-fulfillment of Similarity Condition 9 is of little importance. For an arch dam it may be of more importance, but the deviations in the behavior of the model will be comparatively small and can be accounted for to a large extent.

It was thought that this new material would permit the building of an arch dam model that would be not only a scalar representation of the prototype, but also an engineering model, the structural behavior of which is similar in every respect to the behavior of the prototype.

(III) Conditions Governing the Method of Building the Model

In the building of an engineering model of a dam, consideration should be given to the methods used in the building of the prototype and to the necessary adaptations of the model that should be made to insure the proper similarity of all conditions.

---

[7] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 322.

Similarity Conditions 5, 6, and 7 govern the building of the model. The exact fulfillment of these conditions is somewhat difficult, due to a number of uncertainties inherent in any arch dam, such as: Uncertainties of the dam proper (Similarity Conditions 5 and 6); and uncertain boundary conditions of the dam where it meets the foundation and abutments (Similarity Condition 7).

Uncertainties of the Dam Proper.—Similarity Condition 5 establishes the ultimate unit tensile strength across the horizontal joints of the model and depends on the strength of the horizontal joints of the prototype. All existing arch dams are designed so that stresses will be considerably below the ultimate strength of the concrete. The horizontal construction joints, however, are usually subjected at a number of points to tensile stress that is higher than can be carried across such joints and, as a consequence, the joints open or crack, thus relieving such stress.

The tension that can be carried across a horizontal joint is rather uncertain and depends largely on the time interval between the placing of two successive layers of concrete. To ascertain the conditions at Calderwood Dam a few preliminary tests were made under conditions that simulated as closely as possible the actual conditions in the dam. These tests showed that the ultimate tensile strength of the horizontal construction joints that were tested, ranged from 60 to 88 lb per sq in. This justifies the conclusion that 25% of the ultimate tensile strength of concrete is about the maximum stress that can be carried in this manner and, in many cases, a much lower stress will open the joint. The horizontal joints in the prototype were spaced about 10 ft apart vertically and under such conditions no vertical tensile stress of any magnitude can be built up in the prototype. In order to simulate these conditions in the model, it was built so that no tensile stresses could be carried across the horizontal joints; but the number of joints was reduced, so that they correspond to a 20-ft vertical spacing in the model instead of the actual 10 ft in the prototype.

Similarity Condition 6 defines the width of the vertical construction joints of the model as compared with the prototype. It is certain that these joints in the prototype cannot carry any stress, but their width is somewhat uncertain.

In Calderwood Dam, as in every commercial dam, the concrete was not placed continuously as in monolithic construction, but in independent blocks, by placing in alternate piers. Considerable time elapsed from the beginning to the end of the concrete work. This procedure resulted in vertical construction joints, formed by the contraction of the concrete in the adjoining blocks. Customary methods were used to fill them by subsequent pressure grouting,[8] but due to the large size of the individual blocks, the time interval between the placing of the concrete and the application of the water load caused internal stress to be developed in the blocks of the prototype. Considering the large size of the blocks and the considerable tension that the concrete can withstand, it is probable that the internal tensile stress developed in these blocks is rather high. Pressure grouting reduces the size of these joints, but probably has little, if any, effect on the internal stress developed in each block.

---

[8] "Grouting Dam Foundations and Construction Joints," by James B. Hays, M. Am. Soc. C. E., *Civil Engineering*, November, 1933, p. 606.

When the water load is applied, the concrete blocks are subjected to compression and then they contract. This contraction will be greater in a block that has a preponderance of internal tensile stress than in one without such stress. If the zero readings are taken before the first application of load, this additional contraction will be included in the measurements. The same conditions of increased contraction could be produced by building a dam of blocks without internal stress, but with wider vertical construction joints.

The rubber compound used in the blocks of the model dam had practically no internal stress when they were assembled. Any subsequent stress that has been introduced is due to differences in temperature of the model at the time of its construction and at the time of loading. Such stress, if any, is so small as to be negligible.

In order to retain the similarity conditions between the prototype, in which the concrete has internal tensile stress, and the model, in which the material has no such stress, the size of the vertical construction joints of the model must be made relatively larger than the theoretical size stipulated by the similarity conditions. The size of vertical construction joints is also influenced by the differences in Poisson's ratio for the material of the prototype and its model.

Uncertain Boundary Conditions of the Dam Where It Meets the Foundation and Abutments.—Similarity Condition 7 covers the condition at the boundaries; the deflections of the foundation and abutments of the model must be similar and in a proper ratio to the deflections of the prototype. The fulfillment of this condition would be fairly simple if sufficient information were available concerning the deflections of foundations and abutments in general and of the Calderwood site in particular. Little is known, however, about the deformation and stress in the bed-rock due to the dead load of a massive structure like a high dam and the additional stress and deflection superimposed by the subsequent water loading of the dam. The scarcity of information made it necessary to include a study of foundation deformation in the testing program.

In order to make such a study possible, the model was arranged so that the deflection of the foundation could be adjusted over a fairly wide range, and with as little disturbing influence on the model *per se* as possible. This increased flexibility of the foundation was obtained by applying screw-jacks, not under the model itself, but on the rubber compound foundation strip on which the model rested, the idea being that any unnatural change in stress or deflection resulting from such adjustments would be kept away from the model or at least smoothed out by the action of the flexible foundation strip.

The lower part of Fig. 2 shows the arrangement of the vertical and horizontal jacks which permitted increased flexibility in vertical and horizontal directions.

Comparative Prototype-Model Table.—Assuming the scale of the model as 1 : 50 and basing it on the theoretical considerations discussed previously, as well as on the properties of the material of the prototype (see Appendix I) and the properties of the material of the model (see Appendix II), the major factors are arranged for comparison in Table 1.

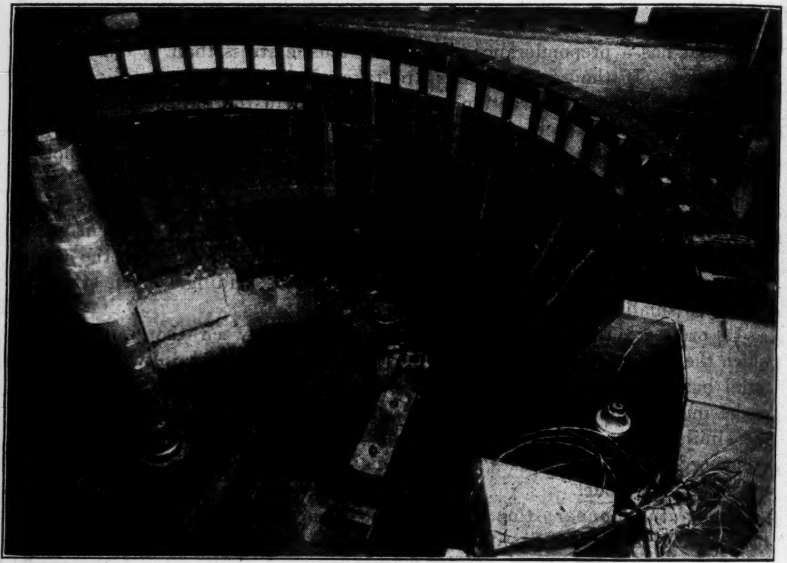

FIG. 2.—HORIZONTAL JACKS TO CHANGE THE SIZE OF VERTICAL CONSTRUCTION JOINTS AND HORIZONTAL AND VERTICAL JACKS TO REGULATE THE FLEXIBILITY OF MODEL FOUNDATIONS.

MEASUREMENTS MADE ON CALDERWOOD DAM

In connection with the study of the model of Calderwood Dam, four sets of measurements on the prototype are available, as follows: Measurements made in April, 1930, before, during, and immediately after the filling period; and those made in September, 1930; May, 1931; and September, 1931. As the lake elevation has not been lowered materially since the initial filling in April, 1930, the dam has been continuously and quite uniformly loaded.

During each set of measurements the lake was maintained at approximately its maximum level, so that as regards the loading conditions, all four sets are similar. There is, however, a difference in temperature conditions.

The noticeable difference in the behavior of the dam as determined by these four sets of measurements can scarcely be attributed entirely to the temperature difference and indicates clearly that a number of additional factors influence the behavior of a dam. These factors may be referred to as "time effect," and the difference between the results of the subsequent tests probably represents the influence of such "time effect." The recognized factors that may produce "time effect" are: The plastic flow of the foundation, abutments, and the concrete of the dam; the difference in concrete temperatures caused by change in climatic conditions; the aging of the concrete; the volumetric changes in concrete caused by shrinkage due to aging; swelling due to the absorption of moisture from the lake or air; and shrinkage due to evaporation of water from the concrete. After a sufficiently long time a continuously and uniformly loaded dam should attain the final or permanent condition. After that, the behavior of the dam will depend only on the changes in climatic conditions.

The storage capacity of the lake behind Calderwood Dam is relatively small and it took less than six days to fill the lake and to load the dam fully.

Since the zero readings were taken immediately prior to the closure of the dam, when the water first began to rise, and the full load readings were taken immediately after the lake was full, the elapsed time between the dates of the two readings was short. The influence of the "time effect" can be noticed only after the dam has been loaded for some time. This combination justifies the assumption that, because of the short filling period, the "time effect" on the dam was so small that it did not influence its behavior. Such an assumption makes it possible to separate the "time effect" and study it in the light of subsequent measurements.

The present model study was made under the assumption of no "time effect" in conjunction with the measurements made on the prototype in April, 1930. The intention is to continue the model study in conjunction with subsequent measurements on the prototype, so as to obtain a better understanding of the influence of the "time effect."

During the first filling, three kinds of measurements were made on the prototype: Deflection, strain, and temperature measurements.

Deflection Measurements.—When the dam was built, provision was made for obtaining deflection measurements. A concrete pier was placed at the center of the crest circle and from this pier the distances were measured to a number of points on the down-stream face of the dam by means of a special apparatus and a measuring tape.

The apparatus consists essentially of the three-legged frame shown in Figs. 3 and 4, in which a swivel-frame is swung. The frame, in turn, supports a pulley over which the tape is reeved. The reference points for measurements are drilled on a block. Suspended by the tape, from the pulley, is a 120-lb weight hung from another pulley similar to that fastened to the swivel arm. When raised from the floor of the pit in which it is suspended this weight subjects the tape to a constant tension of 60 lb. Ball-bearings are provided at either end of the frame as well as for both the tape and weight pulleys. The pulleys and the tape reel were made of aluminum alloys. The reel was constructed with internal reduction gears so as to reduce the force required to raise the weight, and was provided with a spring-brake to prevent the tape from leaving the reel or becoming loose and tangling. Means were provided to lock the reel so that it was not necessary to touch the apparatus while readings were being taken.

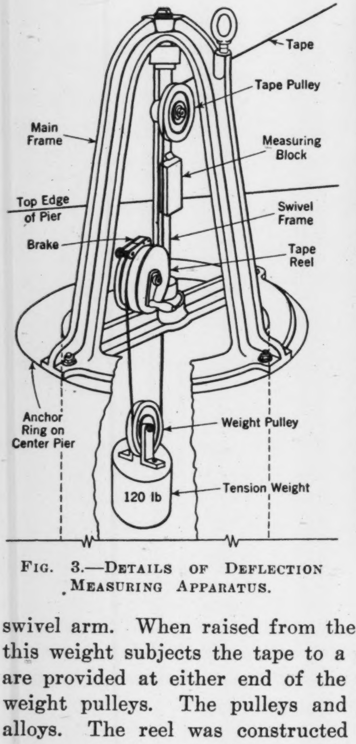

FIG. 3.—DETAILS OF DEFLECTION MEASURING APPARATUS.

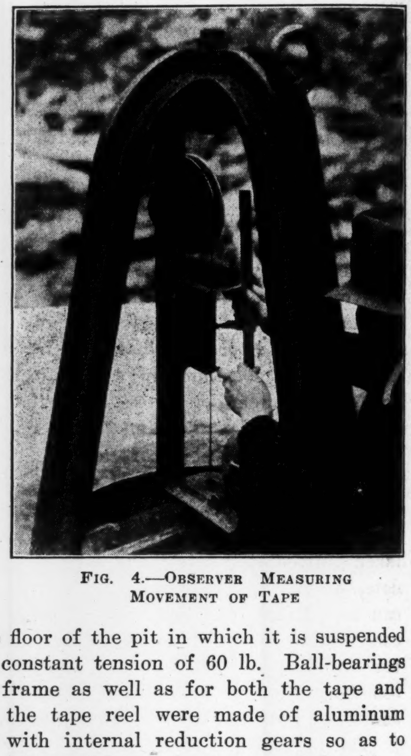

FIG. 4.—OBSERVER MEASURING MOVEMENT OF TAPE

The measuring or reference block bolted to the swivel-frame had a shallow slot along one edge in which the tape moved. Four reference holes were drilled in this block, with a No. 57 drill (0.043 in. in diameter), one on either side of, but close to, the slot at the top and bottom of the block. The swivel arm was offset in such a manner that the edge of the tape reeved over the pulley, passed through the hole in the bottom of the swivel-frame and the center of the cross-member of the outer frame, lay in the slot of the measuring block, and coincided with the center of rotation. The other end of the tape was provided with a hook that was inserted in stainless steel eye-bolts set into the down-stream face of the dam at each deflection measurement station.

Fig. 4 shows the offset of this swivel-frame and also serves to illustrate the method of measuring the movement of the tape, which corresponded to a movement or change in the deflection of the station on the down-stream face of the dam to which the tape was hooked. Each brass sleeve on which the foot graduations of the steel tape appear, was marked with suitable punch holes. The distance between the nearest of these marks and a corresponding reference hole on the measuring block of the apparatus was determined, using a standard vernier caliper, to each jaw of which was fastened a detachable hardened steel point, conical in shape. This change in distance could be determined to the nearest 0.001 in. Since the change in distance from the deflection station to the center pier was the desired measurement, the difference in reading of the vernier caliper, when adjusted to the same footmark and reference point each time, and properly corrected for temperature, angularity, etc., was a measure of the deflection of the dam at that point.

Making the deflection measurements at night and in fair weather it was possible to obtain the unusual over-all accuracy of ± 0.02 in. Since a single reference pier was used, the deflections could be measured in one direction only; that is, from the point on the down-stream face of the dam toward the reference pier. No provision was made to measure vertical displacements; hence it was necessary to assume that all deflection was horizontal, and to correct for the deviation. Due to the topographical conditions it was impractical to measure deflections at the lower elevations of the dam.

In this paper only the deflection measurements on the prototype made in April, 1930, are considered, the zero readings being taken after the dam was completed and before the water load was applied, and the load readings after the dam was loaded by the water in the full reservoir. That means that the measurements included in this paper show deflections due to water load only; or, in other words, the deflections caused by the dead weight of the dam are not considered.

Strain Measurements.—Strain measurements on the prototype were made on the down-stream and the up-stream faces of the dam. Those on the down-stream face were made at a number of rosettes where the strain was measured in four directions, vertically, horizontally, and in two diagonal 45° directions. These rosettes were set when the concrete was placed; each rosette consisted of eight steel inserts fastened to the inside of the forms on a gauge circle 10 in. in diameter. When the forms were removed, these inserts were anchored in the concrete. A small hole was drilled in each insert, and any change in distance between the gauge holes in two opposite inserts was measured with a 10-in. Whittemore strain-gauge.

The state of stress on the surface of a uniform solid may be obtained from strain measurements on three intersecting gauge lines, but at every rosette a fourth measurement was made which served as a check on the other three, and thus a number of inconsistent readings was eliminated.

Strain measurements on the up-stream, submerged face of the dam have not been made heretofore, although they are just as important—and may be even more important—than those on the down-stream face. Since there was no previous experience as a guide, an attempt was made to make such measurements at a few points.

The method consisted essentially of using a comparatively long gauge length (10 ft), at one end of which a piece of 0.091-in. invar wire was anchored to a heavy pin which was set about 2 ft into the concrete. (The invar wire had a modulus of elasticity of 20 300 000 lb per sq in.; a proportional limit of 14 000 lb per sq in.; a yield strength of 38 000 lb per sq in.; and an ultimate strength of 66 000 lb per sq in.) At the other end of the gauge length, this wire was attached to the short arm of a bell-crank lever anchored to the face of the dam by another pin which was machined to provide proper bearing. This bell-crank lever had a ratio of 5 to 1. To the long end of the lever was attached a piece of 0.048-in. galvanized hard steel wire which was carried almost vertically along the face of the dam and through a protecting pipe to the crest where the upper end of the wire was again attached to a lever and dead-weight arrangement so as to maintain a constant tension in the entire lever and wire system. (The hard steel wire had a modulus of elasticity of 29 000 000 lb per sq in.; a proportional limit of 140 000 lb per sq in.; and an ultimate strength of 180 000 lb per sq in.)

Corresponding to each vertical wire a second wire was fastened at its lower end to the lever fulcrum and at its upper end to a second lever-weight system. This second wire furnished a zero reference point in every case. The two wires leading up from any single gauge line were close enough to each other so that a microscope could be focused on first one and then the other, without moving the barrel of the microscope, except in the direction of the travel of the focusing screws. The use of the second wire automatically eliminated temperature corrections as well as corrections for movement of the top measuring point relative to the fulcrum of the lever. It was also possible with this set-up to measure the strains at all points with the same microscope by simply transferring the mounting. This mounting consisted of a vertical standard set into a block which could be clamped to the side of the guard-pipe by a hinged strap and a thumb-screw. A swinging arm fitted on the shouldered top of the vertical standard. The microscope was clamped directly to this swinging arm.

Fig 5 shows the arrangement of the pins and levers in the rosettes; Fig. 6 shows the wires entering the guard-pipe; and Fig. 7 shows the lever arrangement and microscope mounting at the top of the guard-pipe.

Strains were measured on three gauge lines at each station, one vertical, one horizontal, and one at 45° to the other two. A measurement consisted of determining the change in the difference in elevation between two scratches, one made on the stationary or dead vertical wire fastened to the fulcrum of the bell-crank, and the other made on the moving wire attached to the long arm of the bell-crank lever. Measurements were made with a precision filar microscope, which was mounted on the top of the guard-pipe in

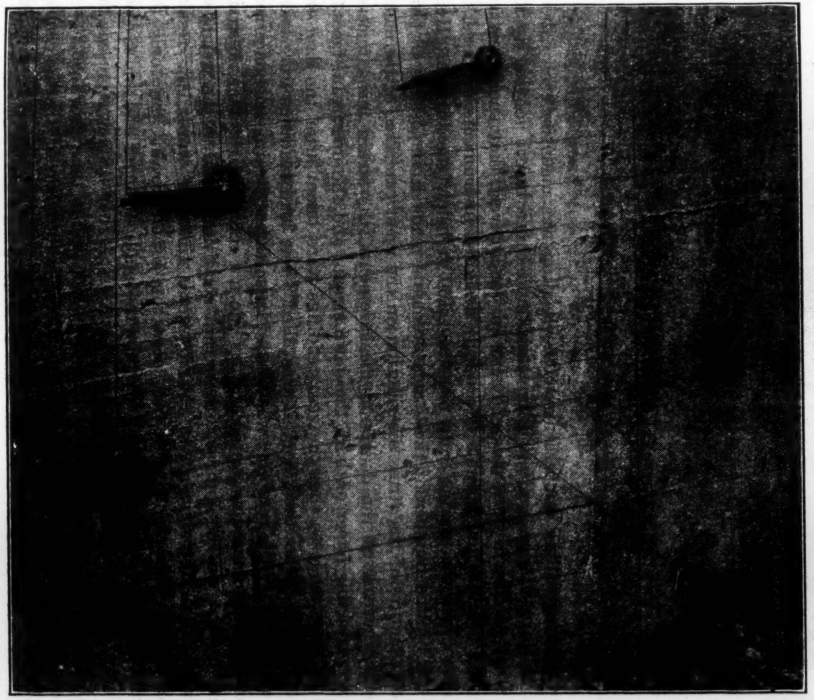

Fig. 5.—Arrangement of Pins and Levers in the Rosettes.

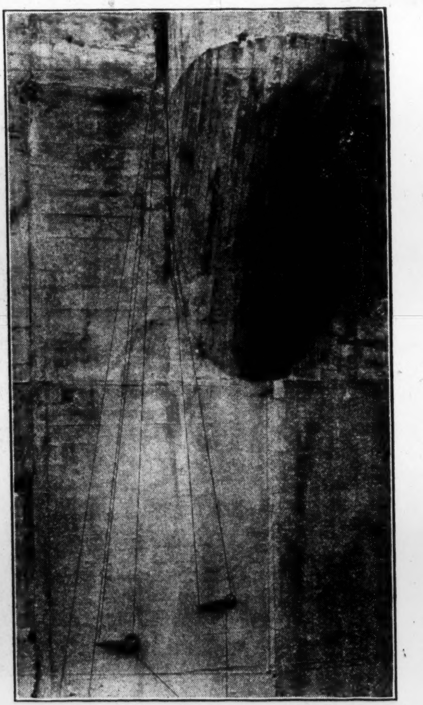

Fig. 6.—Wires Entering Guard-Pipe.

such a way that it could be focused on any pair of wires without changing the elevation of the microscope mounting. The interval of time between reading the live or moving wire and reading the dead or fixed wire was made as short as possible to eliminate any changes that might be caused from rising or falling temperature. One reading was made on each pair of wires of a rosette and repeated at least three times before moving to the next rosette. The results obtained showed conclusively that such measurements are possible and feasible if properly designed instruments are used.

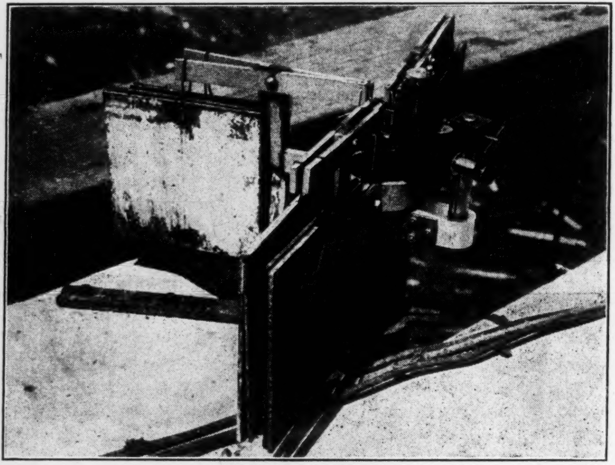

FIG. 7.—LEVER ARRANGEMENT AND MICROSCOPE MOUNTING AT THE TOP OF THE GUARD-PIPE.

In one case the strains were measured 160 ft below the surface. However, the limited number of these measurements made it impossible to form a correct picture of the stress distribution on the up-stream face of the dam.

As in the case of the deflection measurements, the strain measurements considered in this paper on both the down-stream and the up-stream faces of the dam were made so that the zero readings were taken after the dam was completed, but before the reservoir was filled. The load readings were taken immediately after the reservoir was filled. In so far as strains are concerned, the readings designated as "zero readings" do not represent the true no-strain conditions, but, on the contrary, the strain conditions, due to the weight of the concrete in the dam above the rosettes. In other words, the results of the strain measurements do not give the actual strains, but only the difference in strains which resulted from the application of the water load. Similarly, after the strains are reduced to stresses, they do not represent the actual stresses in the dam but only the difference due to the water load.

Temperature Measurements.—By means of a number of thermo-couples distributed through the prototype at different elevations and at different distances from the faces of the dam, a rather complete picture was obtained of the temperature conditions. The temperatures were recorded automatically at definite time intervals during each set of measurements. The temperature differences of the concrete during the filling period, except at the surfaces, were small and, consequently, were neglected as were the other "time effects."

MEASUREMENTS MADE ON THE MODEL

In devising the method of making measurements on the model, it was kept in mind: (1) That such measurements could be simulated, reasonably well, on the prototype; and (2) that a number of additional measurements which could not be made on the prototype could be made on the model. Three kinds of measurements were made on the model, namely, deflection, strain, and temperature measurements, and these will be discussd separately.

Deflection Measurements.—Unlike the prototype, deflection measurements on the model could be made in any desired direction, so that true deflections could be evaluated. Fig. 8 and Fig. 9 afford a clear conception of the deflection measurements. Fig. 8(*a*) shows the section of the model and prototype at the elevation corresponding to Elevation 945.0 on the prototype, and gives the correct horizontal deflections of the model. The individual blocks are numbered and the vertical construction joints are indicated. The true deflections were determined by making measurements from two reference piers, one a permanent (center) pier and the other an auxiliary (removable) pier.

The deflection of a number of points on the down-stream face of the model was determined and deflection vectors similar to Fig. 8(*b*) were drawn to an exaggerated scale in the proper direction. The end points of these vectors were connected by straight lines, thus giving a diagrammatic representation of the deflection of the down-stream face of the model. Fig. 8(*a*) shows that in the middle horizontal section of the model, where the deflections are nearly radial, those measured toward the center pier approximate, closely, the true deflections. However, toward the abutments there is an appreciable difference between the radial and the true horizontal deflections.

Fig. 9 shows the condition at Block 10. The down-stream face of this block, indicated by the heavy full line, is drawn and the corresponding elevations of the prototype are indicated. As shown in Fig 9(*a*), the true deflection of a point at the down-stream face is determined by making two deflection measurements, one horizontal and the other at an angle to the horizontal. The deflection vectors of a number of points on the down-stream face of the model are drawn to an exaggerated scale in the proper direction and the end points of these vectors are connected by straight lines.

The dotted line in Fig. 9 gives the horizontal deflections on the model; the dashed line the true deflections which can be determined, provided the vertical deflections are considered. The solid line gives the deflections as measured on the prototype, multiplied by 2.68, the theoretical ratio of the model to the prototype deflections, to make them directly comparable with the model deflections. The prototype deflections are horizontal only. Here, again, it appears that near the top of the model the difference between the hori-

zontal and the true deflections is rather small, but it increases toward the lower parts of the model. In order to maintain as true a comparison as possible, the horizontal-radial, rather than the true, deflections of the model were used for comparison with the measured deflections of the prototype.

The location of the center reference pier of the model corresponds exactly to the location of the center pier of the prototype. In determining the horizontal-radial deflections of the model, the horizontal distances were measured from this pier to different points of the down-stream face of the model.

Strain Measurements.—In making strain measurements on the model at its down-stream face, the general method used on the prototype was followed. Instead of steel inserts, eight bent metal pins were set in the model at each measuring station, in a 2-in. gauge circle. However, a compound filar microscope, supported by a special traveler, was used instead of the 10-in. Whittemore strain-gauge (see Reference (*b*)[4]). The down-stream strain-measuring stations were distributed along the entire face of the model.

Strain measurements at the up-stream face were made with specially designed strain-gauges that gave measurements simultaneously in three directions. These gauges, which were beneath the surface of the water, were read by means of a flash-light (see Reference (*b*)[4]). The up-stream stations were distributed only over one-half the up-stream face of the dam between Blocks 10 and 18.

After the model was built, the zero readings, which included the dead load stresses, were taken. The full load readings were taken after the water load was applied. In this way the measured strains represent the strain or stress decrements due to water load only and correspond to the strain measurements on the prototype.

Temperature Measurements.—As in the prototype, a number of thermocouples were distributed in the model at different distances from the faces. Due to the low thermal conductivity of the material of the model, it was comparatively simple to keep the temperature variations within such narrow limits that it was not considered necessary to introduce temperature corrections.

ADJUSTMENT OF THE MODEL

One of the factors that increases, considerably, the value of the model is its high sensitivity. Extremely slight changes in the conditions of the model produce noticeable differences in deflections and corresponding variations in strains and stresses. At the same time, the model is very stable, and loadings repeated under similar conditions result in very exact repetition of the deflection and strain measurements. The high sensitivity of the model requires that all the conditions be properly adjusted, and makes possible the study, with unusual exactness, of the different factors that influence the behavior of a dam.

The uncertainty of the deflections of the rock foundation on which the prototype rests, made it impossible to determine in advance the dimensions of the foundation of the model so that the foundation deflections in the model would correspond to those in the prototype. Consequently, it was necessary to devise some method of adjustment that would make it possible to vary the flexibility of the foundation of the model, so as to make its deflections agree with those of the prototype which contacts the foundation in two ways. In its central part the dam rests directly on the rock foundation and at the ends it contacts the abutments which, in turn, rest on the rock and re-act against it.

The model was built so that the arch proper, and its abutments, rested on a rubber-compound foundation strip of limited size, and the abutments of the prototype were reproduced to scale in the model.

The deflections and stresses developed in the prototype may be considered as due to two factors: (1) Those that were developed after the dam was completed, but before the water load was applied (these are the dead load deflections and stresses); and (2), those that were developed by application of the water load (these are the water-load deflections and stresses and are the only ones considered in this paper).

The stress measurements on the prototype showed that the abutments of the dam received only a small part of the water load so that the resulting deflection of the foundation due to such load was limited. On the contrary, in the arch section the water load influenced considerably the deflections and stresses of the foundation. Consequently, in adjusting the model it was necessary only to introduce additional flexibility in the foundation which supported the arch section, without introducing additional flexibility in the foundation of the abutments.

The next adjustments pertained to the vertical construction joints, the size of which was increased by application of horizontal jacks shown on the upper part of the model in Fig. 2. These jacks produced the necessary upstream movement of the model and a corresponding increase in width of the vertical joints. Additional adjustments were made by introducing thin plate fillers in some of the vertical joints. The extent of such adjustment was determined by a number of preliminary tests. The final zero and full load readings were taken after these jacks had been removed and all the fillers had been introduced.

Comparison Between the Behavior of the Prototype and Its Model

If all similarity conditions are fulfilled, the behavior of the prototype and its model should be in exact agreement; but if some of these conditions are violated, a disagreement in relative behavior is introduced, which will be unimportant for minor violations, but will increase as the more important conditions are violated.

Table 1 shows that in so far as the rubber compound in the model is concerned, there is a difference between the actual and theoretical values of the shear modulus and of Poisson's ratio. The difference in shear moduli is not very great; hence this violation is unimportant; but probably the difference in the Poisson ratios is of more importance. There is also some uncertainty in so far as the adjustments of the foundation and the size of construction joints are concerned. This combination of different factors makes it difficult

* Compression is negative; tension is positive.

to set up any strict criteria as to the way in which the adjustment of the model should be made. It is a step-by-step procedure in which the influence of the different factors on the behavior of the model must be studied and the combination found which gives the most satisfactory results.

Deflections.—Fig. 8(*c*) shows the comparison of the deflections of the prototype and the adjusted model and represents the developed down-stream face of the model. The elevations correspond to those of the prototype. The block numbers are shown at the lower part of the dam. The deflections measured at the down-stream face of the model are shown by dotted lines. In order to make the prototype deflections directly comparable with those of the model, they were multiplied by 2.68, which is the theoretical ratio of model to prototype deflection. The deflections of the prototype are shown by solid lines.

Fig. 8(*c*) shows that, following the procedure just indicated, the deflections of the adjusted model are in a very satisfactory agreement with those of the prototype.

Strains and Stresses.—The data pertaining to the strains and stresses in the prototype and adjusted model are given in Tables 2 and 3. (In Table 2(*a*) and Table 2(*c*) Gauge Line 1 is vertical; Gauge Line 2 is at an angle of 45°; Gauge Line 3 is horizontal; and Gauge Line 4 is at an angle of 135 degrees. In Table 2(*b*) and Table 2(*d*), *V, H,* and *S* denote vertical and horizontal stresses, and maximum shears, respectively.) Using these data, the strains and stresses in the adjusted model and the comparison between the prototype and its model may be shown by a number of diagrams, which represent the developed down-stream and up-stream faces of the model, on which are indicated the corresponding elevations of the prototype and the block numbers.

On the submerged surfaces the normal component due to direct water pressure was also taken into consideration.

The vertical stresses at the up-stream and the down-stream faces of the model are of particular interest. In many cases, tension, due to the action of water load, was superimposed on the original dead load stresses on both the up-stream and down-stream faces of the model. If the straight-line distribution of stress were correct, and if tension were superimposed on one face, compression should be superimposed on the other face. The comparison of the vertical stresses actually superimposed on both faces of the model shows that the assumption of straight-line distribution of stress is incorrect, not only at the lower elevations, but probably also at the higher elevations. This is important because often the assertion is made that the straight-line assumption does not apply at the lower elevations, but is close to the actual conditions at the higher elevations, which are influenced less by the foundations.

FIG. 12.—COMPARATIVE DIAGRAMS OF HORIZONTAL STRESSES ON CALDERWOOD DAM AT ELEVATION 900 AND ELEVATION 940.

In order to eliminate, at least partly, the discrepancies due to the different Poisson ratios, the strains in the model may be reduced to stresses by taking Poisson's ratio for the model to be 0.15, the same as in the prototype; the stresses of the prototype should be divided by 50 to have them correspond to the stresses in the model.

The agreement between the stresses is less satisfactory than in the case of the deflections. This discrepancy raises a question as to the reliability of the strain measurements. In so far as the model is concerned, it can be safely assumed that they are reasonably reliable, but the strain measurements on the prototype are somewhat doubtful. As discussed in Appendix III there is a possibility that the strains measured on the prototype are only partly due to actual stresses and partly to other phenomena. Under such conditions, a certain deviation may be expected between the actual stresses of the prototype and those evaluated from strain readings. On the other hand, this discrepancy may be due to the partial non-fulfillment of a number of similarity conditions, such as the flexibility of foundations, size of the joints, and difference in Poisson's ratios.

Figs. 11 and 12 show a comparison of the computed horizontal stresses as measured on the prototype and on its model. To construct these diagrams, the cross-sections of the prototype at Elevations 820, 860, 900, and 940 were drawn. Instead of the customary rectangular system of co-ordinates, a system of concentric circles and radial lines was used. A separate system was adopted for the stresses on the up-stream and the down-stream faces of the dam. These systems were chosen in such way that the up-stream and down-stream faces were taken as the zero lines of the corresponding stress diagrams. All prototype stresses were divided by 50 and the model stresses were computed, on the basis of Poisson's ratio of the rubber compound, to be 0.15. The resulting curves based on this assumption should be indicative at least.

The computed stresses are those used in the design of the prototype. In computing these stresses, gravity action was neglected and the design was made under the assumption that the dam consists of a number of horizontal independent arches with fixed abutments. Figs. 11 and 12 show that:

1.—The computed stresses are radically different from those measured both on the prototype and on its model. This is particularly noticeable at the down-stream face, where at the abutments the computed stresses show a maximum and the measured stresses a minimum, and *vice versa* toward the crown. These differences are most pronounced at the lower elevations where the thickness of the horizontal arches is increased toward the abutments.

2.—The curves of horizontal stress at the prototype are of particular interest since they indicate a considerable increase of stress at some of the vertical joints, which, in turn, indicates that large bending moments in the arches twist the individual blocks and produce a large concentration of stress at certain points. This increase is most pronounced at the sections which, due to the increased thickness, have horizontal arches that are very stiff at the abutments.

3.—In many cases the stress as measured on the prototype and on the model shows a fairly close numerical agreement and there is a similarity in the general shape of the stress curves.

4.—The non-uniform distribution of stress and in particular the reduction of stress toward the abutments on the prototype indicate that conditions might be improved by changing the shape of the horizontal arches.[9]

CONCLUSIONS

In order that a model study may be made to determine the behavior of a commercial arch dam, it is necessary to satisfy the major similarity conditions. The model described in this paper fulfills the most important ones and can be designated, with a considerable degree of accuracy, an engineering model. The pronounced similarity in behavior between the prototype and its model makes it possible to apply to the prototype the conclusions based on a study of the model.

The purpose of a proper design is to create a structure that is safe and economical. An arch dam, like any other structure, is safe and economical if the stresses are not only within the allowable maximum, but are uniform, and if, throughout the structure, they approach, closely, the allowable maximum stress. Too low stress at any point may indicate that the structure is not economical, and too high stress may indicate that it is unsafe. Finally, a non-uniform distribution of stress may make it necessary to reduce the average stress in order to keep the maximum stress low enough, and this may result in an uneconomical structure.

The tests on the prototype and its model show that there are a number of points where the stresses are too high and also too low, thus indicating that considerable improvement in the design of future structures can be made.

From the viewpoint of design, the following conclusions may be drawn:

(1) The foundation conditions have such influence on the behavior of an arch dam that a design which assumes a non-yielding foundation cannot satisfy the actual conditions and, therefore, is inadequate.

(2) The assumption of straight-line distribution of stress is not in agreement with actual conditions, and a design which is based on such assumption appears to be inadequate.

(3) The bending moments in the horizontal arches produce such heavy concentration of stress at some of the vertical construction joints that a design which neglects the influence of such joints and assumes a monolithic structure is inadequate.

(4) The circular shape of the conventional arch dam seems to be responsible for the non-uniformity of the horizontal stresses and introduces additional stresses which should be avoided. Presumably, this can be accomplished by substituting for the circular shape one that will better fit the conditions of the particular canyon.

(5) A design in which gravity action is neglected and all load is assumed to be taken by arch action results in a considerable and unwarranted increase in thickness of the horizontal arches at the abutments; the computed stress in such designs is radically different from the actual stress.

[9] "The Compensated Arch Dam," by A. V. Karpov, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1309; also, *Transactions*, Am. Soc. C. E., Vol 99 (1934), p. 951.

(6) Vertical tension on both faces of the dam seems to be much larger than is usually assumed. The reduction of such stress merits attention.

From the viewpoint of building and testing a model, the following conclusions may be drawn:

(7) The adopted rubber compound permits the building of a model of any dam, reproducing its geometrical shape, the foundation contours, and the construction joints.

(8) Such a model will repeat its behavior under repeated loadings.

(9) The low modulus of elasticity of the rubber compound gives the model a high degree of sensitivity, and the relatively large distortions occurring under load permit the ready measurement of deflections and strains with a high degree of accuracy.

(10) The method of measuring deflections from three references (not in a plane) gives the absolute movements of any point at which deflections are measured.

(11) The method devised for measuring strains on the up-stream face, under water, and the arrangement for measuring strains on the down-stream face proved quite satisfactory as evidenced by the exactness with which readings could be repeated.

Acknowledgments

The work described in the paper is a part of the arch dam investigation that was initiated by E. S. Fickes, M. Am. Soc. C. E., in an endeavor to put the design of such dams on a more scientific basis. The investigation was conducted by the writers, under the general direction of James W. Rickey and J. P. Growdon, Members, Am. Soc. C. E. H. N. Hill, Jun. Am. Soc. C. E., was directly responsible for the measurements made on both the prototype and the model. Recognition is also due to R. G. Sturm, Assoc. M. Am. Soc C. E., and to Messrs. C. Dumont and R. L. Moore, of the Research Staff of the Aluminum Company of America, for valuable assistance given in connection with the work.

APPENDIX I

Properties of the Prototype Material

In order to determine the proper relationship between the prototype and its model, it was necessary to secure reliable information concerning the behavior of the concrete of the prototype. The tests to determine the physical properties of this concrete were made on cylinders 2 ft. in diameter and 4 ft long, prepared as follows.

The concrete from which the specimens were made was taken from the batches that were being placed in the dam at the time of moulding the cylinders. It was dumped from the mixer into a 4-yd bucket, taken to the dam, and dumped on a flat-car, which was shifted to a side-track where the concrete was shoveled into the moulds, first removing all stone larger than 6 in. The concrete was placed in three layers, each of which was vibrated for 1½ min. Immediately after moulding, the cylinders were covered with planks to prevent excess evaporation and checking. After 18 to 24 hours, water was allowed to run over the tops of all cylinders for 14 days, the forms being stripped within 1 to 3 days. The cylinders were then allowed to weather until ready for shipment to the National Bureau of Standards, United States Department of Commerce, Washington, D. C., where they were tested.

Modulus of Elasticity.—Stress-strain determinations were made on eight cylinders to determine the modulus of elasticity of the concrete. The average results were found to be, as follows:

Stress, in pounds per square inch	Average strain, in inch per inch	Stress, in pounds per square inch	Average strain, in inch per inch
0	0.0	600	0.0001615
100	0.0000279	800	0.0002125
200	0.0000542	1 000	0.0002665
400	0.0001063		

The stress-strain curve represents a practically straight line and the modulus of elasticity of the concrete of the prototype was found to be, $E_p = 3\,770\,000$ lb per sq in.

The exceptional regularity of this stress-strain curve seems to indicate that if the average values of the moduli of elasticity are considered, the material of the prototype satisfies perfectly the similarity requirement that the material must follow Hooke's law. At the same time it leaves the impression that for stress less than 1 000 lb per sq in., a properly mixed and vibrated concrete is a much more uniform product than is usually assumed.

Poisson's Ratio and Other Factors.—The average value of Poisson's ratio of the concrete was determined and was found to be 0.15. The shear modulus was not determined, but was computed in accordance with the formula,

$$S_p = \frac{E_p}{2\,(1 + \mu_p)} \quad \text{.......................} \quad (1)$$

in which, E_p is the modulus of elasticity, and μ_p, Poisson's ratio of the concrete; and, from which, $S_p = 1\,640\,000$ lb per sq in.

The average specific gravity of the concrete was determined by weighing twenty-four test cylinders, and was found to be, $\rho_p = 2.375$. The coefficient of thermal expansion per degree Fahrenheit of the concrete was not determined, but was assumed as, $c_p = 0.000006$.

APPENDIX II

PROPERTIES OF THE MODEL MATERIAL

In securing the material for the model, it was clear from the tests that the laboratory specimens of the rubber-litharge compound satisfied the necessary requirements. The laboratory testing methods have been described elsewhere.[10] The method of testing this compound was to cut three cylinders from the material in three different directions and apply the proper tests. This gave the necessary information regarding the uniformity of the material, but such methods are not well adapted to shop inspection and are practically unknown to the rubber industry. Therefore, it was necessary to develop a method, suitable for shop inspection, which would be familiar to the manufacturers; this method should be such as would insure a much higher uniformity of material than is customary in the commercial rubber compounds.

A number of preliminary tests indicated that for the inspection of a rubber compound manufactured under definite procedure and delivered in sheets of equal thickness, "durometer" readings give a satisfactory indication as to uniformity of the material.

Consequently, the uniformity criterion was established within narrow limits of variation in thickness, specific gravity, and durometer readings. These limits were, as follows:

Specific gravity	2.38 ± 0.03
Thickness of rubber slabs, in inches	$1 \pm \frac{1}{32}$

In the total number of durometer readings:

Not less than 90% must be within ± 2% from the average reading
Not more than 10% may be within ± 3% from the average reading

Durometer readings were taken at each 4 by 4-in. square on both surfaces, and one reading at intervals of 4 in. along the edges of each slab.

After the material was received from the factory, a number of test cylinders were cut from slabs in three directions and the elastic properties were determined as described fully elsewhere.[10]

Modulus of Elasticity.—Stress-strain determinations were made on six sets of cylinders to determine the modulus of elasticity of the rubber compound. Each set consisted of three cylinders cut from the same slab. The average results of these determinations are, as follows:

Stress, in pounds per square inch	Average strain, in inch per inch	Stress, in pounds per square inch	Average strain, in inch per inch
0.0	0.00	10.25	0.01835
2.56	0.00461	12.81	0.02290
5.12	0.00921	15.37	0.02740
7.68	0.01380	17.92	0.03190

The stress-strain curve drawn from the foregoing data is practically a straight line, and the modulus of elasticity was found to be, $E_m = 563$ lb per sq in. Strain-stress curves of these data compared with those for the prototype show that in both cases the curves are straight lines within the limits of stress of the prototype and its model.

[10] "Methods for Determining the Physical Properties of Certain Rubber Compounds at Low Stresses," by R. L. Templin, M. Am. Soc. C. E., and R. G. Sturm, Assoc. M. Am. Soc. C. E., *Proceedings*, Am. Soc. for Testing Materials, Vol. 31, 1931.

Poisson's Ratio and Other Factors.—The average value of Poisson's ratio of the model material was found to be 0.5. The shear modulus was not determined, but was computed and found to be $S_m = 188$ lb per sq in. The average specific gravity of the model material was determined by a number of tests, and was found to be $\rho_m = 2.38$.

For the material of the model the coefficient of thermal expansion per degree Fahrenheit was determined by a number of tests and found to be, $c_m = 0.00008$. Specimens of the model material were soaked in water from 10 to 14 days. The increase in weight and elongation due to this increase was negligibly small.

APPENDIX III

Suggestions Based on Experience Gained During the Work on the Prototype and Model

Considerable experience, gained during the progress of the work on the prototype and its model, was applied to the investigation, but some of it was gained too late to apply directly to this work *per se*. Nevertheless, this experience is of general interest, and the following suggestions may be helpful to those who expect to carry on similar investigation.

Measurements on the Prototype

First.—Deflection Measurements.—The method used to make the measurements from a central concrete pier by means of an invar or steel tape, gives satisfactory results, but this work must be done under favorable weather conditions, preferably at night. Measurement of deflection in the direction of only one pier does not seem to be sufficient; the use of two or perhaps three piers is recommended.

There is some indication that after the water load is applied, a certain movement of the entire foundation takes place in the vicinity of the dam, so that it is essential to tie in the reference points used for deflection measurements with other points at such a distance from the dam that they cannot be influenced by movement of the foundation.

Because of the foundation movement, deflection measurements made at the lowest elevations of the dam and, perhaps of the ledge adjoining the dam, should be of considerable value.

Second.—Strain Measurements.—The generally accepted methods of strain measurement seem to give results that are much less reliable than the deflection measurements. Even if it is possible to arrange the measurements in such a way that only a comparatively short time elapses between the zero and the full load readings, the changes that take place in the concrete may influence the strain readings considerably, so that the measured strains are due partly to stress and partly to the swelling and contraction of the concrete. This is probably a particularly disturbing element during the first loading. If it were possible to load and unload the structure a number of times and take a number of zero and full load readings during the subsequent no-load and full-load conditions, this uncertainty could be removed, at least partly. Even then it is practically impossible to determine the actual stress in the concrete; probably only the stress change due to water load could be determined.

It seems necessary to devise a method by which it would be possible to determine, under any conditions, the load and zero strain readings at short time intervals. The best method would be to take a complete set of strain measurements at any desired point of the dam without the necessity of making any previous measurements under no load conditions. The method suggested for that purpose is illustrated in Fig. 13. The procedure would be as follows:

Drill at the proper places the necessary holes in the concrete of the dam and grout short steel plugs in these holes. The plugs are to be used as measuring points for the strain-gauge. Instead of drilling holes in the concrete, it might be preferable to fasten to the surface of the concrete, using proper adhesive, the required number of thin, small-diameter, pieces of metal, with suitable indentations for the gauge points. The full load readings would be made under full load conditions. Next, using suitable equipment, cut a circular groove on a diameter larger than that of the gauge-line circle. The depth of the groove would be determined by check-strain readings. When a further increase of the depth of the groove does not influence such readings the desired condition of no surfaces stresses has been obtained.

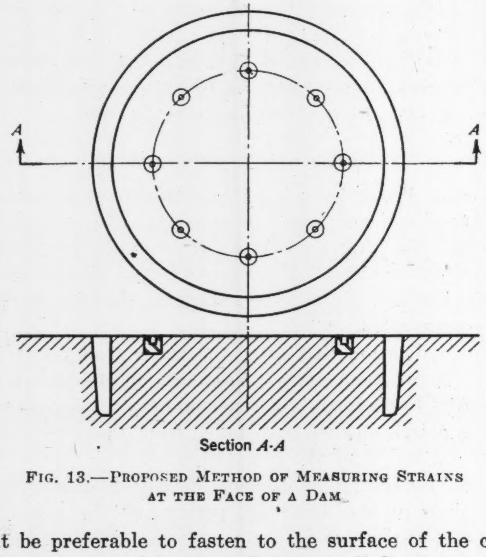

FIG. 13.—PROPOSED METHOD OF MEASURING STRAINS AT THE FACE OF A DAM

The groove thus constructed will remove all stress from the surface of the concrete within the boundaries of the groove and, in this way, the zero readings may be obtained, not only under full water-load conditions, but without being influenced by the aging of the concrete, or by temperature changes, since the time interval between the full load and no load measurements may be short. Strain measured in this way will represent more closely strain due to stress alone. If the modulus of elasticity of the concrete is unknown a test cylinder may be cut from the dam at the same time and the modulus determined in the laboratory.

It is believed that the foregoing method would make it possible to determine the actual stress at any surface point not covered with water, on any existing dam, with great accuracy.

If it is deemed advisable to make strain measurements in the usual way, much longer gauge lines are suggested, and instead of the usual 10-in. gauge line, 5-ft, or even 10-ft, gauge lines are possible and preferable. Since such long distances cannot be measured by ordinary gauges it would be necessary to devise special instruments, which could be arranged so that the readings may be made at the top of the dam. It is of utmost importance to make strain measurements on both the up-stream, water-covered face of the dam and on the down-stream face.

Model Work

The rubber-litharge compound developed for the model of the Calderwood Dam seems to be superior to any other known material, but it still has the drawback of a high value of Poisson's ratio. Future progress in model work, which is so essential for the proper design of arch and gravity dams, depends to a large extent on developing a material similar in its properties to this compound, but with a much lower value of Poisson's ratio.

In designing a model the importance of a sufficiently extended foundation strip, particularly in the horizontal direction, should not be under-estimated. Improved methods of adjusting foundation deflections seem to be important. It does not seem necessary to reproduce a large part of the canyon, but rather to provide arrangements for adjustment which will make possible the simulation of a wide range of conditions.

DISCUSSION

A. W. SIMONDS,[11] ASSOC. M. AM. SOC. C. E. (by letter).—With the construction of arch dams of heights of 200 ft, or more, in recent years the problems involving design have become of increasing importance. Any research pertaining to the action of such structures should be welcomed by members of the Engineering Profession.

Models have long been of value in studying the action of indeterminate structures, such as arch dams, arch bridges, rigid frame structures, etc., and considerable can be learned from them; but it is not sufficient to build a model of a structure and test it and then, as a result of such tests, to magnify the model fifty or one hundred times, or more, as a basis of design. There are too many uncertainties involved, and a mathematical analysis of reasonable exactness should be used as a basis for the design of such structures.

The greatest uncertainty in building a model of an arch dam is in the foundation conditions. How thick should the base be and how should the elastic properties of the base and the abutments compare with those of the model? Actual field conditions of the foundations and abutments can not be reproduced exactly. In their tests the authors state that screw-jacks were used under the foundation strip and that the model was tested under a fairly wide range of foundation conditions. What effect did a change of foundation conditions have on the action of the model? Were the deflection and the strain distribution affected materially by a change in the adjustment of the jacks? Was there sufficient material in the abutments to allow any shear deflection to occur; and what was the effect of jacking on such deflection? Having the results of observations on the Calderwood Dam available for comparison, the authors were able to select a foundation condition for the model which would furnish a close agreement between the deflections of the model and those of the dam. What were the foundation conditions that were used in obtaining the deflection curves shown in Fig. 8? If observations on the action of Calderwood Dam had not been available at the time of making the model tests, what foundation conditions would have been used in the final results of the tests?

The choice of a suitable material for a model is an uncertainty. The rubber and litharge compound is nice to work with, but the material itself is not like concrete. The high value of Poisson's ratio for this material makes it altogether different from concrete in its action, in that it deforms at constant volume. This may lead to peculiar results in tests of models built of this material, which would not be encountered in tests of models built of other materials having Poisson's ratios nearer that of concrete. For example, the writer was recently engaged in measuring the radial deflection of a model of a thick arch dam built of this rubber and litharge compound. As was customary, the deflection measurements were made at the down-stream face of the model. However, in this case, small holes had been drilled in the model and invar steel rods were anchored at the center lines of the arch elements and at the up-stream face. It was found that the deflection at the center line was somewhat greater than at the down-stream face, while the deflection at the up-stream face was about twice that at the down-stream face. This squeezing has been noted in models built of other materials, but not to such a marked extent.

---

[11] Engr., U. S. Bureau of Reclamation, Boulder, Colo.

A further investigation of the squeezing effect showed that both the foundation and the abutments deformed when the load was on the arch. Vertical deflection measurements showed that the model deflected upward at both the up-stream and the down-stream faces, the vertical deflection at the top of the model being about 20% of the horizontal radial deflection. This excessive vertical deflection actually stretched both the up-stream and down-stream faces in a vertical direction and, as a result, strain measurements indicated tensile cantilever strains on both faces simultaneously. This fact confirms the authors' statement that "in many cases, tension, due to the action of the water load, was superimposed on the original dead load stresses on both the up-stream and down-stream faces of the model." Further research by the writer involved the testing of a model of a thick arch dam composed of a compound of commercial building plaster and diatomaceous earth, a material having a Poisson's ratio of 0.20. Some squeezing was noted of the up-stream face of this model toward the down-stream face in the deflection measurements, but it was not so pronounced as in the rubber and litharge model. This was accompanied by a similar vertical deflection of the model, but it was rather small.

For partial loads, the measurements indicated tensile cantilever strains on the down-stream face. For this condition, the maximum deflection of the cantilever elements occurred below the top of the model; as the elevation of the surface of the load was increased, the maximum deflection of the cantilever elements occurred nearer the top of the model and the area of tensile cantilever strains became smaller. Finally, a point was reached at which there was no contraflexure in the cantilever deflection curves, the maximum deflection occurring at the top of the model. For this condition no tensile strains were found on the down-stream face of the model.

Apparently, the phenomenon of tension appearing simultaneously on both the up-stream and down-stream faces of the cantilever elements is found only in a material having an abnormally high Poisson's ratio. Further investigation is being made by the writer to ascertain whether models built of other materials will show tension on both faces of the cantilever elements simultaneously.

Eldred D. Smith, Jun. Am. Soc. C. E., has built and tested a model of a gravity dam composed of a compound of finishing plaster and a commercially treated diatomaceous earth having a weight of 42 lb per cu ft and a Poisson's ratio of 0.20.[12] This model was loaded with a film of mercury applied in a rubber bag. In order to secure a correct strain distribution, weights were applied to increase the unit weight to 13.6 times that of concrete. The results of the strain measurements showed that the vertical stress along the foundation line did not vary as a straight line. Above the foundation, however, this variation became less, and in the upper elevations where the model was thinner, it followed closely to a straight line. This was the result of tests of a gravity section which had no arch thrust. If a thrust had been applied the distribution of vertical stress might have been changed somewhat, but not to any great extent. In view of the results of these tests, the writer is inclined to disagree with the authors' statement that "the comparison of the vertical stresses actually superimposed on both faces of the model shows that the assumption of straight-line distribution of stress is incorrect, not only at the lower elevations, but probably also at the higher elevations."

---

[12] A Thesis by E. D. Smith, Jun. Am. Soc. C. E., at the Univ. of Colorado, in partial fulfillment of the requirements for the degree of Master of Science.

An arch dam is acted on by a complex system of forces. The water load acts normal to the up-stream face. The thrust of the arch tends to produce rib-shortening. The weight of the structure is downward. The resistance of the structure to deflection introduces couples. What effect do these forces have on an arch dam built of a material with a high Poisson's ratio, such as the rubber and litharge compound? Since rubber deforms at a constant volume, the material in the model deflects in the direction of least resistance which, in this case, is vertical. The resulting measured cantilever strains therefore, are tensile. Would this condition occur in a concrete arch dam?

The conversion of such strains to stresses is likely to lead to errors of considerable magnitude. To change the value of Poisson's ratio from 0.5 to 0.15 is not justifiable even for the purpose of comparison. This ratio is too important in the calculation of stresses as can be seen in the formulas for vertical and horizontal stress:

$$\sigma_v = \frac{E}{1 - \mu^2} (\epsilon_v + \mu \, \epsilon_h) \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

and,

$$\sigma_h = \frac{E}{1 - \mu^2} (\epsilon_h + \mu \, \epsilon_v) \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which, σ_v is the vertical stress; σ_h is the horizontal stress; ϵ_v, the measured vertical strain; ϵ_h, the measured horizontal strain; μ is Poisson's ratio; and E is the modulus of elasticity.

It has never been the fortune of the writer to build and test a model of a variable radius arch dam. In making some mathematical analyses of such dams, however, it was noticed that the maximum compressive cantilever stresses usually occurred in the lower elevations of the cantilever elements. Were the cantilever strains measured in the model of Calderwood Dam near Elevation 780 and what was their magnitude? Did the strain measurements show a concentration of stress around the closure tunnels? No indications of the strains in these locations are shown in Fig. 10. If the tunnels were effectively plugged no great concentration of stress should occur around these openings.

The chief advantage in using the rubber and litharge compound for models of dams is that strain-gauges that operate under water can be mounted on the up-stream face. It is presumed that the up-stream strains were measured with the apparatus illustrated in a previous paper[13] by the authors. What degree of precision can be expected of these strain-gauges when operating under water? It has been the writer's experience that some variation in results can be expected in regions of considerable deformation. The gauges were mounted on pins driven in the rubber. If the depth to which the pins were driven varied, a variation of measurement was encountered. Even the use of a jig in driving the pins was not altogether satisfactory as the pins had a tendency to spring up after driving.

The discussion of the properties of the model material given in Appendix II is of particular interest. On account of its excessive deformation, soft rubber is somewhat difficult to test for elastic properties. The usual apparatus found in most laboratories is not at all suitable for testing this material. The test specimens frequently present unusual problems.

In testing the rubber and litharge compound for physical characteristics, the writer has observed that it has pronounced directional properties. For compression tests, the specimens used were 6 by 6 by 12-in. rectangular prisms which were built up from slabs of 1 in. in thickness. These specimens were built up in several ways. One type was made from a single 24 by 24 by 1-in. slab. In building these specimens care was taken to keep the direction of the grain of the rubber the same in each lift. In another type, the direction of the grain of the rubber was alternated in each succeeding lift. In the third type the specimens were built of 6 by 6 by 1-in. slabs, with no attention paid to the direction of the grain of the rubber. Tension and torsion specimens consisted of 3 by 12-in. cylinders of two types, one with longitudinal and the other with transverse joints.

The results of the compression tests showed that the material had three different moduli of elasticity and six different Poisson's ratios depending on the direction of measurement. The moduli of elasticity varied from 320 to 420 lb per sq in. and Poisson's ratio from 0.38 to 0.64. The results of the tension tests disclosed that the moduli of elasticity of the different types of specimens varied from 350 to 395 lb per sq in. and Poisson's ratios from 0.39 to 0.51. In torsion tests, the shearing modulus varied from 120 to 140 lb per sq in. These values were obtained after correcting for the change in dimensions of the specimen for both strain and stress. The coefficient of thermal expansion per degree Fahrenheit was not constant but varied with the temperature at which the tests were made. It varied from 0.000065 to 0.000078 which is slightly less than the value obtained by the authors.

From these tests it was found that the average value of Poisson's ratio for any one specimen was about 0.5. In some cases, however, it was slightly greater, in one case being as much as 0.544. The writer is fully aware of the fact that for a truly isotropic material a value of Poisson's ratio greater than 0.5 indicates an increase in volume under a uniform pressure which is not possible. According to Karl Pearson[14] and St. Venant[15] it is possible for a non-isotropic material to increase in volume when subjected to pressure. An increase in volume of soft rubber compounds in compression tests has been noted by R. Ariano.[16]

---

[13] "Building and Testing an Arch Dam Model," *Civil Engineering*, January, 1932, p. 11.

Whether the value of Poisson's ratio is 0.5, or slightly greater than 0.5, is not of material consequence and should not reflect on the manner of making the tests for physical properties. Either value should serve as a warning that soft rubber is materially different from concrete and that the conversion of strains measured on soft rubber to predicted stresses in concrete is questionable.

LARS R. JORGENSEN,[17] M. AM. SOC. C. E. (by letter).—A most interesting account of the most unusual performance of a model of an arch dam and the prototype is contained in this paper. The stresses given in Table 2 for the Calderwood Dam and its model are amazing, since they differ greatly from what would ordinarily be expected especially for the prototype.

On the Calderwood Dam there is 20 ft of water on top of the overflow crest, held back by Stoney gates and, therefore, the arch is heavily loaded from the very crest. The stress sheet shows vertical tension on the down-stream face of the dam for the upper 100 ft, with a maximum of 348 lb per sq in. at Elevation 860, and 295 lb at Elevation 840, Block 10, where considerable compression would always be expected. There could be zero vertical surface stress in the down-stream face of the Calderwood Dam and the cantilever would still be capable of supporting some load on the up-stream face. In such a case the horizontal shear would have a parabolic distribution in the triangular cross-section in which the apex was approximately at the maximum water level. The vertical surface stress being high in tension, however, the cantilever action has evidently been reversed from that which is usually expected and the arch, therefore, will be required to carry all the water load, in addition to giving an up-stream push to the cantilever, or holding it from deflecting down stream as much as it would otherwise.

The arches presumably must carry more than their design load, and, nevertheless, develop horizontal arch stresses less than those calculated (except at Elevations 860 to 840 at the down-stream face at the crown, where tensions of 117 and 196 lb per sq in. are shown to exist), and a somewhat higher compression in Block 6, Elevation 860, than was anticipated.

At the abutments the stresses are much less than those calculated, and it appears as if the abutment stresses had been transferred to the points of contraflexure by the action of punching shear, or in some other manner. That the horizontal arch stresses in general are less than those calculated might indicate a better stress distribution than a straight-line variation but it is difficult to explain why the horizontal arch stresses should be so much less at the abutments than farther out on the arch, near the points of contraflexure.

[16] "The Resistance of Rubber to Compression," by R. Ariano, *The India Rubber Journal*, August 11, 1928, p. 8.

[17] Cons. Hydro-Elec. Engr., Berkeley, Calif.

The maximum arch stresses are not horizontal, as shown in Fig. 10, but meet the abutments at an angle with the horizontal, as would be expected and, therefore, are not given directly in Table 2. The difference between the measured horizontal arch stresses and the calculated or anticipated arch stresses at the abutments is so large, however, that it can not be explained thereby.

The greatest departure from what would ordinarily be expected is that the cantilevers instead of helping to carry the load, apparently act in the opposite direction practically from the crest of the dam to about 30 ft above the river bottom. Presumably, they must be held back by the arch. If the deflection of an arch dam under load can be kept small by efficient grouting while low temperatures prevail in the structure, the dam can be considered almost monolithic and this should always be the aim.

The contraction joints of the Calderwood Dam were grouted but, being a diversion dam, from which it is impossible to remove the load after the structure has taken its permanent set and has cooled off, the grouting could only be, say, 50% effective. Many dams are in the same class, and one has to be contented with the best possible grouting under the circumstances. Nevertheless, the fact that there was less than 100% efficiency in grouting does not explain the peculiar cantilever action of this dam. The writer will be much interested in future check measurements on account of the unexpected behavior of this dam. When the plans were made, the design was regarded as good and the action disclosed by Table 2 was not anticipated.

Cutting the arch into narrow voussoirs, which will adjust themselves under load relative to each other, will most likely produce an ideal arch; that is, an arch that will carry a greater proportion of the total load as pure arch action without bending, than any other kind,[18] but the question arises, whether it is not more practical to keep the individual voussoirs not less than, say, 30 ft long and take advantage of about 50% of the shearing strength of the concrete, as well as the smaller number of joint details. In the Calderwood Dam the shear stresses seem to be the dominating load carriers at the abutments.

Castigliano[19] has shown that it was possible in a certain arch bridge to reduce the maximum stress from 61 kg per sq cm to 41 kg per sq cm at the abutments by using mortar of a much lower modulus of elasticity (100 times) than that of the granite voussoirs between 11 voussoirs at the abutments and 10 at the crown (of a total of 48). He had the thickness of the mortar wedge-shaped, with the larger thickness in the heavy compression zone as did Mr. Karpov in a previous paper.[20]

Castigliano's calculations have led the writer to experiment with a grout mixture consisting of plaster of Paris and Portland cement, which, when setting, is practically without volume change and is quite plastic especially at first. Therefore, it has a tendency to flow from places of higher stress to places of lower stress, as the load increases on the structure. The plaster of

[19] "Elastic Stresses in Structures," tr. by Ewart S. Andrews, Lond., 1919, p. 357.

[20] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), Fig. 8(*a*), p. 1328.

Paris crystallizes faster than the cement hydrates and takes most of the mixing water. Later, the cement finishes hydration by means of capillary action some time after the water covers the up-stream face of the dam, and the grout gets some elastic properties, or it may deteriorate, in which case it expands. The grout is between two water-stops and several recesses on the face of the contraction joint wall and can not escape no matter how plastic it is.

The authors' Conclusion (5) is that "a design in which gravity action is neglected * * * results in a considerable and unwarranted increase in thickness of the horizontal arches at the abutments." The purpose for which the thickness is increased at the abutments at lower elevations does not require this increase in thickness to be extended entirely to the middle of the dam; it can generally be tapered toward the points of contraflexure and does not require so much material. It may look better architecturally to taper this added thickness gradually from a maximum at the abutments to zero in the middle of the dam at the down-stream face, as was done on the Calderwood Dam. According to Table 2, the arch stresses in the Calderwood Dam do not increase as expected from the points of contraflexure toward the abutments, the abutments having, so to speak, been moved to the points of contraflexure. This is a rather strange performance, but still more unexplainable is the phenomenon that the cantilever action (also according to Table 2) is opposite to that which has always been assumed. This is difficult to understand and, therefore, still more difficult to take care of in a design. Such a vertical tension as 348 lb per sq in. at Elevation 860 in the down-stream face of the Calderwood Dam, the writer can scarcely comprehend.

It is true, that when an arch dam is designed by dimensioning each horizontal arch slice separately, an approximation is made by assuming that individual slices can slide relative to each other. It seems that this assumption should be on the side of safety, and this is important for an uncertain problem. The shearing strength between the imaginary slices would make possible a transfer of stress from high to low points, compensating for some irrigularities of the canyon sides. The radial shear stresses are greatest at the abutments and this may warrant increasing the thickness for that reason alone. These shear stresses can not be measured or, at least, have not been measured. It seems reasonable to conclude that to widen the contact area between the structure and the rock foundation by thickening the dam in the joint zone, would be material well spent, serving as a "filler" between the structure and the infinite base.

It is surprising to find the measured arch stresses generally less than the calculated arch stresses inasmuch as the cantilever stresses evidently are opposite to what they were assumed. The designers of the Calderwood Dam did not plan the cantilever to help the arch carry the water load; it was not suspected, however, that the arch would have to carry extra load because the cantilever leaned back on it. This is a rather startling discovery if it is actually the case.

Additional measurements on the Calderwood Dam are most desirable in order to clear up several doubtful points. It seems entirely unreasonable, for instance, that a cantilever subject to bending one way or the other should have tension in both faces at the same time, or even that it should have extensive tension in the down-stream face at any time when loaded.

The writer has always believed that an arch dam should be designed so as to carry all the load with a reasonable margin of safety. Unless theory and experiments agree better than they have in the past, it is not on the safe side to "skin" the arch by assuming or figuring that the cantilever will support part of the load. The paper does not inspire confidence in the prediction of accurate actual stresses by means of calculation.

A. C. Janni,[21] M. Am. Soc. C. E. (by letter).—The care with which these tests were conducted, has produced results that deserve the attention of the profession. The writer has called attention,[22] in a general way, to the principal uncertainties attending the analysis of an arch dam, and these uncertainties seem to be confirmed, once more, by the tests and conclusions described in this paper.

The trouble is neither with the designer, nor his method of analysis; but with the assumptions he is compelled to make, and which he knows are not correct. Indeed, some of the assumptions are entirely contrary to the laws of equilibrium. Consequently, the results obtained by analysis, including the uncertainties that creep in with questionable assumptions, render them illusory, to a great extent.

The paper is concerned with measurements of the deformation of a rubber litharge model of Calderwood Dam, caused by hydrostatic pressure. From these measurements the authors reach the conclusion that the stresses that actually occur in arch dams are not the same as those determined by theory. The writer is in agreement with this conclusion. One of the reasons for this difference is that theory takes temperature effects into consideration, which cannot be measured by tests, because they do not deform the structure.

Every engineer knows that the stresses caused by temperature change in an arch dam are often more important than those due to the hydrostatic pressure. Dams are exposed to the most sudden and violent changes of temperature, and this fact is due to their location. For example, in a mountainous region, where dams are usually built, a sudden and important temperature change can occur almost over-night. Then the dam will have its down-stream face exposed to the surrounding temperature of the air, whereas its up-stream face is in contact with a body of water the temperature of which is quite different from that of the air. In other words, while the up-stream face of the dam has a temperature of about 32° F, the down-stream face may have a temperature of, say, − 20° F. Every engineer can realize the unfavorable condition to which a concrete structure is subjected, when such temperature drops occur (as they often do).

Furthermore, the law of temperature transmission, in large masses of concrete, is not known, and this adds still more uncertainty to the analysis of temperature stresses. Assume, for example, that the temperature is the same for the entire structure, and that it is known. Although this assumption is almost certain never to occur, it will be made here, to simplify the argument.

---

[21] Cons. Engr., New York, N. Y.

[22] "A New Type of Dam," by A. C. Janni, M. Am. Soc. C. E., *Proceedings*, Am. Concrete Inst., December, 1933.

Let t_e be the change of temperature at the extrados and t_i that at the intrados of the elemental arch of the dam. As a further simplification, assume that the law of transmission of temperature from the intrados to the extrados, or *vice versa,* is a linear one. (The latter assumption is known to be incorrect as applied to large masses of concrete.)

The static effect caused by a change in temperature may be considered as the algebraic summation of that caused by a uniform change, $\frac{1}{2}(t_e + t_2) = t_0$, plus that caused by a change, $\frac{1}{2}(t_e - t_i)$, at the extrados, and $-\frac{1}{2}(t_e - t_i)$, at the intrados. Assume that both t_e and t_i represent a temperature increase and that $t_e > t_i$. Let *AB,* in Fig. 14, be the elemental arch of the dam, and *CDEF* (Fig. 15), a voussoir of it. If End *A* were free, Section *CE* would take the position, $C_1 E_1$, after the arch expands, because $CC_1 = c\ t_e\ \Delta s$ and $EE_1 = c\ t_i\ \Delta s$. This total deformation consists of a displacement of the section, *CE,* to $C_2 E_2$, *CE* and $C_2 E_2$ being parallel (caused by the uniform change of temperature, $\frac{1}{2}(t_e + t_i) = t_0$, and by a rotation, $d\ (\Delta\phi)$), bringing the section, $C_2 E_2$, into the position, $C_1 E_1$, which is given by:[23]

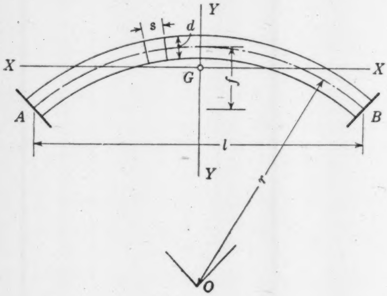

FIG. 14.

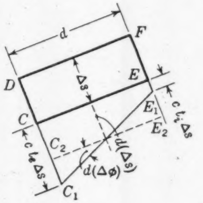

FIG. 15.

$$d\ (\Delta\phi)\ \frac{c\ (t_e - t_i)\ \Delta s}{d} = \frac{c\ \Delta t\ \Delta s}{d} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The first deformation (to $C_2 E_2$) would cause a displacement of *A* (Fig. 14) to the left, an amount equal to $c\ \frac{t_e + t_i}{2}\ l = c\ t_0\ l$.

However, End *A* of the arch is fixed and, therefore, there will be a reaction at that abutment of the same nature as that caused by the hydrostatic pressure. In other words, since Point *A* will not rotate, the reaction at that abutment will act along the *X*-axis and to the right (Point *G* being at the elastic center of the arch). The value of that reaction will be, $H_t = \frac{c\ t_0\ l}{I_x}$, which, after some substitutions and transformations, becomes: $H_t = E\ c\ t_0 \dfrac{d^3}{6\ \delta\ r^2}$, in which, all the letters have the usual meanings, and,

---

[23] "Statica delle dighe per Laghi Artificiali," by C. Guidi.

$$\delta = \frac{s}{l} + \frac{r - f}{r} - \frac{2\ l}{s} + \frac{d^2}{6\ r^2}\left(2\ \frac{s}{l} - \frac{r - f}{r}\right)$$

Concerning the second part of the deformation, it is observed that if End A were free, then it, together with the elastic center, G (assumed to be rigidly connected with A), would rotate through an angle given by Equation (4), when that equation is extended to the entire arch, that is: $\Delta\phi = c\ \Delta t\ \Sigma\ \dfrac{\Delta s}{d}$.

At the same time, Center G would be displaced in a direction, the components of which, along the X and Y-axes, respectively, are:

$$\Delta x = c\ \Delta t\ \Sigma\ \frac{\Delta s}{d}\ y \text{ ....} (5)$$

and,

$$\Delta y = c\ \Delta t\ \Sigma\ \frac{\Delta s}{d}\ x \text{ ....} (6)$$

Since d is constant for the entire arch, the center of gravity of the arch will coincide with the elastic center, G (center of gravity of the elastic weights of the entire arch). In fact, the elastic weight of an element of the arch is given by $dG = \dfrac{ds}{E\,I}$, in which, $I = \dfrac{1}{12} \times 1 \times d^3$ = a constant; therefore, dG is proportional to ds; and the two centers of gravity of the arch will coincide. Because of this fact, Equations (5) and (6) will give:

$$\Sigma y\ \Delta s = \Sigma x\ (\Delta s) = 0 \text{ ....} (7)$$

and,

$$\Delta y = \Delta s = 0 \text{ ....} (8)$$

Equation (8) reveals that, during the second part of the deformation of the arch to $C_1\ E_1$ (Fig. 15), if End A were not fixed, it would rotate about the elastic center, G. However, End A is fixed and, therefore, it will develop a reaction which, according to the theory of the ellipse of elasticity, will be a force infinitely small and infinitely far from Abutment A; that is, a couple, M. Since, according to the theory of the ellipse of elasticity, $\Delta\phi$ is always equal to $G\ M$, the rotation will be given by:

$$M = E\ \frac{\Sigma d\ (\Delta\phi)}{\displaystyle\sum \frac{\Delta s}{I}} \text{ ....} (9)$$

In the presence of Equation (4), with d constant:

$$M = \frac{E\,I\,c\;\Delta t\;\Sigma\,(\Delta s)}{d\;\Sigma\,(\Delta s)} = \frac{E\,I\,c\;\Delta t}{d}$$

but, since $I = \dfrac{d^3}{12}$:

$$M = \frac{E\,c\;\Delta t}{12}\,d^2 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Thus far, this discussion has been concerned with an analysis of stresses due to a temperature change as it applies to the conclusions offered by Messrs. Karpov and Templin. Next, consider the nature of the deformation caused by the foregoing temperature stresses.

As stated previously, the effect upon the dam of that part of change in temperature, which has been considered as uniform (to $C_2\,E_2$, in Fig. 15), is perfectly similar to the effect upon the dam caused by hydrostatic pressure. As in the latter case, the unit shortening of the geometrical axis of the arch is given by $\dfrac{p\,r}{E\,d}$, in which, p = hydrostatic pressure, and r = radius, so, in the case of a uniform change in temperature, t_0, the same axis will be translated a unit distance, caused by $\pm\, c\, t_0$.

Therefore, if the equation for the deflection of the crown of the elemental arch of the dam, caused by hydrostatic pressure, is:[24]

$$\Delta f_p = \frac{p}{E}\,\frac{r}{d}\,f\left\{1 + \frac{1}{\delta}\left[2\,\frac{l}{s} - \frac{l^2}{4\,f\,r}\left(1 - \frac{d^2}{6\,r^2}\right)\right]\right\} \ldots\ldots (11)$$

and if $c\;t_0$ is substituted for $\dfrac{p\,r}{E\,d}$, the final result will be:

$$\Delta f_t = \Delta f_p\,\frac{E\,c\;t_0\,d}{p\,r} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

which is the formula for the vertical deflection of the crown of the arch, caused by the uniform change in temperature.

For the second part of the deformation (to $C_1\,E_1$, in Fig. 15), the deflection of the crown of the arch is zero. In fact, imagining, again, that End A of the arch is free, the two sections, CE and DF (Fig. 15), would rotate, with respect to each other, at an angle, $d\;(\Delta\phi)$, as given in Equation (4); but End A is fixed, which creates a couple that acts upon every element of the arch; and the value of its moment is given by Equation (10). Furthermore, the rotation of the two sections, CE and DF, is given by:

$$d(\Delta\phi) = \frac{M}{E\,I}\,\Delta s = \frac{\dfrac{E\,c\;\Delta t\;d^2}{12}}{E\,\dfrac{d^3}{12}}\,\Delta s = \frac{c\;\Delta t\;\Delta s}{d}$$

which expression coincides with Equation (4), and demonstrates that the elastic deformation caused by the reaction at End A is equal and opposite to the thermal deformation. This fact is very important because it demonstrates that, although stresses are developed, the geometrical axis of the arch does not deform.

Obviously, models are useless for the determination of these last stresses; on the other hand, while theory shows that those stresses may be very important, the assumptions upon which the theory is based are known to be uncertain. At first, this phenomenon may appear inconsistent; but if a cube of concrete is imagined as held firmly between the plates of a compression machine, and if by some means the temperature of the cube is increased, the concrete is then known to be subjected to considerable compression, whereas its height is not changed.

By their conclusions, the authors have given an additional warning to the profession; and they have made a worthy contribution to the literature on dams.

P. Wilhelm Werner,[24] Assoc. M. Am. Soc. C. E. (by letter).—Many important points pertaining to the design and construction of high dams, and to the application of tests on models of such dams are contained in this paper. Under "Measurements Made on the Model (Temperature Measurements)", the authors state that for the model "it was comparatively simple to keep the temperature variations within such narrow limits that it was not considered necessary to introduce temperature corrections." Referring to Similarity Condition 8,

$$T_m = T_p \frac{c_p}{c_m} \qquad \text{.......................(13)}$$

it would be of value to know in what manner the temperature difference, T_m, for the model was, and, for future measurements, will be, controlled in the special case under consideration. Even if it may be fairly safe to conclude that the coefficients, c_p and c_m, are sufficiently uniform to be assumed constant, it seems rather difficult to make the temperature difference, T_m, comply with Equation (13) at a sufficient number of points, when considering the irregular distribution of temperatures that occurs in a structure the size of the prototype. Because of the different thermal conductivity, and probably also, the different emissivity, of the materials in the prototype and the model, it would scarcely prove adequate to control only the temperatures of the media surrounding the model.

For a prospective dam there would appear a further complication in that the distribution of the temperatures in the prototype is not known beforehand. This latter obstacle, however, will probably be overcome in the future through the knowledge obtained by the increasing number of temperature measurements on existing dams and on dams in course of construction.

Similarity Condition 8 will be of importance especially when it comes to determining the effect of the progressive dissipation of the chemical heat in the concrete, and of the changes in the climatic conditions. It is well known (although probably not always fully realized even in the most modern dam designs) that an irregular distribution of the temperature may have a marked influence on, and may even be the dominating factor in, the elastic behavior and stress conditions of a structure of the type in question.

---

[24] Civ. Engr., Stockholm, Sweden.

The state of stress in an arch dam due to an irregular distribution of the temperature is very complex in its nature. The behavior of an elementary arch subjected to a differential temperature with a linear distribution between the faces has been referred to elsewhere.[25] Another aspect of the problem is demonstrated in Fig. 16, representing a vertical element of an arch dam with triangular cross-section. Assume that, with the mean temperature kept constant, a certain difference in temperature (ΔT) is introduced between the up-stream and down-stream fibers. (Note that this is not the same as the difference in temperature between the media surrounding the dam, as there will be a drop in temperature also along the contact surfaces between the media and the dam as shown in Fig. 16(*b*)). Whatever the law of transmission of temperature between the up-stream and down-stream fibers may be, it is evident that the difference in temperature will cause a tilting of the cantilever. If $\Delta T < 0$, that is, if the up-stream fiber is cooler than the down-stream fiber, the tilting will be in the up-stream direction, which means that the horizontal arches will be stressed in tension and, probably, the vertical joints open up (if they are not already open). This, in turn, means that the cantilevers will be required to carry a still greater part of the load than otherwise, before the arches take any load. Theoretical considerations, based on some simplifying assumptions as regards the distribution of temperature, will show that this condition may be of great importance in practical cases.

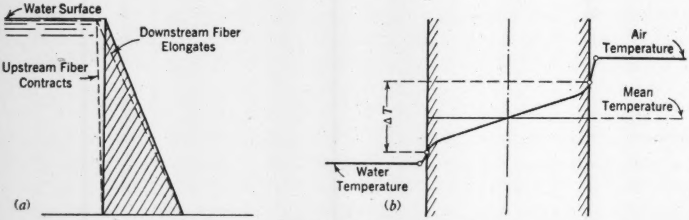

FIG. 16.

When analyzing the results of the measurements on the prototype, it is well to remember the uniform and ordinary elastic properties of the concrete used (see Appendix I of the paper). That the cantilevers in an arch dam built of this material should have tension on both sides simultaneously, due to water load, is very improbable. On the other hand, it is quite possible that an irregular distribution of the temperature, or irregular volumetric changes due to shrinkage, etc., may cause tensile stresses on both sides of a cantilever simultaneously, and these stresses may be of such magnitude that they will outweigh those due to water load and dead load.

---

[25] "Die Staumauern", by N. Kelen, Berlin, 1926.

As far as the writer is aware, the phenomenon of tensile stresses occurring simultaneously on both sides of the cantilever was definitely observed by the authors for the model only. In this case, the question enters as to whether an irregular distribution of the temperature was responsible to some degree for the unexpected results of the measurements. If, on the other hand, the explanation should lie wholly with some peculiar elastic or plastic properties of the model material, then the results obtained when using this material for model study of arch dams may be questioned. This point is of considerable importance, and it would seem desirable that the authors make an attempt to present some theoretical analysis for the explanation of the phenomenon.

That the cantilevers in a concrete arch dam should have excessive tension on the down-stream face due to water load, may also seem unusual and is considered unreasonable by some engineers. In the writer's opinion, however, this condition does not seem impossible although the magnitude of the tensile stresses found experimentally by the authors is rather startling. The so-called cantilever stresses may be looked upon as bending stresses in vertical beams which are supported by an elastic medium constituted by the horizontal arches. It is easily conceivable that under certain conditions contraflexure may occur in the upper parts of the beams. This may be elucidated by another loading case, which is similar in principle, but which is much simpler and, therefore, much more easily and clearly realized than an arch dam. Such a loading case is shown in Fig. 17(*a*), representing a cylindrical vessel subjected to hydrostatic pressure.

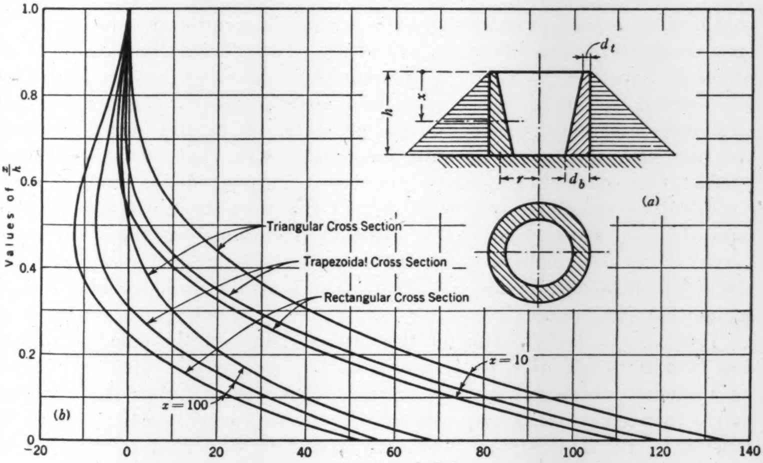

Fig. 17.—Cantilever Bending Moments in a Cylindrical Vessel Subjected to Hydrostatic Pressure, $M_x = a\ F(x)\ h^3$.

The upper edge of the vessel is free like the crest of the arch dam, whereas the lower edge is entirely fixed so as to make the cantilever action more pronounced. Evidently, cantilever tensile stresses on the inner side of this vessel could not be expected any more than on the down-stream face of an arch dam. Nevertheless, it is easily shown that such stresses may occur in the vessel under certain conditions.

The problem of finding the stresses in the cylindrical vessel (bending in the vertical cantilevers and direct stress in the horizontal arches) may be solved, with sufficient accuracy, by a method developed by Dr.-Ing. Th. Pöschl[26], and based on the principle of least work. Pöschl shows that the elastic behavior of the cylindrical vessel is dependent to a considerable degree upon a dimensionless quantity:

$$\kappa = \frac{12\,h^4\,(1 - \mu^2)}{r^2\,d_b^2} \quad \dots\dots\dots\dots\dots\dots\dots\dots (14)$$

in which (see Fig. 17(a)), h = the height of the vessel; r, the mean radius of the vessel; d_b, the wall thickness at the bottom of the vessel; and μ, Poisson's ratio.

The bending moment in the cantilevers may be written,

$$M_x = a\,F(x)\,h^3 \dots\dots\dots\dots\dots\dots\dots\dots (15)$$

in which, a is a constant and $F(x)$ is a function of x. This function has been determined by Pöschl for triangular, trapezoidal ($d_t = 0.5\,d_b$,) and rectangular cross-sections, and is graphically represented in Fig. 17(b) for $\kappa = 10$ and $\kappa = 100$.

Fig. 17 is interesting inasmuch as it shows that, under certain conditions, considerable positive moments may occur in the cantilever, causing extensive tensile stresses on the inner face of the vessel. The writer is fully aware of the fact that the arch dam is different from the vessel in that the former has bending moments in the horizontal arches, whereas the latter has no such moments; but, nevertheless, the character of an arch dam (especially the part near the crown) is quite comparable with that of the cylindrical vessel. Consequently it would seem rather natural, under similar conditions, to find cantilever tensile stresses at the down-stream face of an arch dam due to water load. The general dimensions of the Calderwood (arch) Dam also imply that a minute analysis of the dam would probably show this tendency, under the assumption that the dam would act as a monolithic structure.

However, as the grouting of the vertical joints in the dam probably is less than 100% effective, it is scarcely to be expected that the dam will act as a monolithic structure. The vertical elements will then, to a greater extent than otherwise, act as true cantilevers, with compression or decreased tension on the down-stream side, and tension or decreased compression on the up-stream side. A yielding foundation under the base of the dam would probably have the reverse effect, and thereby would cause an increase in the tensile stresses on the down-stream side. The relative effect of these two factors depends, of course, upon local conditions.

---

[26] "Armierter Beton", by Th. Pöschl, Berlin, 1912, p. 169.

As indicated in the foregoing discussion, the stress distribution may also have been influenced by other factors, namely, temperature changes, swelling, shrinkage, etc. The authors state, that all time effects were excluded from the investigations. In this connection it would be of interest to know more exactly the relative dates of the closing of the dam, the filling of the reservoir, the taking of measurements, and the temperature variations during these periods.

In Appendix I, the authors state that the material in the proto ype follows Hooke's law very closely and that it gives the impression of being a very uniform product. Under these conditions the distribution of the stresses could not depart very much from a straight line in the upper part of a triangular element loaded with hydrostatic pressure up to the crest. However, in the cantilevers of an arch dam there are several factors that will cause a redistribution of the stresses: The cross-section may not be exactly triangular; the distribution of the part of the load taken by the cantilevers will be far from the shape of the hydrostatic pressure; etc. The effect of these factors is difficult to determine; but they are of minor importance when the apex angle of the cross-section is comparatively small, so that the "depth" of the cantilevers (base width of dam) can be considered as small in relation to its "span" (height of dam) at any given elevation. In view of this the writer believes that for the upper parts of the Calderwood Dam the assumption of a straight-line distribution of stresses, due to water load, would not involve great uncertainties and, in any case, would cause far less discrepancies between actual and calculated stresses than, for instance, disregarding the stresses due to an irregular distribution of the temperatures.

ELDRED D. SMITH,[27] JUN. AM. SOC. C. E. (by letter).—A clear and concise statement of the similarity conditions involved in the problem of arch dam model analysis is presented in this paper. It is apparent that the authors are attempting to make a model test by which the action of the prototype can be predicted from the action of the model by applying a single factor of conversion. In attaining this result, it was necessary to violate some of the similarity conditions in order to satisfy others, which may have considerable effect on the final similarity of their results.

In their similarity conditions, the authors state (and go to considerable pains to prove) that the specific gravity of the model and its loading liquid must be in the same proportion as in the prototype. In other words, for a water loading, the specific gravity of the model must be 2.4. However, the manner in which this much emphasized property is used is rather obscure. Their results contain no reference to dead load stresses or deflections which are the only stresses or deflections affected by the specific gravity of the structure. Theoretically, this specific gravity requirement is quite desirable, but in order to utilize it, it presupposes the ability to measure simultaneously the dead load strains along with the live load strains as a single quantity. If this cannot be done the advantage of the specific gravity requirement is lost.

---

[27] Care, U. S. Bureau of Reclamation, Denver, Colo.

In proving the specific gravity requirement the authors state a condition of the principle of superposition:

> "Any increase or decrease in the loading will cause a proportional increase or decrease of the stresses and deflections, provided the deflections are sufficiently small."

The principle in general states that: "The resultant effect of all forces acting on a structure is equal to the sum of the component effects of each force." If the first-named condition holds, the stresses and deflections produced in a structure by a given system of forces, is independent of the stresses and deflections produced by another set of forces. To illustrate, consider the section of a dam as shown in Fig. 18 (not drawn to scale), in which, W = the water load and D, the weight of the dam.

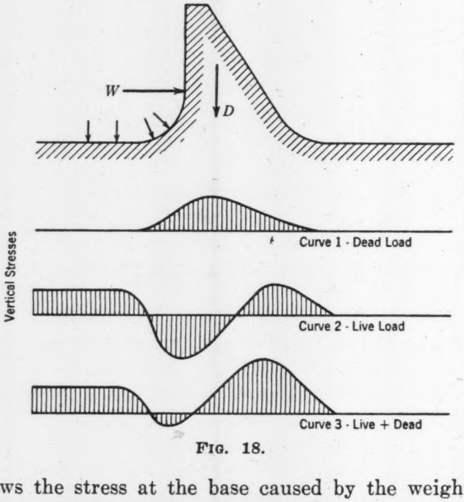

FIG. 18.

Curve 1 shows the stress at the base caused by the weight of the structure; Curve 2 shows the stress at the base produced by hydrostatic pressure; and Curve 3 shows the resultant stress, which is the sum of Curves 1 and 2. Curve 1 and Curve 2 are absolutely independent if the condition of superposition holds. Therefore, the stress distribution due to the water load on the structure is independent of the specific gravity of the material in the structure.

This fact has been proved by three separate experimental investigations of gravity dams on which the writer has been engaged. The models were made of a very light-weight material, but by properly distributed external loads, the equivalent specific gravity was increased to 2.4 × 13.6, or 32.64. The live load liquid was mercury, with a specific gravity of 13.6, so that the specified ratio of specific gravities was maintained. In each of these studies, the effect of the mercury pressure on the structure was the same, whether or not the dead loads were applied. In these tests it was possible to measure the effect due to dead load only, to live load only, and to the combined live and dead loads. Naturally, if the total stress only is to be measured, the theoretical proportion between live load and specific gravity of the structure should be maintained; but, if the dead load stress can be measured as a separate quantity, and the live load as a separate quantity, the experimenter will have considerable latitude in the selection of his model materials, providing the similarity of the elastic properties is maintained.

Consider a model arch dam of a scale, $R = \frac{1}{60}$, with reference to the prototype. The model to be used to predict the stresses in the prototype has a specific gravity of 2.4 and will be loaded with water. All other similarity conditions are assumed to be fulfilled. The ratio of stresses between model and prototype for dead load stresses will be:

$$\frac{1}{R} \times \frac{\rho_p}{\rho_m} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which, ρ_p and ρ_m are the specific gravities of the prototype and model, respectively. Equation (16) with the specific gravities of the loading liquids substituted, will give the ratio for the live load stresses. Assume that strains can be measured from a zero or weightless condition (this involves many practical difficulties) so that both dead load and live load strains can be obtained. At a certain point assume that the strain measurements indicate a compressive stress due to dead load only of 10 lb per sq in. and a tensile stress due to live load only of 5 lb per sq in. The stresses in the prototype predicted from these measurements, applying Equation (16) to the model stresses, will be:

$$\text{Dead load} = 10 \times \frac{1}{R} \times \frac{\rho_p}{\rho_m} = 10 \times 60 \times \frac{2.4}{2.4} = 600 \text{ lb per sq in.}$$

and,

$$\text{Live load} = -5 \times 60 \times \frac{1}{1} = -300 \text{ lb per sq in.}$$

This gives a resultant total stress of 300 lb per sq in., compression.

Next, consider the same scale model as before, but loaded with mercury of a specific gravity of 13.6 and, in order to change the proportionality of weights of dam and loading, the material may have a specific gravity of 1.2, or one-half that of concrete. For the same point under consideration, by applying the principle of superposition, the dead load stress in the model will be one-half the previous value, or 5 lb per sq in., compression. By the same token, the live load stress must be 13.6 times that obtained before, or $5 \times 13.6 = 68$ lb per sq in., tension. These stresses will now be referred to the prototype, using the new constants of specific gravity:

$$\text{Dead load} = 5 \times 60 \times \frac{2.4}{1.2} = 600 \text{ lb per sq in., compression}$$

and,

$$\text{Live load} = -68 \times 60 \times \frac{1}{13.6} = -300 \text{ lb per sq in., tension}$$

This gives a resultant total stress of 300 lb per sq in., compression, the same result as obtained before. In this latter case, the specific gravity requirement, as specified by the authors, has been grossly violated, but the stresses predicted for the prototype are the same.

Thus, the question of the fulfillment of a definite specific gravity requirement rests on the ability of the experimenter to measure dead load stresses. It is obvious that to measure the stresses in a structure due to its own weight is a difficult matter. Under "Measurements Made on the Model: Strain Measurements", the authors state:

> "After the model was built, the zero readings, which included the dead load stresses, were taken. The full load readings were taken after the water load was applied. In this way the measured strains represent the strain or stress decrements due to water load only and correspond to the strain measurements on the prototype."

Although the reference to dead load stress given in this statement is not clear, it is plain that the results include only the effect of the water load. Therefore, from the principle of superposition, which states the independence of forces, the writer contends that the authors would have measured the same strains and deflections on their model, regardless of the specific gravity of the material, providing the elastic constants of their material remained the same.

If an attempt to measure dead load stresses in an arch dam model is made, there are two methods which may be followed, without applying external dead loads. The first method is to mount strain-gauges on the layers of material as the model is built so that they will measure the accumulated strain as the height of the model increases. This process would require considerable time, and the accuracy of the results would be affected by: (1) Changes in temperature during the time of construction; (2) the shrinkage or volume changes of the cementing material; and (3), especially in rubber compounds, by the time yield or plastic deformation of the material. Furthermore, if this method were used on the Calderwood model, the strain would be considerably affected by the jacking of the foundation. The second process of determining dead load stresses is a reverse of the first. When all the tests on the model are completed, gauges are mounted on the faces of the model and their change in deflection noted as the model is removed, layer by layer. These readings will be subject to some of the inaccuracies mentioned previously. The time effect will be less and the shrinkage of the cement will have become constant. The latter method was used on a rubber-litharge model on which the writer was engaged.

The apparent goal of the authors was to obtain complete similitude between the action of the model and its prototype; but if the model is to be used as a step in the final design of the structure, this may not be desirable, especially in regard to the construction joints. High tensile stresses in any direction are undesirable in a dam, and the design should eliminate them as far as possible. Therefore, it is more useful to construct the model as a monolith so that no tension will be relieved by the construction joints. In this way, the strain measurements will indicate the areas of tension, and, if necessary, a re-design of the structure may be made to eliminate them. If the model is not constructed as a monolith, the joints will be free to open to relieve tension; therefore, the strain-gauges, unless they should be placed across a joint, would not locate these tension areas. If the gauge were placed across a joint, there would be a question as to how much of the deflection was an actual strain and how much represented a crack opening.

An interesting comparison between two model tests which involved a check with the mathematical theory of arch dams was developed in the laboratory where the writer was engaged. An arch dam model was constructed of a mixture of plaster of Paris and diatomaceous earth and was loaded with mercury to determine the live load stresses and deflections. The trial-load method of analysis was used to determine the distribution of live load between arch and cantilever elements which would produce the measured deflections. Then, as a separate experiment,[38] a model of the crown cantilever alone was constructed to the same scale and of the same material as the model previously tested. This model was loaded by weights with the component of the mercury load which was computed to act on the cantilever element. It was found that this load produced practically the same deflection of the cantilever section as the full mercury load produced in the complete model. The slight difference was accounted for from the larger foundation used in the cantilever model and its freedom from lateral restraint. The most interesting point in this second test was that the cantilever model was loaded artificially by weights acting through pins in the model to produce an equivalent specific gravity of 32.64, so that the relationship specified by the authors was fulfilled; yet the live load deflection of this model checked the deflection of the complete model which was loaded with mercury only.

To summarize this discussion a few points of importance in relation to model studies are offered:

1.—In two-dimensional stress, the stress distribution is independent of the elastic properties of the material, providing Hooke's law holds. Therefore, any elastic material is theoretically suitable for models under two-dimensional stress.

---

[38] "An Investigation of the Crown Cantilever Section of the Boulder Dam by Means of a Plaster-Celite Model", by Charles W. Fletcher, Jun. Am. Soc. C. E.; thesis presented to the Univ. of Colorado in partial fulfillment of the requirements for the degree of Master of Science.

2.—In three-dimensional stress, the stress distribution is not independent of the elastic properties of the materials, but is dependent on the volumetric changes of the material under stress. This requires that Poisson's ratio be the same for both model and prototype if the same distribution of stress is to be obtained.

3.—If the effect of external loads only is to be investigated, the specific gravity of the material of the model is not a factor.

4.—If the static effect of the weight of the structure itself is to be measured, only the ratio of the specific gravities of the model and prototype need be known.

5.—If the combined effect of dead weight and external forces is to be measured as a single quantity, the specific gravity of the model and its external loads must be in the same proportion as in the prototype.

ELMER O. BERGMAN,[29] ASSOC. M. AM. SOC. C. E. (by letter).—The literature of model testing has been enriched by this comprehensive paper on the Calderwood Arch Dam, and the Engineering Profession is indebted to the authors for their efforts in making available such a complete record of their methods and results. The testing of models of dams is a relatively new field of engineering research and, therefore, it is important that the assumptions, theory, and methods which are proposed, be subjected to careful scrutiny in order that their validity may be established before they are accepted as the basis for further work in the field.

The first of the questions which the writer wishes to raise has to do with the authors' insistence on Similarity Condition 2 which they state, as follows: "The ratio of the specific gravities of the material of the prototype and its loading fluid, $\frac{\rho_p}{\gamma_p}$, must be equal to the same ratio of the model, $\frac{\rho_m}{\gamma_m}$."

If the deflections and stresses to be determined are those due to combined dead and live load, the writer agrees that this is a necessary condition. It would require that the zero readings be taken on a weightless dam and the final readings after the weight of the dam and the water load have been applied. The authors point out the difficulty of such a procedure. If the strain and deflection measurements are to represent the effect of water load only, then the dimensional equation[30] reduces to:

$$\delta_p = \psi' \, (\gamma_p, E_p, g, l) = l_p \frac{(\gamma_p \; g \; l_p)^u}{E_p} \quad \ldots\ldots\ldots\ldots\ldots (17)$$

in which, as before, the exponent, u, $= 1$ and $\delta_p =$ the deflection of the prototype; $\psi' =$ an unknown dimensionless function; $\gamma_p =$ mass per unit volume of the loading liquid of the dam (water); $E_p =$ modulus of elasticity in flexure, of the material of the dam; g = acceleration due to gravity; and l = length scale, so that,

---

[29] Assoc. Prof. of Civ. Eng., Dept. of Civ. Eng., Univ. of Colorado, Boulder, Colo.

[30] "Theory of Similarity and Models", by Benjamin F. Groat, M. Am. Soc. C. E.; Discussion by A. V. Karpov, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 311.

$$\delta_p = \frac{\gamma_p \, g \, l^2_p}{E_p} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

and,

$$\frac{\delta_m}{\delta_p} = \frac{(l_m)^2}{(l_p)} \frac{\gamma_m}{\gamma_p} \frac{E_p}{E_m} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

without any requirement that $\frac{\rho_m}{\rho_p} = \frac{\gamma_m}{\gamma_p}$.

The law of superposition may be used to prove that Similarity Condition 2 must be satisfied in order that correct values of combined dead and live load may be obtained. It can not be used to prove that the maintenance of the specific gravity is necessary when only live load effects are to be determined. On the contrary, the law of superposition may be used to prove just the opposite; namely, that any ratio of $\frac{\rho_m}{\rho_p}$ may be used in determining the effect of live load, as long as the condition that the deflections are small is not violated.

A dam is subjected to two different systems of loading. One is the weight of the dam itself, which is proportional to the specific gravity of the material of the dam, and the other is the pressure of the loading liquid, which is proportional to its specific gravity. These systems may be compared to a load, P, at a point, A, in a beam and a load, Q, at a point, B. The deflections and strains in the beam can be measured by taking zero readings before either load is applied and final readings after both loads are applied. Obviously, in accordance with Similarity Condition 2, the deflections and strains due to P and Q could be obtained by applying the loads, $2P$ and $2Q$, and then dividing the measured results by two.

If, however, loads of $2P$ and $3Q$ are applied and, as before, zero readings with both loads off, and final readings with both loads on, the beam are taken, there is no way in which the readings can be adjusted to yield the deflections and strains that are produced by the loads, P and Q. On the other hand, if zero readings are taken with both loads off, intermediate readings with the load, $2P$, on, and final readings with both the loads, $2P$ and $3Q$, on the beam, the effect produced by P and Q is equal to one-half the increment of reading, due to $2P$, plus one-third the increment due to $3Q$. The argument is the same as that used in the proof of Maxwell's theory of reciprocal deflections. There is nothing unique about the action of a dam that would serve to exempt it from obeying such a universal principle.

It is difficult to see how Fig. 1 proves anything more than that Similarity Condition 2 holds for combined loads. The diagram itself is likely to be misleading. The area between the solid line, AB, and the dotted line, AB, represents the vertical stress at the foundation line due to an unstated percentage of the dead load. If the vertical distances between the two curves are plotted on a horizontal base line, the curve shown in Fig. 19 is obtained.

This would indicate that the dead load weight of the dam produces tension along the down-stream part of the foundation line, which is unusual to say the least.

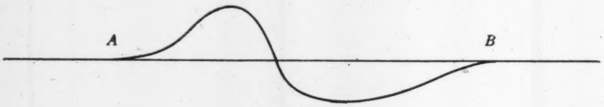

FIG. 19.

The writer also questions the validity of the second reason for considering the relative weights of the loading liquid and the dam material. Provided the deflections remain small, it would seem that doubling the density of the material in the dam would cause a uniform 2:1 increase in the foundation reactions along the entire periphery of the dam.

The third reason seems to be well taken. However, the same change from tension to compression may occur when there is such a marked increase in Poisson's ratio as that from 0.15 to 0.50.

The authors next make the statement (see "Conditions Governing the Properties of the Model Material") that,

> "The only conclusion that can be derived from a model of a gravity dam, in which the ratio of the specific gravity of loading liquid to the material is many times higher than in the prototype, is that every gravity dam will fail."

By what process do they arrive at such a conclusion?

To the ten specifications for a material suitable for constructing a model should be added the requirement that the relation of the tensile strength to the compressive strength should be the same as for concrete. This requirement is of major importance.

The authors do not give sufficient weight to the condition that the value of Poisson's ratio should be the same for the material of the model and the prototype. Such easy acquiescence in regard to a factor of major importance is not in keeping with their insistence on the maintenance of the specific-gravity ratio. It is true that a small divergence might be passed over as insignificant in its effect on deflections and stresses, but can such a difference as that between 0.15 and 0.50 be passed over lightly? Moreover, it should be noted that a material with a Poisson ratio of 0.50 presents a special case. For such a value of the Poisson ratio the material deforms with no change in volume, so that if it is compressed at one point, it must expand at another. The deflections, stresses, and strains in a model built of such a material will differ markedly from those in a model built of a material that will undergo considerable change in volume under load, except perhaps for a dam of thin section. It seems doubtful whether reducing the strains in a rubber model to stresses by using a value of Poisson's ratio of 0.15 will give stresses that are even indicative of those in the prototype, as the authors suggest in connection with Figs. 11 and 12.

In connection with the "Uncertainties of the Dam Proper," it is stated that the time interval between the placing of the concrete and the application of the water load causes rather high internal tensile stress to be developed in the blocks of the prototype. Furthermore, the authors state that when the water load is applied, the blocks undergo a contraction under compression which is greater in a block that has a preponderance of internal tensile stress than in one without such stress. Will the authors explain these statements?

In testing the model an unknown factor was introduced by the jacks that were used to change the position and shape of the model and its foundation. The jacks were adjusted until deflection readings at a considerable number of stations were obtained, which corresponded closely with the deflections measured on the prototype, as shown in Fig. 8(*c*). It is then assumed, at least implicitly, that a reasonably close correspondence will exist between the strains and stresses in the model and in the prototype.[31] It is interesting to check the validity of such an assumption when applied to a simply supported beam. Consider a beam, *A,* loaded with a total uniformly distributed load of 5 600 lb and a similar beam, *B,* loaded with a central load of 3 500 lb. The ratio of the deflection of Beam *B* to that of Beam *A* is 1 at the center line and $\frac{55}{57}$ at the quarter-points, while the ratio of the extreme fiber stress is $\frac{5}{4}$ at the center line and $\frac{5}{6}$ at the quarter-points. If loads of 3 200 lb are placed at the quarter-points and a load of 1 300 lb at the center line, the deflections are the same as those of Beam *A* at the quarter-points as well as at the center line; but now the ratios of the stresses in Beam *B* to those in Beam *A* are $\frac{45}{21}$ at the center line and $\frac{11}{6}$ at the quarter-points. Evidently corresponding deflections at five points along the beam do not produce corresponding strains and stresses. There must be correspondence at a sufficient number of points in order that the loads on Beam *B* (model) shall become approximately equivalent to the load on Beam *A* (prototype). Whether the number of points shown in Fig. 8(*c*) is enough to insure reasonable correspondence of strain and stress values between the model and its prototype is at least debatable, particularly in view of the lack of agreement shown in Figs. 11 and 12.

The sum of the horizontal and vertical strains at a point is equal to the sum of the strains in the 45° and 135° directions. This relation may be applied to the data in Table 2 to check their consistency. Deviations may arise from the fact that the measured strains are the average over the gauge line instead of the strain at the point where the gauge lines intersect, and to instrumental and personal errors. Table 2 shows reasonably good agreement. The agreement is better in the model than in the prototype.

With regard to Conclusion (7), the writer believes that a material composed of a mixture of plaster and diatomaceous earth and having a low modulus of elasticity is a better model material than rubber, because its strength properties resemble more closely those of concrete. The chief advantage of rubber as a model material is that it enables strain measurements to be made on the up-stream face.

---

[31] See the authors' discussion of a similar case in "Actual Deflections and Temperatures in a Trial-Load Arch Dam", by A. T. Larned and W. S. Merrill, Members Am. Soc. C. E.; Discussion by A. V. Karpov and R. L. Templin, Members Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 951.

DR. ING. E. PROBST[32] (by letter).—The intention of the authors to check the theoretical bases of the design of an arch dam by the use of a model is remarkable in many respects. During recent years a number of measurements have been made on small and larger models of different proposed structures. There are fields, however, in which no direct conclusions can be made based on such tests. Dams belong in that field because they represent structures, the design of which is influenced by the ground conditions to a much greater extent than any other kind of structure. The model can not represent, properly, the condition at the base and abutments of the dam.

In their Conclusion (1), the authors state that a design based on the assumption of non-yielding foundations does not come close to the actual conditions. Differences between the elastic properties of the bed-rock and the material of the dam will change the stress distribution at the base, and that change will increase with the increase of the height of the dam; but the same conclusion can be reached by theoretical considerations.

If, in order to make possible improvements in future designs, it is intended to determine the over-stressed and under-stressed parts of the dam, then the representation in the model of the connections between the dam and the abutments is of particular importance.

The most formidable difficulty in designing the model is the choice of the material, which should have properties different from those of the prototype. The relatively smaller scale of the model makes it impossible to use the same material as in the prototype. The elastic properties and the strength of the concrete are influenced to the greatest degree by the ratio of the different ingredients; these conditions cannot be properly represented even in a large sized model.

Even if it is perfectly mixed and placed, concrete is non-uniform due to the non-uniform distribution of particles of different size. It can be stated that in not a single vertical cross-section of a dam is concrete uniform from the top to the bottom, even if its composition is the same. If the attempt is made to simulate such a complex substance by substituting a uniform material in the model, the conditions of the model will be quite different from those that would be necessary to represent the actual dam. This difference will be in addition to that due to the impossibility of representing, properly, the conditions at the abutments. These considerations and the circular shape of the horizontal cross-section seem to be responsible for the non-uniformity of the horizontal stresses measured on the model. The distribution of horizontal stresses could be improved or could be made uniform by changing this shape.

---

[32] Karlsruhe, Germany.

Quite properly, the authors state in Conclusion (5) that to design an arch dam neglecting gravity action will result in an unwarranted increase in the thickness of the arch at the abutments; furthermore, the evaluated stresses will be quite different from the actual ones.

The authors compare the measurments made on the model with those made on the prototype. In many cases, the deflection measurements may be of some value as an addition to the strain measurements as, for example, in bridges or in structures in which the measuring apparatus is influenced by climatic conditions to a less degree than in dams. The writer knows of cases of deflection measurements on dams which, due to such influences, appeared so unreasonable that they could not be used. Furthermore, all the deflections were so small that, in many cases, even with the greatest possible precision, the small deflection changes could not be determined.

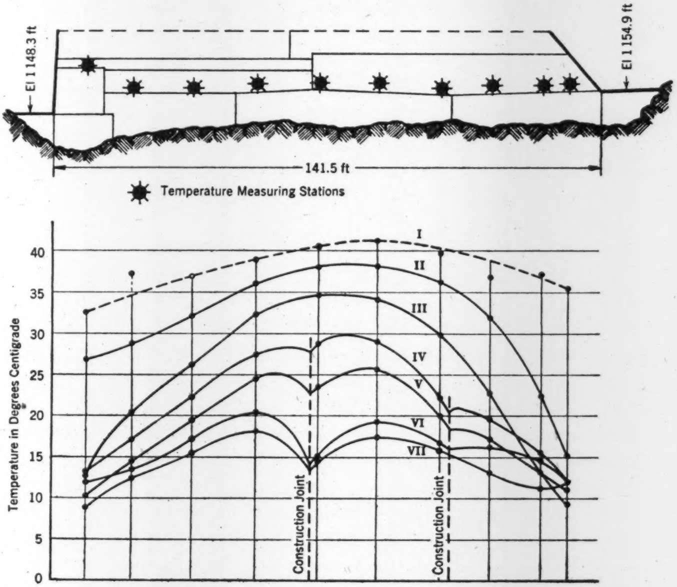

FIG. 20.

The influence of climatic conditions is most pronounced if the strain measurements are made at the faces of a dam as was the case in the measurements made by the authors. Such measurements cannot disclose the strains and stresses within the dam. Even if the measurements made at the faces gave the proper values of the strains, these measurements could not be used to support conclusions regarding the actual stresses in a cross-section of the dam.

All efforts to increase current knowledge concerning the bases of design, necessarily will lead to the necessity of making measurements on the structure itself. Of course, such measurements must be carefully planned based on previous experience. They must be painstakingly accurate, from the beginning of the construction work and must be continued as long as possible after the dam has been put in service. Such measurements can be made only from a distant reference point so arranged as to eliminate the influence of the weather on the measurements.

If it is intended to form a picture of the deformations and stresses within the dam, measurement methods must be used that will disclose the influence of all forces within the thickness of the structure. Besides the influence that is due to the outside and inside temperatures, the stresses at each point will be influenced to a considerable degree by the change in moisture content, due to the continuous setting of the concrete.

A detailed report of such measurements made on the Bleiloch Dam, in Thuringen, Germany (207 ft high), has been presented by the writer elsewhere.[33] At a depth of 197 ft below the crest of this dam, thirty telemeters were inserted at ten stations. Some new data on this subject are shown in Fig. 20, with supplementary information concerning temperature measurements, as follows:

Curve No. (see Fig. 20)	Date of measurements	Time elapsed, in years, since date of first measurement
I	May 15, 1931	0.0
II	October 10, 1931	0.5
III	April 29, 1932	1.0
IV	November 7, 1932	1.5
V	May 5, 1933	2.0
VI	November 6, 1933	2.5
VII	May 24, 1934	3.0

The strains, measured 10 ft above the ground-line joint, show that the changes in strain due to temperature influences are such that no conclusions can be drawn about the strains inside the dam, based on measurements made on the surface. It was shown also that the final conditions in a cross-section were not arrived at three years after the beginning of the construction and nearly two years after the dam was put into service. The final conditions will be reached after some time that depends on the thickness of the dam; but no matter what the conditions, no proper conclusions can be drawn concerning the distribution of stress inside the dam based on measurements made at the face.

The best guaranty of a safe and economical design is to create conditions under which the design assumptions can be controlled clearly and simply. This objective can scarcely be accomplished by model studies.

Comparative measurements on the actual structure should not be limited to surface measurements since the distribution of deformations throughout the cross-section are of the utmost importance as far as the value and location of the unfavorable or objectionable stresses are concerned.

Based on these considerations, the writer would like to suggest that, in the future, measurements be made on each large dam instead of on models.

---

[33] First International Conference on Dams, Stockholm, Sweden.

A. V. KARPOV[34] AND R. L. TEMPLIN,[35] MEMBERS, AM. SOC. C. E. (by letter).—Seven discussions were published applying to this paper, two of which came from abroad. The writers are much impressed with the exceptionally high character of each of these contributions. The different points developed in the discussion can be broadly summarized as follows: (I) The use of models in investigation of arch dam problems; (II) similarity conditions; (III) type of models; (IV) results of tests on Calderwood and other models; and, (V) design methods and theories. It will better answer the purpose of the closure to discuss each of these topics separately, rather than to consider individually the contribution of each discusser.

(*I*) *The Use of Models in Investigation of Arch Dam Problems.*—Two discussers, Mr. Janni and Dr. Probst, question the advisability of using models in the design of arch dams. Mr. Janni considers the temperature stress of utmost importance and does not believe that this stress can be measured on a model.

In a number of points the writers disagree with Mr. Janni. In so far as the theoretical computations are concerned, they are correct so long as the assumption can be made that there is a monolithic arch between fixed abutments on a non-yielding foundation. It seems that the usual simplified assumption of fixed abutments and a non-yielding foundation is quite firmly fixed in the engineering mind. For a number of structures such an assumption does not involve any considerable mistakes; but for an arch dam, consisting of a number of blocks between abutments, such simplified assumption leads to radically wrong conclusions.

Thinking in terms of the total deflections of an arch dam, the abutment, and particularly the foundation, deflections are large and the abutments and foundation should be considered as very flexible. Fig. 9 makes clear the comparative magnitude of the deflections of the foundations and the dam proper. Under such conditions the conclusions based on the formulas by Mr. Janni are incorrect. On the contrary, temperature variations may involve changes in deflections that are accompanied by insignificant changes in stress.

TABLE 4.—DATA PERTAINING TO TEMPERATURE CURVES IN FIGS. 21 AND 22

Description	Block 6	Block 10
Thickness of block, at temperature station, in feet	58	26
Elevation of temperature station above datum,* in feet	795	895
Concrete placed at temperature station	July 9, 1929	July 30, 1929
Concrete placed at adjacent blocks	July 26, 1929	October 17, 1929
Block exposed to water	April 15, 1930	April 17, 1930
Distances from Down-Stream Face of Block, in Feet:		
Test 1	31	14
Test 2	14	22
Test 3	2	..

* Datum is 122.62 ft above mean sea level.

Figs. 21 and 22, with Table 4, show the results of temperature measurements, extending over a period of nearly two years, on the Calderwood Dam.

[35] Chf. Engr. of Tests, Aluminum Co. of America, New Kensington, Pa.

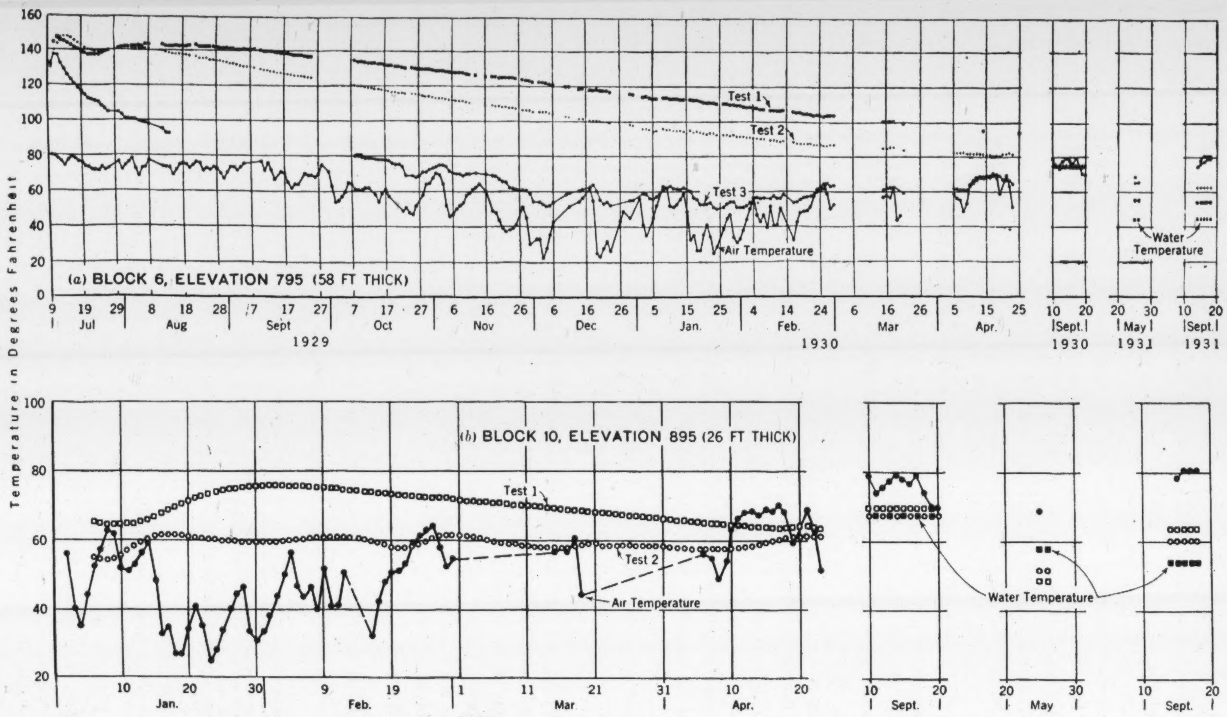

FIG. 21.—TEMPERATURE MEASUREMENTS, CALDERWOOD ARCH DAM; DAILY AVERAGES.

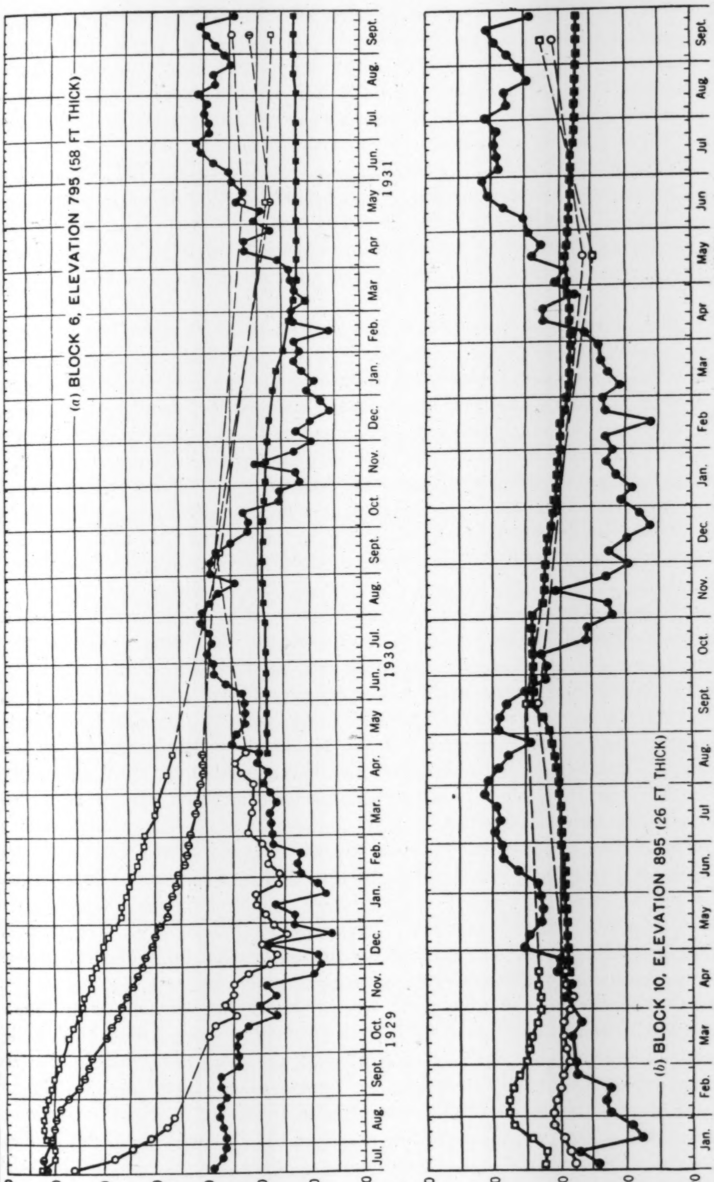

Fig. 22.—Temperature Curves, Calderwood Arch Dam; Weekly Averages. (For Identification of Curves See Similar Curves in Fig. 21.)

During that time four sets of measurements were made; the first set was begun at the time of placing the concrete until, and including, April, 1930; after that, tests were made in September, 1930, May, 1931, and September, 1931.

Figs. 21(*a*) and 22(*a*) show the daily and weekly averages at Elevation 795 of Block 6 (see Fig. 8). The temperature measuring stations were located 31, 14, and 2 ft from the down-stream face of a block, 58 ft thick. Figs. 21(*b*) and 22(*b*) show similar temperature measurements at Elevation 895 of Block 10, the stations being located 14 and 22 ft from the down-stream face of a block, 26 ft thick. The time when the concrete blocks were completely surrounded by adjoining blocks, as well as the time since, when they were exposed to water at the up-stream faces, is indicated in Table 4.

A study of these temperature curves, as well as of temperature curves of any dam, will show that the concrete only a few inches from the surface does not undergo sudden temperature changes. On the contrary, the temperature within the dam changes very slowly; only a few feet from its face, the temperature changes are due principally to the latent heat of the concrete and its rate of dissipation, and to a much less extent to the changing air or water temperatures. Nevertheless, if any stresses are developed in the prototype, they can be simulated and measured on a model properly built and operated. Some method analogous to the one described in connection with Fig. 13 will disclose strain and stress irrespective of the actual deformation.

In his discussion Dr. Probst presented, quite ably, the general arguments against the use of models in arch dam design. The writers are in full agreement with a number of points that are brought out in his discussion, although they cannot agree with his conclusions. In conformity with the ideas expressed in the paper he states that the ground and abutment conditions are of paramount importance in so far as the behavior of the dam is concerned. Furthermore, he declares that these conditions cannot be properly represented in a model. That was one of the ideas on which models of dams were built in the past; to-day, however, it is clear that such a statement cannot be justified because the ground and abutment conditions, as well as the conditions of the dam proper, can be represented in a model. Fig. 8 of the paper, giving the comparative model-prototype deflections, is a striking proof of that statement. Investigators know better now than in the past how to represent the ground conditions in a model, and with further study the methods of ground representation will be improved.

As the matter now stands, there are no particular difficulties in representing the ground conditions. The main difficulty lies in determining the properties of the ground; and, in that respect, the work done during the last few years, particularly in Germany, in applying the vibration method for determining the properties of the ground, seems to be of cardinal importance. If such work on actual ground is continued and is followed by model studies, engineering science will dispose of one more mystery, and the ground material will be treated as every other material used in engineering.

As an argument against the use of models, Dr. Probst makes the statement that the stresses within the structure are of more importance than the surface stresses and only measurements at the dam itself can disclose the stresses within the structure. The writers scarcely can agree with that statement. First, the stresses within the structure are undoubtedly of importance and should be studied and determined; but why they should be more important than surface stresses is not clear. After all, considering the practical point of view, the deterioration of concrete starts at the surface and the surface stresses are at least as important as the stresses within the dam. Second, the stresses within the structure can be determined with considerable saving of time and much more reliably, if the measurements made on the dam are supplemented by a model study.

Dr. Probst considers also the long-discussed question of the non-uniformity of concrete. Of course, concrete is non-uniform to a greater degree than, for instance, many commercial metals; but, again, the concrete of to-day is much more uniform than the concrete of yesterday. It is rather surprising to what extent the uniformity of concrete can be improved by proportioning and mixing in a central plant with rigidly controlled ingredients, proper water-cement ratio, and the liberal use of vibrators. Concrete aggregates in large masses act as a uniform material even if the aggregates are non-uniform. The best possible illustration is probably the one taken from the ordinary commercially used metals. Every metal is composed of crystals that may have different elastic and pronounced directional properties. Nevertheless, so long as these crystals are distributed at random, but not preferably oriented, the material has a high degree of uniformity in pieces that are large when compared to the size of a single crystal. The elastic properties of such materials represent some average of the integrated values of the properties of the individual crystals. Proper proportioning, mixing, placing, and vibrating of the concrete will prevent any preferential orientation of the particles and in that respect a large mass of concrete probably is quite uniform, relatively speaking.

Dr. Probst arrives at the conclusion that since it is impossible to build a proper model of a gravity dam or an arch dam, no model tests should be attempted, but rather that measurements should be made on actual dams. The writers do not believe that measurements made on a prototype exclude the necessity of measurements on a model, or *vice versa.* From a theoretical viewpoint, measurements made on a prototype are the best. From a practical viewpoint, considering the magnitude of a dam, the inevitable limitations of such testing program and the impossibility of varying arbitrarily the loading conditions, such measurements are of relatively little importance and scarcely justify the time, work, and expense involved. These measurements, however, become of the utmost importance if accompanied by an adequate model study.

Taking as an illustration the measurements on the Bleiloch Dam mentioned by Dr. Probst: These measurements undoubtedly will give interesting results, but the practical application of these results is uncertain unless they are used in connection with a model study. Every investigation of this kind should disclose how improvements can be made and how safer dams can be built with the least possible material. Measurements made on a dam scarcely can give an answer to these questions unless supplemented by a model study.

Contrary to the opinions of the past, one cannot expect to use the results of measurements to develop an improved theoretical method of design. The question of to-day is not how to supplant one arbitrary set of assumptions by another just as arbitrary, but to find a method that will give results approaching the actual conditions and in this manner make possible an improved design.

Fig. 20 of Dr. Probst's discussion is of considerable interest, but does not support the contention that the stresses within the dam cannot be predicted from measurements on its faces. First, should be noted the unusual distribution (from the American viewpoint) of the construction joints. Second, the changes in the character of the temperature curves should be studied. Curves I, II, and III show the temperature before the dam was put in service and Curves IV, V, VI, and VII, after water was stored above the dam. The breaks in these latter curves are an indication that water circulated through the construction joints. Such circulation increased when the concrete blocks cooled and the size of the joints increased; this is manifested by the shape of the breaks of the temperature curves at the left construction joint shown on the diagram. If these joints were differently arranged and better grouted, no water would circulate through them and no breaks would have occurred in the temperature curves. Even under present conditions, however, after the concrete has cooled and the dam has attained its final service conditions, the breaks in the temperature curves should disappear. The regular shape of the temperature curve (Curve VII) at the right construction joint, is a rather convincing argument to that effect.

(*II*) *Similarity Conditions.*—There seems to be an agreement of opinion that the similarity conditions established in connection with the Calderwood model are complete and that a perfect model must meet every one of them. Mr. Smith is perfectly correct when he states that the writers took pains to prove the importance of the specific gravity requirements. It is rather discouraging, therefore, to the writers that this question is raised again, and attempts are made to minimize the importance of these conditions.

Considerable discussion comes from those who advocate the advisability of building an imperfect or only a partly correct model. In connection with such model, the relative importance of the different similarity conditions are discussed. Messrs. Simonds, Smith, and Bergman allege that the specific gravity requirements are of importance only if both the dead load and the live load stresses are measured, but that this requirement is of no importance if only live load stresses are measured and hence an imperfect model that neglects the specific gravity requirements is satisfactory for practical purposes.

The writers emphasize the dangers of the misapplication of the dimensional theory by the omission of a quantity that is difficult to handle, as was done by Professor Bergman in the derivation of his Equations (17) to (19).

By using such a method, almost any desired statement can be proved and any improper similarity condition can be established. In order to apply the dimensional theory properly, all quantities entering into the problem must be considered. Only quantities that are negligible in their effect can be omitted without appreciable error. The omission of such an important quantity as the weight of the material of the dam will result in similarity conditions applicable to a weightless dam. Such similarity conditions could be used if a dam is investigated, the material of which has a very small specific gravity as compared with the loading liquid. These conditions, however, cannot be used with reference to an actual dam, the material of which has an appreciable specific gravity.

Fig. 18 of Mr. Smith's discussion and his elaboration on the subject as well as Equations (17) to (19) of Professor Bergman's discussion and his Fig. 19 are all based on the fallacious assumption that it is admissible to evaluate, separately, the dead load and live load stresses and to arrive at the total stress by simply adding these stresses.

A proper understanding of the more complicated three-dimensional stress problems is possible only if the principle of superposition is properly applied. The simple addition of the gravity and live load stresses would be permissible if a straight-line distribution of stress could be assumed. In addition to Fig. 1, Fig. 23,[36] shows clearly the incorrectness of the straight-line assumption.

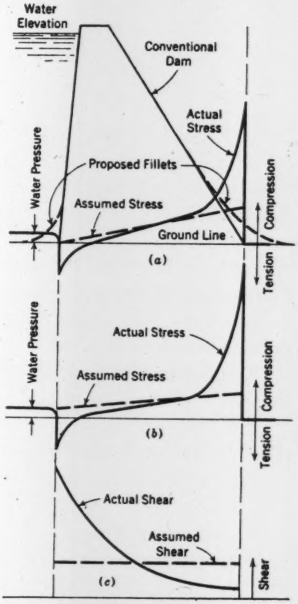

FIG. 23.—VERTICAL STRESS AND SHEAR AT THE GROUND LINE.

Professor Bergman states: "That a material with a Poisson ratio of 0.50 presents a special case." So far as a structural model is concerned, only a practically non-existent material with a Poisson ratio of zero could be considered as a special case. In such a material the application of stress in one direction would not produce strains or stresses in any other direction.

Due to the application of stress in one direction, any material having a Poisson ratio of 0.15 or 0.50 will induce strains or stresses in other directions, the only difference being in the magnitude of the strain or stress. In that connection it would seem that Professor Bergman's statement, "for such a value of the Poisson ratio [0.50] the material deforms with no change in volume, so that if it is compressed at one point, it must expand at another," is unfortunately worded, because there is no difference in the behavior of the material having a Poisson ratio of 0.15 or even 0.50. There is no question that "it must expand," but in both cases it will have the tendency to expand; if restrained from expansion both materials will develop stresses similarly, the only difference being in the amount of expansion and in the value of the induced stresses.

---

[36] "Stability of Straight Concrete Gravity Dams," by D. C. Henny, M. Am. Soc. C. E. Discussion by A. V. Karpov, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), Fig. 12, p. 1083.

All the discussers who stress the importance of Poisson's ratio and the non-importance of the specific gravity requirements apparently overlook the importance of the proper representation of the foundations, abutments, and joints in the model. Mr. Smith even goes so far as to make the statement that the representation of joints in a model is undesirable and advocates the building of models that intentionally violate this similarity condition. All of which brings the entire problem back to the fundamental question : What is a modern structural model?

(*III*) *Type of Models.*—There seems to be a considerable difference in opinion as to the purpose of structural models and what constitutes an up-to-date engineering model. It should be realized that present engineering knowledge is limited[37] and that in many structures a wide discrepancy exists between the actual stress in the structure and the stress evaluated by the use of conventional methods. This discrepancy is very pronounced in statically complicated structures, the design of which is based upon assumptions that were satisfactory in the design of simple structures. Consequently, a rapid change in the conception of the theory of stress is currently taking place. Many assumptions that were considered axiomatic a few years ago are now not only challenged but often discarded.

The major problem of modern engineering is to determine the correct design assumptions which will suit the particular structure under consideration. The next in importance is the selection of a proper mathematical treatment which will make it possible to evaluate the different phases of the behavior of the structure. The limitations of present mathematical knowledge makes it impossible to obtain a complete and exact solution of the differential equations set up by introducing the theory of stress. Consequently, the strains, deflections, and stresses can be evaluated only approximately. The discrepancy between the actual and the theoretically determined behavior of a structure depends upon the correctness of the design assumptions and upon the approximations involved in the particular mathematical method used.

A correctly designed model has the important advantage that it eliminates the approximations of the mathematical methods and gives results that depend only on the correctness of the design assumptions, thus making possible an independent solution of the major engineering problem.

The uncertainties regarding some of the conditions of an arch dam, and particularly with respect to the foundation conditions, are used by Mr. Simonds as an argument against the use of models and in favor of the substitution of a mathematical analysis as the basis of design. It should be realized that the same uncertainties that enter into the design, the building, and the testing of a model, also enter into the mathematical analysis of the prototype.

---

[37] "The Use of Engineering Models," by A. V. Karpov, M. Am. Soc. C. E., *The Military Engineer*, November–December, 1934.

If, for instance, the actual ground conditions are not known, some assumptions regarding these conditions must be made and applied equally to the mathematical analysis of the prototype and to the building of the model. Any reasonable design assumption can be represented in an adequate model; but there is this radical difference between the mathematical analysis and the model study: The uncertain assumptions upon which the mathematical analysis is based will be imposed upon the ground assumptions which are used in the mathematical analysis. Due to the uncertainty of the ground assumptions and of the mathematical method the final results will differ from actual conditions. The part of the discrepancy that is due to the uncertain ground assumptions may be small when compared with the part that is due to the currently accepted mathematical methods. On the other hand, the same ground assumptions, if properly incorporated in an otherwise correct model, will be the only uncertainty, and the discrepancy between the actual behavior of the prototype and the predicted behavior, based on the model study, will depend only upon the correctness of the ground assumptions.

It was not the intention of the writers even to suggest the elimination of the mathematical analysis. The results of proper model studies can, and should, be used to develop and check a reliable design theory which could be finally incorporated in a mathematical design method. The writers contend that a mathematical theory which is checked by an incorrectly designed model cannot be considered as satisfactory; only a theory that can be checked on a correctly designed model may be considered satisfactory and hence should be used.

By the use of models there are two methods of approach to the major problem. The first method, often used in the past, is to make a set of assumptions which may appear to be either more simple or more reliable, and thereby attempt to obtain proof of the more complicated or less reliable assumptions. In an arch dam investigation numerous assumptions of this type are possible. The mercury loaded plaster-celite model of an arch dam is based on a series of such assumptions, some of which are: (*a*) That the total stress can be determined from the summation of the dead load stress, determined without considering the hydrostatic pressure, and the live load stress, determined under zero weight conditions; (*b*) that the behavior of an arch dam model with fixed foundations and abutments is similar to that of a prototype arch dam with flexible foundations and abutments, so that tests made on a model with fixed foundations and abutments will determine the condition of a prototype built on flexible foundations and abutments; and (*c*) that a dam having joints will behave similarly to a dam that is built as a monolithic structure. This method is a simple one. The assumptions can be chosen so that no particular attention need be paid to any similarity conditions. The mercury loaded models are usually scalar representations of the prototype; but even that is not necessary and an arbitrarily shaped model could be used. However, it should be realized that this method does not give any proof of the accuracy of the assumptions made; it merely substitutes one more or less arbitrary set of assumptions for another.

The second method is based on the omission of all arbitrary assumptions. This is accomplished by the determination of the similarity conditions that will establish a natural relation between the behavior of the model and its prototype. By building a model that satisfies these similarity conditions and its testing, the actual behavior of the prototype can be determined and the correctness of the design assumptions can be checked. A concise definition of such an up-to-date engineering model is given by Mr. Arthur C. Ruge,[38] who states:

> "The true criterion is that it must be possible to deduce the behavior of the prototype, under an arbitrary set of conditions, from the behavior of the model when subjected to a similar and properly proportioned set of conditions."

Some of the discussers prefer mercury-loaded models because they consider the high value of Poisson's ratio of the rubber-litharge compound a serious drawback of the water-loaded rubber-litharge model.

Table 5 permits a comparison with respect to the specific gravities of the model materials used in the three kinds of models referred to in the discussions.

TABLE 5.—SIMILARITY CONDITIONS WITH RESPECT TO SPECIFIC GRAVITY OF THE MODEL MATERIALS

Kind of model	Specific Gravity		Ratio of actual to required weight (percentages)
	Required	Actual	
Mercury-loaded plaster-celite	32.84	0.7	2.1
Mercury-loaded concrete	32.84	2.4	7.3
Water-loaded rubber-litharge	2.4	2.4	100.0

Comparing the mercury-loaded, plaster-celite model with the water-loaded, rubber-litharge model, it should be realized that the comparison is to be made between a model having only 2% of the required weight and without a proper representation of the foundations, abutments, and joints, and a model having 100% of the required weight and built of a reasonably uniform material, with properly represented foundations, abutments, and joints, but having a deficiency in Poisson's ratio. The difference between these two kinds of models can be visualized clearly by comparing three dams of the same size—an actual dam and two imaginary dams. The first imaginary dam is assumed to be built as a monolithic structure, on foundations and abutments that are very many times as stiff as the actual foundations and abutments, and using a material that has only 2% of the weight of the concrete of the actual dam. The second imaginary dam is assumed to be built in exactly the same way as the actual dam, on the same foundations and between the same abutments, using a material that has the same properties as the concrete of the actual dam, except the high value of Poisson's ratio.

---

[38] "The Determination of Earthquake Stresses in Elastic Structures by Means of Models," by Arthur C. Ruge, *Bulletin*, Seismological Soc. of America, Vol. 24, No. 3, July, 1934.

The behavior of the first imaginary dam would be radically different from that of the actual dam, and it would be impossible to establish a rational inter-relation between the respective stresses and deflections of this imaginary dam and the actual dam. The behavior of the second imaginary dam would be substantially the same as that of the actual dam, the only difference being due to the different Poisson ratios. Applying secondary corrections, that will be necessary to account for the difference in Poisson ratios, it would be possible to compare directly the respective stresses and strains of the second imaginary dam and the actual dam.

In comparing the plaster-celite and rubber-litharge models a number of statements were made in the discussion concerning the uniformity of the plaster celite and the non-uniformity of the rubber litharge. There are no supporting data to confirm the statements to the effect that the plaster-celite material is uniform. It is known[39] that this material is unstable in so far as its elastic properties are concerned. The presence of moisture in the model material, or high humidity of the surrounding air, may result in pronounced plastic instead of the presumed elastic properties. Such qualities make the conditions uncertain. The statements regarding uniformity should be supported by results of tests properly made under conditions and on specimens that would assure that the test results are representative in so far as the material in the model itself is concerned.

The rubber litharge used in the Calderwood model was reasonably uniform. In so far as statements concerning the non-uniformity of the rubber-litharge compound of the Boulder Dam model are concerned, it should be kept in mind that this compound requires special technique in testing because if tested by conventional methods it is quite probable that incorrect results will be obtained.[10] The maximum value of Poisson's ratio of 0.64, stated by Mr. Simonds, makes the writers somewhat doubtful as to the reliability of the procedure and testing methods used.

The statement by Professor Bergman that "the chief advantage of rubber as a model material is that it enables strain measurements to be made on the up-stream face" is incorrect. The possibility of using strain-gauges on the water-covered face of the model is merely an incidental advantage, but it cannot be termed the "chief advantage." The chief advantage in using the rubber-litharge material is that measurements made on a water-loaded model will enable the prediction of the behavior of the prototype with satisfactory accuracy. No such predictions are possible where the measurements are made on a mercury-loaded plaster-celite model.

For future models it is very desirable to use a material that has a low modulus of elasticity, a specific gravity of 2.4, and a Poisson ratio between 0.15 and 0.20.[39] It would also be desirable to have a more uniform material, that is, with less than ±15% variation in the modulus of elasticity. Such refinements would improve future model work.

One of the most significant features of the work done on Calderwood Dam and its model is the proof of the important influence that the behavior of the ground and abutments exerts on the behavior of an arch dam. An arch dam cannot be considered as an isolated independent structure, but must be investigated as an integral part of the surrounding canyon. Considering the present status of the art, any model that neglects the proper representation of the foundation and abutments cannot be considered as an up-to-date model.

---

[39] "Materials for Use in Structural Engineering Models, with Special Reference to Rubber Compounds," by A. V. Karpov, M. Am. Soc. C. E., *Proceedings*, Am. Soc. for Testing Materials, Vol. 34, Pt. II, 1934.

Mr. Simonds asks a number of pertinent questions regarding the representation of the foundations in the Calderwood model. It was stated in the paper that the investigation of the foundation conditions was necessarily one of the objectives. In studying the Calderwood model, the writers had at their disposal the measurements made on the prototype and could adjust the foundations and abutments accordingly. If such measurements were not available, or in case of the building of a new model on a foundation for which sufficient information is not available, the writers probably would attempt to determine the behavior of the model in a number of steps, each of which would disclose the behavior of the dam under different flexibility conditions of the foundations. Having at their disposal the results of the tests on the Calderwood model, it is assumed that for any other prototype, model conditions could be obtained that would closely approximate the actual ones.

Professor Bergman's discussion as to the possible difference between the stress in a beam having the same deflections, but different loadings, is perfectly correct. However, under the conditions of a model having the proper specific gravity ratio, an additional condition must be introduced; that is, the impossibility of arbitrarily varying the loads. If that is taken into consideration the conclusions based on the example of the action of a straight beam will be quite different.

Referring to Mr. Werner's inquiry concerning the temperature control, the writers had in mind to utilize the low thermal conductivity of the rubber-litharge compound. If and when the testing of the model is resumed, it is planned to conduct a number of tests keeping the room temperature high for a period of time sufficiently long to have the temperature of the model material uniformly high. Next a series of tests should be run with lower room temperature and with a considerably lower water temperature. It seems that such a method of testing will result in a series of deflection and strain readings that will correspond to different temperature conditions of the dam, air, and water. The low thermal conductivity of the rubber-litharge compound should make it possible to obtain distribution of temperatures throughout the model quite similar to that of the prototype.

So far as Mr. Smith's work is concerned, the writers again point to the danger of the indiscriminate use of models. To build a model of a material that weighs only 42 lb per cu ft and, by applying external weights, increase its total weight about forty-nine times, or to about 2 050 lb per cu ft, would seem to indicate a serious violation of fundamental similarity conditions. At present, such models cannot be justified, because the procedure is contrary to modern ideas regarding correct model design and particularly since materials of proper specific gravity for use in water-loaded models are now readily obtainable.

(IV) *Results of Tests on Calderwood and Other Models.*—The results of tests on the Calderwood model differ from expectations based on conventional design ideas and also from results of tests made on mercury-loaded models.

The results of measurements of the vertical stress on the up-stream and down-stream faces of the model are probably the ones that raised the most questions. These questions cannot be answered under conventional assumptions; but if these assumptions are disregarded and if it is conceded that there is no straight-line distribution of stress and that the total stress is not equal to the sum of the dead load and live load stress determined separately, the results of these measurements are very logical. The application of the live load results in a redistribution of the dead load stress; the character of this redistribution may be rather complicated on account of the influence of the foundations and abutments.

The present design methods do not disclose such redistribution of stress; neither can a model in which the weight of the material is subdued, and the weight of the loading fluid considerably exaggerated, show the redistribution of stress that will correspond to the actual conditions in the prototype.

Mr. Werner gives a convincing answer to the doubts raised with reference to the possibility of having vertical tension stress on the down-stream face of the dam. The instance of a cylindrical vessel cited in his discussion could not be improved upon by the writers.

Mr. Simonds refers to the measurements on the up-stream face of the model. It is only natural that there should be a difference in measured strains if pins of different lengths are used. Since the measurements should give the strains at the face of the dam, the shortest possible pins should be used. Indeed it may be advisable to substitute for the pins some device that would make it possible to attach the gauge points directly to the surface of the model.

Mr. Jorgensen's conclusion that the vertical elements of the dam impose additional loads on the upper arches and reduce the loads on the lower arches is correct. In so far as the deviation of the principal stresses from the vertical-horizontal directions is concerned, Fig. 10 shows that such a deviation is much smaller than is usually assumed and is pronounced only near the abutments. For dams that do not have a considerable increase of thickness toward the abutments, the deviation of the principal stresses from vertical-horizontal directions will be still less. Mr. Jorgensen believes that the assumption customarily made in designs neglecting the effect of gravity—that the horizontal arches slide frictionless between the adjoining arches—is on the side of safety. The writers would like to state that in the design of a complicated structure the only safe procedure is to base the design on correct assumptions and to eliminate all incorrect assumptions. If in such designs incorrect assumptions are made, it is impossile to foresee the complications that may arise, and it is very unlikely that an incorrect assumption can be made which will bring the design on the side of safety. The effect of gravity was neglected in the design of Calderwood Dam. This assumption, which was supposed to be on the safe side, resulted in the increased stiffness of the dam toward the abutments in the lower elevations. Fig. 11 shows clearly that this stiffness is responsible for the increase of stress between Blocks 6 and 7 at Elevation 860. Such increase of stress, of course, cannot be considered as making the dam safer.

Mr. Simonds' Equations (2) and (3) are correct only if the vertical and horizontal stresses are, at the same time, the principal stresses. If that is not the case, more complicated expressions should be used.[40]

Professor Bergman questions the method used to compare the stresses that were measured on the prototype and the model. Figs. 11 and 12 speak for themselves and show a reasonably close agreement between these stresses. The writers do not contend that this is the correct method but, as stated in the paper, believe that these diagrams are "indicative at least."

The writers are very much impressed by the two model tests described in Mr. Smith's discussion. First, a complete plaster-celite model of an arch dam was loaded with mercury. The deficiency in weight of that model was 98 per cent. The deflections of the crown cantilever were measured. Second, a slice model at the crown cantilever was built using the same plaster-celite material, but loading it by additional weights to about forty-nine times the weight of the original material. This model was loaded, not with mercury, but by using a wire pulley and weight arrangement, so as to have the load correspond to the mercury load that was carried by the cantilever. These loads were evaluated by the trial-load method. The cantilever deflections in both cases were found to be practically the same. To the writers the procedure seems wholly inadequate and was made necessary on account of the type of model used.

Nevertheless, Mr. Smith arrives at the conclusion that the trial-load method is correct and that the weight of the model material is of no importance. Actually, the deflections of the cantilever depend on the ground conditions and on the weight of the material of the dam. There does not seem to be any rational inter-relation between the two models and between these models and the prototype.

(*V*) *Design Methods and Theories.*—The different methods used in the design of arch dams are summarized in a paper by one of the writers.[18] Typical cross-sections are given[41] of a number of dams designed by the two design methods that are most used at present. One design neglects the gravity action and the other uses the trial-load method in which an attempt is made to consider the gravity action.

The measurements made on Calderwood Dam and the model work described in the paper seem to indicate that the neglect of the gravity action leads to a radical discrepancy between the actual and the design conditions. From the current engineering point of view such a method cannot be considered satisfactory. The trial-load method represents some improvement.[41] However, this method is far from being satisfactory or even reasonably approaching a method that should find general recognition.

A tendency seems to be developing in arch dam design to consider everything highly satisfactory and to disregard any evidence to the contrary. The supporters of the trial-load method seem to be going very far in that direction. It may be of interest to survey the present conditions. More or less satisfactory measurements were made on two commercial dams: Calderwood Dam, on which the most extended series of deflection and stress measurements were made, and Ariel Dam, on which deflection measurements were made, but stress measurements were omitted. On the Gibson Dam preparation for making measurements was included, but unfortunately no measurements of value could be taken. The measurements made on Calderwood Dam could not be verified by the use of the "trial-load" method. The Ariel Dam was designed by the use of the trial-load method and the deflection measurements disclosed a rather startling difference in the evaluated and measured deflections.[81]

[40] "The Determination of Stresses from Strains on Three Intersecting Gage Lines," by William R. Osgood and Rolland G. Sturm, Assoc. Members, Am. Soc. C. E., *Research Paper No. 559*, National Bureau of Standards, *Journal of Research*, Vol. 10, May, 1933.

[41] "The Compensated Arch Dam," by A. V. Karpov, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 98 (1933), Figs. 1 and 2, pp. 1310–1311.

The only tests by which the trial-load method could be verified are the model tests made on mercury-loaded models on which the specific gravity requirement was grossly violated and on which neither the foundation and abutment conditions nor the joint conditions were properly represented. Under such conditions it seems that the statements so often made in recent years, that the designs of arch dams are based on proven test data, are over-optimistic. It is no secret to the Engineering Profession, that the safety of high arch dams is not obtained on account of sufficient engineering knowledge, but rather to the contrary: The present limited engineering knowledge makes it necessary to use in such dams a much larger amount of material—unsatisfactorily distributed—than would be necessary if the design could be based on proved assumptions. In that respect the horizontal cracks or the openings of horizontal construction joints in arch dams are very significant. In the latest designs, and in particular in the trial-load designs, vertical tension stress that could produce cracks or joint openings of such character presumably are absent; consequently, the tendency is to attribute such cracks to faulty construction methods, contraction of the concrete, etc. In fact, such an explanation was accepted a few years ago on one of the arch dams with which the writers were connected. The tests on Calderwood Dam and its model show very clearly that such cracks, not caused by faulty construction methods or by shrinking concrete, may be caused by high vertical tension stress at both the up-stream and the down-stream face of the dam. Such stresses cannot be evaluated by using one of the conventional design methods; nor can they be disclosed on mercury-loaded models.

The proper design of an arch dam should give consideration to the following items: (1) Flexibility of foundations and abutments; (2) non-linear distribution of stress; (3) substitution of properly shaped horizontal arches instead of the arbitrarily chosen circular arches; (4) influence and proper utilization of the construction joints; and (5) necessity of liberal use of fillets.

These items can be investigated on a model in which the specific gravity requirements are satisfied. A low value of Poisson's ratio would make a more satisfactory model, but even when using a material with a high Poisson ratio satisfactory conclusions can be drawn.

The mercury-loaded plaster-celite model does not make possible the proper investigation of any of these most important requirements and, consequently, no satisfactory design theory can be developed from studies on such models.

Conclusion.—In conclusion, the writers would like to emphasize a few points which often seem to be neglected, but which are of considerable importance in the model study of structural problems.

1.—It should be realized that the new conceptions in physical and chemical sciences necessarily involve engineering. Designers of important structures should take cognizance of the fact that the conventional stress theories do not represent the actual conditions, and that, in the building up of the new theories, many engineering assumptions must be revised and many rejected, notwithstanding the fact that until recently they were considered perfectly sound.

2.—The present design methods do not disclose the importance of obtaining reasonably flexible structures. No matter how massive or stiff an engineering structure may be, it acts substantially as an elastic structure. The applied load introduces stresses that result in strains, deformations, and deflections. The value of the actual stress can be determined accurately if very refined design methods, based on proper assumptions, are utilized. Very often, due mostly to lack of knowledge, less refined design methods combined with unreliable assumptions are used. Then the actual stresses, at least in some parts of the structure, will be higher than the evaluated stresses; and stress concentrations that were not foreseen in the design, will occur.

Comparing two similarly designed structures of a different degree of flexibility, the stress concentrations in a more flexible structure will be not as high as in a stiffer structure, the more flexible structure having a better opportunity to distribute the stress more uniformly.

In some cases an increase in material in some parts of the structure may increase considerably the stiffness and thus result in much higher stress concentrations. Under such conditions, contrary to the design data, the actual stress may be higher in some parts of a structure in which more material is used as compared with a structure in which less material is used. Designs obviously should not be used in which the stresses are increased on account of the use of an increased amount of material.

3.—A properly designed model, if used discriminately, is one of the most valuable of engineering tools and permits the correct solution, among others, of the most complicated structural problems; but models are not miraculous tools, and valuable results are obtainable only if theoretically correct models are used.

4.—In any model study it is necessary to approach the problem without preconceived ideas to be proved or confirmed. Only a model which is given a fair chance to act naturally and in a manner similar to the prototype will give reliable results. Models that are forced to act in a certain way dissimilar to the action of the prototype, in nearly all cases will be misleading, and should not be used.

FORMATION OF FLOC BY FERRIC COAGULANTS

By Edward Bartow,[1] M. Am. Soc. C. E., A. P. Black,[2] Esq., and Walter E. Sansbury,[3] Esq.

With Discussion by Messrs. Edward S. Hopkins, W. D. Hatfield, L. B. Miller, Linn H. Enslow, and C. J. Brockman.

Synopsis

Ferrous sulfate (oxidized by atmospheric air in the presence of alkali), ferric chloride, chlorinated copperas, and ferric sulfate are used as coagulants in water purification. Natural waters contain varying quantities of sulfate ion, chloride ion, sodium ion, calcium ion, etc. An experimental determination of the action of these ions on the formation of floc with ferric salts at different pH-values shows the following results: (1) On the acid side the sulfate ion has a much greater effect on coagulation than the chloride ion; (2) using from 25 to 250 ppm of sulfate ion, there is little change in the effect produced; (3) between a pH-value of 6.5 and a pH-value of 8.5, there is a zone in which ferric floc forms slowly or not at all; and (4) in and beyond this zone, sodium and calcium ions are most effective in coagulation.

The assumption of a change in the sign of the colloidal ferric floc from positive, where it is more affected by sulfate or chloride ions, to negative will explain the zone of no floc formation and the more effective action of the sodium and calcium ions beyond this zone.

The quantity of residual iron in solution is roughly proportional to the time required for the floc to form.

Note.—Presented at the meeting of the Sanitary Engineering Division, New York, N. Y., January 19, 1933, and published in December, 1933, *Proceedings*.

FERRIC COAGULANTS

It has long been recognized that ferric compounds may be utilized in the formation of floc for the removal of color or turbidity from natural waters, but it is only in recent years that they have become available in adequate quantity and at a price sufficiently low to compete with alum.

With the possibility of increased use of these ferric coagulants, the writers have undertaken a study similar to that made by Messrs. Bartow and Ben. H. Peterson[4] and by Messrs. Black, Rice, and Bartow[5] on aluminium sulfate. It is known that aluminium salts and iron salts differ in their action when used as coagulants in water treatment, and the purpose of this paper is to try to determine and explain these differences.

Ferrous Sulfate as a Coagulant.—Ferrous sulfate with lime was first used by Mr. W. B. Bull, at Quincy, Ill. According to Mr. Dow R. Gwinn[6] the experiments were begun in July, 1898, the ferrous sulfate being made by burning sulfur and passing the gas into water and over scrap iron. Chlorinated copperas made by adding chlorine to a solution of ferrous sulfate was used by Messrs. F. W. Mohlman and J. R. Palmer,[7] at Chicago, Ill., in the coagulation of sewage sludge. It has since been adapted to water purification.

Since the coagulation takes place after oxidation to ferric salt by the oxygen of the air, ferrous sulfate is really a ferric coagulant. It is unsuitable for the treatment of certain types of waters. Soft, colored waters, or soft, turbid waters, are best coagulated on the acid side of the neutral point—at pH-values of less than 7. (pH is equal to the log of the reciprocal of the hydrogen-ion concentration.) The color appears to become fixed or set by the addition of alkali. The use of ferrous sulfate is limited, therefore, to those waters in which alkalinity will not interfere with color removal. It has been shown by Mr. L. B. Miller[8] and, later, by Messrs. Jacob Cornog and Albert Hershberger[9] that when alkali is added to a dilute solution of ferrous sulfate, a small fraction of one equivalent increases the pH to about 7.5. It remains practically constant at this figure until nine-tenths of an equivalent of alkali has been added; then it rises again rapidly to a pH of about 11.0. Further addition of alkali up to the theoretical two equivalents produces little change in the hydrogen-ion concentration. According to Mr. Miller (see Fig. 1), the first zone of fairly constant hydrogen-ion concentration is due to the formation of a basic salt. It is obvious, therefore, that ferrous salts are precipitated by alkali only at comparatively high pH-values.

A more important factor is the atmospheric oxidation of the ferrous coagulant to the ferric state. Messrs. J. A. N. Friend and E. G. K. Pritchett[10] and Messrs. Cornog and Hershberger[9] have shown that the rate of oxidation of ferrous salts by atmospheric oxygen depends upon both the concentration of the ferrous salt and the hydrogen-ion concentration. For the exceedingly low concentrations met with in water-works practice, the rate of oxidation increases as the hydrogen-ion concentration decreases; that is, the rate increases with increased pH-values.

Mr. C. V. Smythe[11] has shown that certain anions greatly influence the rate of atmospheric oxidation of ferrous compounds. The theory is advanced that the ferrous ion forms un-ionized complexes with the anions in question and that it is easier to remove an electron from such a neutral complex than from a doubly charged ferrous ion. In terms of this theory the oxidation of ferrous salts in alkaline solution would involve the formation of insoluble neutral molecules of ferrous hydroxide which are far more readily oxidized than the ferrous ion. These considerations also apply in the removal of iron from natural waters by aeration.

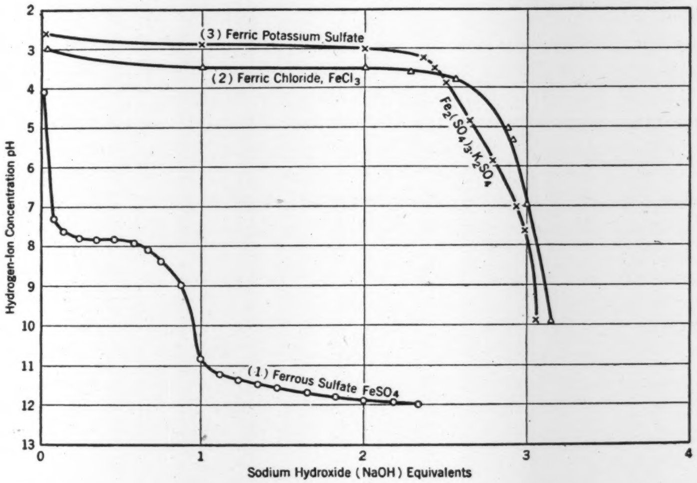

FIG. 1.—COMPARISON OF CHANGE IN HYDROGEN-ION CONCENTRATION (pH), DURING PRECIPITATION OF FERROUS HYDROXIDE AND FERRIC HYDROXIDE BY SODIUM HYDROXIDE.

Ferric Salts as Coagulants.—Ferric chloride made by treating scrap iron with gaseous chlorine obtained directly from a chlorine cell was used experimentally in 1910 in Chicago and in Toledo, Ohio, by Mr. Bull.[12] Ferric chloride in concentrated solution, shipped in rubber-lined tank cars, has been available since about 1930. Ferric sulfate in dry form was placed on the market in 1931.

In coagulation or formation of floc, the action of ferric salts is very different from that of ferrous sulfate. According to Mr. Miller[8] a very dilute solution (0.01 M) of ferric sulfate, when treated with an alkali, has a pH-value of 3 when two equivalents of alkali have been added; of 4 when two and one-half equivalents have been added; and of 7 when the three equivalents theoretically required have been added. (The symbol, M, denotes mols, or molecules per liter.) With ferric chloride the pH-values are slightly higher. (See Fig. 1.) This means that a ferric floc may be formed in solutions that are much more acid than would normally be encountered in waterworks practice.

Since soft, colored waters and soft, turbid waters may usually be coagulated more satisfactorily on the acid side, alum or a combination of alum and sulfuric acid has been used satisfactorily as a coagulant with such waters. However, since aluminium hydroxide is amphoteric (that is, exhibits both acid and alkaline characteristics), its solubility increases as the hydrogen-ion concentration increases. Messrs. E. J. Theriault and W. M. Clark,[13] Mr. Miller,[14] J. R. Baylis, Assoc. M. Am. Soc. C. E.,[15] and W. D. Hatfield, Assoc. M. Am. Soc. C. E.,[16] state that from the acid side precipitation becomes complete at pH 5.4. At less than pH 5.4 alum floc will re-dissolve and pass the filters unless secondary coagulation is utilized following color removal. However, with many highly colored waters, successful clarification may be obtained only at much lower pH-values. Mr. L. L. Hedgepeth and W. C. Olsen, Assoc. M. Am. Soc. C. E., report[17] an optimum pH-value of 4.9 for Elizabeth City, N. C., and L. H. Enslow, Assoc. M. Am. Soc. C. E., gives[18] the optimum zone for highly colored swamp waters as pH 3.8 to 4.7. Such acidities make coagulation with alum impossible, but satisfactory results may be obtained with ferric salts.

Ferric floc is not only more insoluble at lower pH-values than alum floc, but is also more insoluble at high pH-values. The possible pH-range of floc formation is, therefore, decidedly broader on both sides of neutrality for ferric salts than for alum. The ferric floc as ordinarily formed has a higher specific gravity than alum floc and, therefore, requires shorter sedimentation periods.

Explanations differ as to the exact mechanism of the process by which turbidity and certain types of color are removed. While it has long been thought that the highly adsorptive gelatinous floc plays the leading rôle, Mr. Miller[19] in his fundamental work indicates that color removal is most often accomplished by neutralization of the negatively charged color colloid by the positively charged trivalent aluminium or ferric ion and that as a rule "alum floc" and "iron floc" play relatively unimportant parts.

EFFECT OF VARIOUS ANIONS ON FLOC FORMATION

Waters apparently similar in character may respond in very different ways to the same method of treatment. This is particularly true of the hydrogen-ion concentration, at which optimum floc formation is secured with a given dose of coagulant. The point of optimum coagulation may be as low as pH 3.8, in the case of highly colored swamp waters, or it may be greater than

8.0 with other types of waters. It is often true that the pH-range within which good flocs may be formed rapidly is relatively narrow and in some cases the pH-values must be adjusted closely.

The investigations of Messrs. Bartow and Peterson[4] and of Messrs. Black, Rice, and Bartow[5] have explained in part at least the "individuality" possessed by most natural waters. These investigations have shown that the anions present in the water treated, particularly the sulfate and chloride ions, influence to a marked degree the pH-zone of optimum floc formation when alum is used as a coagulant. The bivalent sulfate ion extends the pH-zone of optimum floc formation far to the acid side and very slightly to the alkaline side, the effect increasing, as would be expected, with increasing quantities of sulfate ion. The monovalent chloride ion has much less influence than the bivalent sulfate ion. It does broaden the pH-zone somewhat, and it is to be noted that its effect is somewhat greater on the alkaline side than that of the sulfate ion.

Messrs. Black, Rice, and Bartow,[5] at the experimental water treatment plant of the University of Florida, have shown that results obtained in jar tests are likewise obtained when large quantities of water are treated.

In view of the marked effects exerted by the sulfate and chloride ions on the pH-zone of optimum alum floc formation, it seemed desirable to determine the effect of these ions on the formation of ferric floc with various ferric coagulants.

Three ferric coagulants are available to-day—chlorinated copperas, ferric chloride, and soluble ferric sulfate—although chlorinated copperas is not sold as a ferric salt. It is a mixture of ferric chloride and ferric sulfate obtained by oxidizing ferrous sulfate (copperas) with chlorine; hence its name. The reaction is as follows: $6FeSO_4 + 3Cl_2 \rightarrow 2Fe_2(SO_4)_3 + 2FeCl_3$.

In practice, 1 lb of chlorine is required for 8 lb of copperas. As stated previously, chlorinated copperas instead of ferric chloride was first used by Messrs. Mohlman and Palmer[7] for dewatering sewage sludge. It proved greatly superior to alum. It was first used in water purification by Messrs. Hedgepeth and Olsen[17] in 1928 for the treatment of the highly colored water supply of Elizabeth City, N. C. The so-called "color floc" produced at low pH-values by the action of the trivalent ferric ion on the negatively charged color colloid was stated by them to have adsorptive properties far superior to those of a true ferric hydroxide floc. Following its highly successful use at Elizabeth City, trials were made elsewhere, and several papers describing the results obtained are available in the literature. A. C. Decker, M. Am. Soc. C. E., and Mr. H. G. Menke[20] used the process at Birmingham, Ala. Mr. E. S. Hopkins,[21] at Baltimore, Md., studied the floc produced by this material.

Messrs. E. C. Craig and E. H. Bean,[22] at Providence, R. I., have used the three ferric coagulants interchangeably and conclude that there is less than 10% variation in the results obtained with any of them when they are compared on the basis of equal iron content.

EXPERIMENTAL

Coagulation experiments have been made in the stirring apparatus used by Messrs. Black, Rice, and Bartow[5] in the study of the effect of various anions on the formation of aluminium floc.

For these experiments six battery jars (3.5 liter capacity) were used; 2 liters of water were used for each test. Glass stirrers were used to mix the water in the battery jars. They were composed of glass blades, each 3 by 15 cm, attached to vertical glass rods, 1 by 25 cm, which, in turn, were attached to vertical steel drive shafts by heavy walled rubber tubing, so that each might be disconnected and the jars removed during a run. The vertical shafts were supported on an iron framework and on the upper end had pulleys, all driven by one continuous belt from a small electric motor. Identical conditions of illumination and the formation of Tyndall cones were produced by rays from 100-watt electric light bulbs, controlled by a single switch, the light from which passed through $\frac{3}{8}$-in. holes in a long wooden box placed behind the jars. The Tyndall cones produced were so sharp that it was usually possible to duplicate the shorter floc times to 15 sec in successive experiments. To exclude heating effect from the bulbs, the side of the box nearest the jars was lined with asbestos board which, together with a 1-in. air gap between the box and the jars, caused a maximum rise of only 1°C during the longest runs. The apparatus with the exception of the motor and gear reducer was built in the machine shops of the University of Florida at little cost. G. E. Willcomb, Assoc. M. Am. Soc. C. E., describes[23] the construction of laboratory stirring machines of this general type.

Method of Procedure.—The determined quantities of alkaline solution and salt solution to be used, were placed in a 2-liter volumetric flask, made up to a volume of 1 975 milliliters, with distilled water, thoroughly mixed and placed in the jars. Stirring was begun and 25 milliliters of coagulant solution was added to each jar. The time of addition was noted with a stop-watch. The time at which well defined floc formed in each jar was carefully noted, and the total elapsed time for each jar was corrected for the time required to add the coagulent.

The equivalent of 1.6 grains of coagulant, calculated as $Fe_2(SO_4)_3 \cdot 9H_2O$, was used for each test. This is the approximate molar equivalent of the 2 grains of alum used in previous work. The quantities of alkali in the various tests required to adjust the solutions to the desired pH-values, were determined by experience.

Standard Solutions.—The purest analytical grade of chemicals was used for the preparation of all solutions, which were made of such strength that convenient small volumes, when diluted to a final volume of 2 liters, gave known concentrations of the desired constituent. In the case of the coagulants, 25 milliliters of working solution represented a dose of 1.6 grains per gal., calculated as ferric sulfate. The solutions of sodium chloride, sodium sulfate, sodium bicarbonate, and calcium chloride were of such strength that each milliliter contained 10 mg of the respective anion. The chlorinated copperas was prepared by passing chlorine gas through a ferrous sulfate solution until oxidation was complete, as shown by testing with potassium ferricyanide. Air was then bubbled through the solution until starch iodide paper showed the absence of excess of free chlorine. Concentrated stock solutions of ferric sulfate and chlorinated copperas were prepared and the exact strengths determined by titration with standard potassium dichromate solution. Since the dilute working solutions were unstable, they were prepared from the stock solutions in small quantities as needed.

---

[23] *Journal*, Am. Water Works Assoc., Vol. 24 (1932), p. 1416.

As soon as the floc had formed in a jar, this jar was removed from the machine without interrupting the stirring of the other jars. A portion of the water from the jar was placed in a clean Erlenmeyer flask, tightly stoppered, and allowed to settle until it was clear and bright. The pH-values of all solutions were determined by the isohydric colorimetric method fully described elsewhere.[5] Samples of solution (10 milliliters) were carefully pipetted into color comparison tubes, filled with air from which carbon dioxide had been removed, each containing 0.5 milliliter of an indicator solution of chosen pH-value. Thorough mixing was secured, without shaking, by allowing the water to flow from the pipette tip into the indicator solution in the tubes. The tubes were stoppered to exclude carbon dioxide and were then compared with buffer-color standards in a comparator. Ordinarily, the pH-value of each sample was determined with indicator solutions of three different pH-values. From the data a value for the hydrogen-ion concentration could be obtained which was reliable to 0.05 pH-unit.

Residual iron determinations were made by the thiocyanate method on samples of the water filtered through two thicknesses of ashless filter paper.

Floc Formation at Varying pH-Values

The time of floc formation was determined at varying pH-values in solutions of coagulant and distilled water, in which the alkalinity was furnished by sodium hydroxide in one case and sodium bicarbonate in the other. The pH-zone in which a ferric floc would form under these conditions was relatively narrow, pH 5.0 to pH 7.0. This is entirely on the acid side of the neutral point. (See Fig. 2.) The minimum time for floc formation occurred at about the same place, pH 6.1 to pH 6.4, but the zone was somewhat wider in the case of sodium bicarbonate.

Effect of Sulfate Ion on Floc Formation Using Ferric Sulfate Coagulant.—Sulfate ion as pure sodium sulfate, $Na_2SO_4 \cdot 10H_2O$, was added to the water in dosages of 25, 50, 125, and 250 ppm, and its effect on the pH-zone of floc formation determined. It was interesting to note: (1) That (see Fig. 3, Curve 1). the zone of rapid floc formation was greatly widened on the acid side (floc formed in 4½ min at a pH-value of 3.9); (2) that the effect of a dose of 25 ppm of sulfate ion (see Curve 2, Fig. 3) was almost as great as that of a dose ten times as large (Curve 5), which was not found to be the case with alum[4]; (3) that the time of floc formation increased markedly in the pH-range, 7.0 to 8.5, after which it again decreased as the pH increased to the maximum used in this work, 9.6; and (4) that the solution containing 25 ppm of sulfate ion, which flocculated rapidly at all pH-values between 4.0

and 7.0, failed to flocculate in 45 min between pH-values of 7.0 and 8.0. This interesting and unexpected behavior of these solutions in this pH-range will be discussed later. (Points marked with an arrow signify that no floc formed within 45 min at the designated pH-value.)

Effect of Chloride Ion on Floc Formation Using Ferric Sulfate Coagulant.—Chloride ion furnished by sodium chloride was added to the water in dosages of 25, 50, 125, and 250 ppm, and its effect on the pH-zone of floc formation determined in the same manner as for the sulfate ion. (See Fig. 4.)

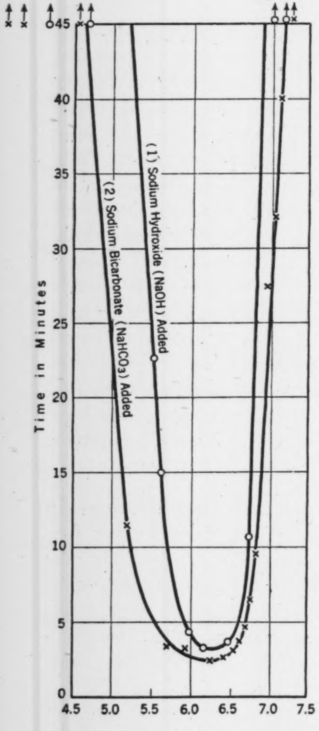

FIG. 2.—RATE OF FLOC FORMATION BY FERRIC SULFATE WITH HYDROGEN-ION CONCENTRATION ADJUSTED BY: (1) SODIUM HYDROXIDE (NaOH); AND (2) SODIUM BICARBONATE ($NaHCO_3$).

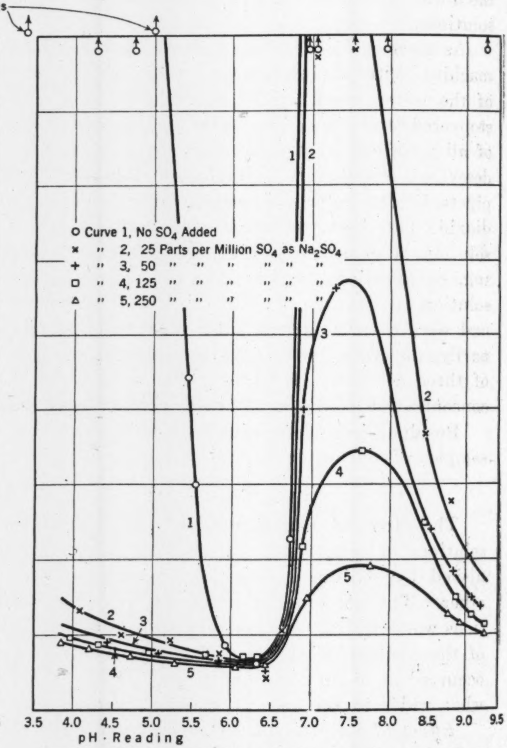

FIG. 3.—EFFECT OF SO_4 AS SODIUM SULFATE (Na_2SO_4) ON THE ZONE OF FLOC FORMATION BY FERRIC SULFATE ($Fe_2(SO_4)_3$) AT VARYING pH-VALUES.

On the acid side the chloride ion was not nearly as effective as the sulfate ion in influencing the formation of floc. While the zone of floc formation was greatly broadened on the acid side, the time required for the floc to form was considerably longer in all cases. This behavior is quite simply explained when it is remembered that the floc forms first as a positive

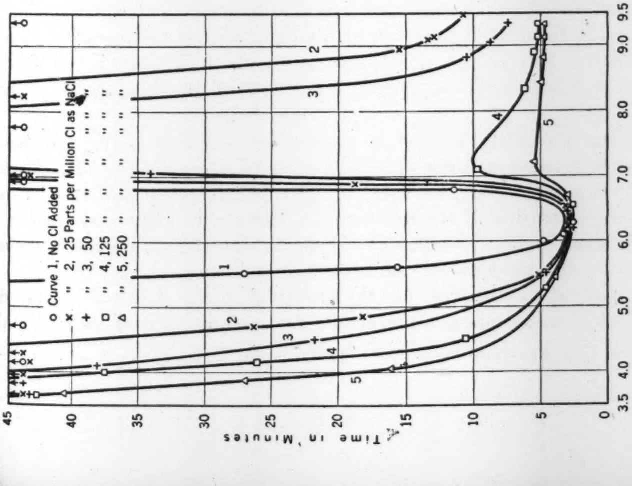

FIG. 4.—EFFECT OF CHLORIDE-ION AS NaCl ON THE ZONE OF FLOC FORMATION WITH FERRIC SULFATE.

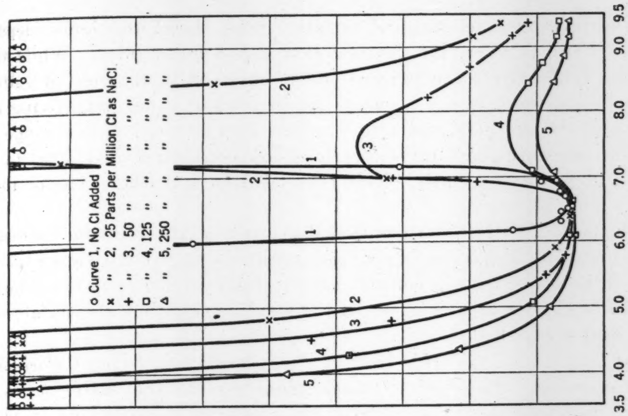

FIG. 6.—EFFECT OF CHLORIDE-ION AS NaCl ON ZONE OF FLOC FORMATION WITH CHLORINATED COPPERAS.

colloid. The precipitating effect of negative ions, therefore, should depend largely upon their valence and should follow the Schultz rule.[14] While this rule explains qualitatively the relative effects observed in the case of sulfate and chloride ions, water-works chemists are in need of exact data giving the quantitative effect of these and other anions over a considerable range of hydrogen-ion concentrations in the various ion concentrations likely to be encountered in water treatment. This investigation furnishes some of these data.

As in the case of sulfate ion mentioned previously, the floc time increased in the pH-zone, 7.0 to 8.5, and decreased again above pH 8.5 (see Fig. 3). It was noted, however, that in concentrations of 125 to 250 ppm, the chloride ion appeared to exert a greater effect on the alkaline side than the sulfate ion. (Compare Fig. 3 and Fig. 4.)

Effect of Sulfate and Chloride Ions on Floc Formation, Using Chlorinated Copperas Coagulant.—In order to check these results, the entire series of experiments was repeated using chlorinated copperas as coagulant in place of ferric sulfate. The quantity of ferric ion added to the solutions was the same in both cases. In the low dosages used, it is evident that the slight differences in the chloride and sulfate content of the two coagulant solutions were not significant. The procedure for obtaining the data was identical in every respect with that described for ferric sulfate. The action was practically identical with that when ferric sulfate was used as a coagulant. (See Fig. 5 and Fig. 6.) The zone of rapid floc formation was greatly broadened on the acid side by the sulfate ion and to a much less degree by the chloride ion. The floc formation was markedly retarded in the pH-zone, 7.0 to 8.5. At the higher concentrations, the effect of the chloride ion appeared to be greater than that of the sulfate ion.

Effect of Sodium and Calcium Ions on Floc Formation.—A possible explanation of this seemingly anomalous behavior of the chloride and sulfate ions at pH-values greater than 7.0 is that the sign of the colloidal floc particles reverses at pH-values in the neighborhood of 6.5. Mr. Miller[19] showed by cataphoresis experiments that the colloidal flocs with which he worked almost invariably bore a positive charge relative to the solution in which they were formed. In certain of his experiments with colored waters, he did obtain negatively charged aggregates which he attributed to the combination of the positive floc with an excess of the negatively charged color colloid.

In studying the adsorption of phosphate ion by ferric oxide hydrosols from solutions of mono-sodium, di-sodium, and tri-sodium phosphate, Messrs. W. Stollenwerk and M. von Wrabgel[24] found that adsorption decreased markedly as the concentration of the hydroxyl-ion increased. They explained it by assuming a reversal of the colloidal charge in the more alkaline solutions probably due to the influence of the hydroxyl-ion.

If the sign of the charge on the colloidal ferric hydroxide floc did reverse as has been assumed, there should be a point or zone in which the floc bears no charge. This should be the point of minimum stability at which precipitation should take place most rapidly. On the alkaline side of this point or zone, the cations present in solution, and not the anions, should act as precipitating agents. Sodium chloride contains approximately 40% of sodium, whereas anhydrous sodium sulfate contains only 32.4%, and the apparently anomalous behavior of the chloride and sulfate ions might be due, not to these anions, but to the greater concentration of sodium ion furnished by the sodium chloride. If this is true, a bivalent cation should exert a greater effect than the monovalent sodium cation at pH-values above 6.5.

---

[24] *Zeitschrift für Electrochemie,* Vol. 33 (1927), p. 501.

In order to test the theory, two series of experiments were made with ferric sulfate as coagulant. In one set chloride ion was supplied in the form of sodium chloride and in the other, in an equal amount, in the form of calcium chloride. The results obtained furnish strong evidence for the correctness of the theory. Flocs formed more quickly in solutions containing only 5 ppm of chloride from calcium chloride than in solutions containing 50 ppm of chloride from sodium chloride. The solutions containing 25 to 50 ppm of chloride from calcium chloride formed more quickly than any other flocs worked with in the entire investigation. (See Fig. 7.) To test the theory further two series of experiments were made using only distilled water and coagulant, supplying the alkali in one series with sodium hydroxide and in

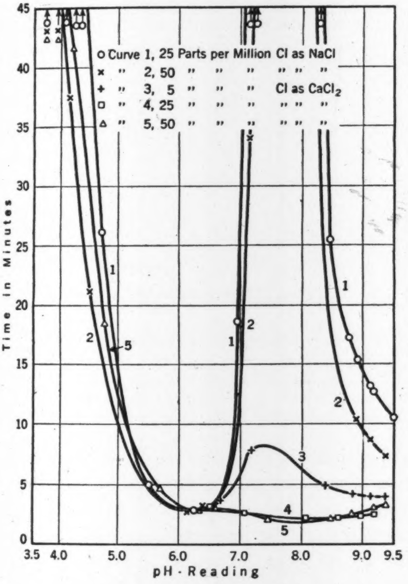

FIG. 7.—COMPARISON OF EFFECT OF SODIUM CHLORIDE AND CALCIUM CHLORIDE ON FLOC FORMATION WITH FERRIC SULFATE.

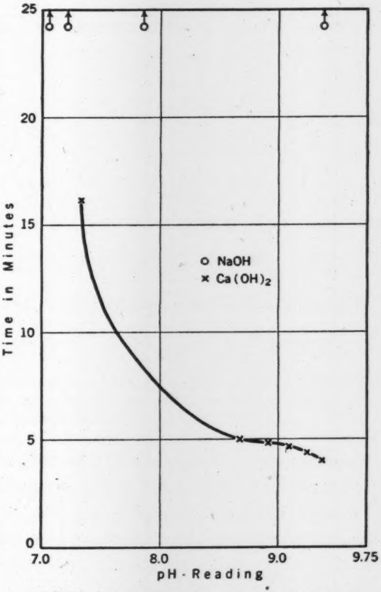

FIG. 8.—COMPARISON OF SODIUM AND CALCIUM IONS ON FLOC FORMATION WITH FERRIC SULFATE.

the other series with calcium hydroxide. Where sodium hydroxide was used, no floc formed in 45 min at pH-values between 7 and 9.0, whereas when calcium hydroxide was used, a floc formed in 16 min at a pH-value of 7.3, and in 5 min between pH-values of 8.6 and 9.4. (See Fig. 8.)

Messrs. Bartow and Peterson,[4] in one set of experiments, made a comparison of the relative effects of equal dosages of sodium and calcium sulfates on the time of formation of alum floc. Their results (see Fig. 9) reveal the interesting fact that, while the differences are not marked, calcium sulfate gave wider zones of floc formation on the alkaline side than were given by sodium sulfate, used in equivalent amounts.

Colloid chemists make a distinction between the rapid coagulation and the slow coagulation of hydrophobic sols. In both cases the ion of charge opposite to that carried by the colloidal particles is the effective agent in causing precipitation. In rapid coagulation there are no differences due to the nature or concentrations of the coagulating ions. In slow coagulation on the other hand, the nature and concentrations of the ions must be considered. M. V. Smoluchowski[25] developed a theory of coagulation from the kinetic point of view, which is confirmed by observations. The colloidal particle is assumed to consist of a central charged particle surrounded by an envelope of ions of opposite charge. This envelope of ions may extend rather deeply into the liquid phase, and the double layer so produced gives rise to a potential difference termed the ζ-potential. The repulsive forces between the sol particles are due to this ζ-potential and in the range of rapid coagulation it is abolished. He developed the following formula:

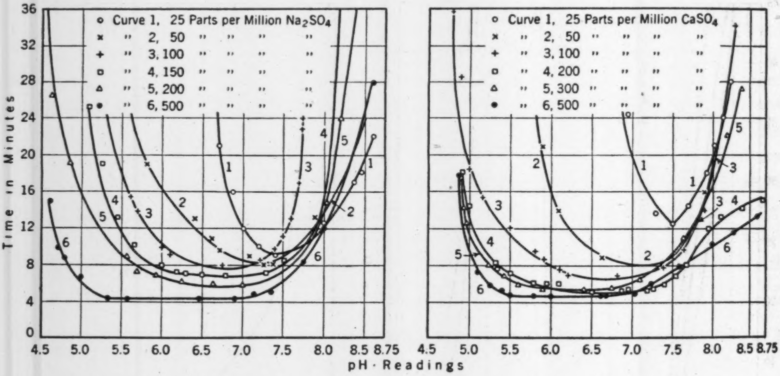

FIG. 9.—COMPARISON OF EFFECT OF SODIUM SULFATE AND CALCIUM SULFATE ON COAGULATION TIME OF ALUM FLOC.

$$K_r = 4\pi D l \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which, K_r is the velocity constant, assuming that the coagulation takes place as a dimolecular reaction: D, the diffusion constant of the particles;

---

[25] *Zeitschrift für Physikalische Chemie,* Vol. 92 (1917), p. 155.

and l, the distance from each other to which two particles must approach, in order that the collision between them becomes effective. There is no factor introducing the nature and concentration of the electrolyte producing coagulation.

For slow coagulation, Mr. Smoluchowski[25] introduces an additional factor into the equation. In this case, the formula is stated:

$$K_s = 4\pi D l \xi \qquad (2)$$

in which, ξ signifies that only a certain fraction, ξ, of all collisions results in coagulation. This fraction, ξ, depends very markedly upon the nature and concentration of the electrolyte. The ion of charge similar to that of the ionic envelope tends to diminish the depth of the envelope, the resulting distortion giving rise to attractive forces. The ion may also be adsorbed on the surface of the particle or even re-act chemically with it. In the zone of slow coagulation, only a certain fraction of the collisions is effective, due possibly to the fact that the particles do not possess sufficient kinetic energy to overcome the ζ-potential. If it is assumed that the distribution of the kinetic velocities of the sol particles follows Maxwell's curve, then the results are as would be expected.

In terms of this theory, the behavior of the ferric hydroxide floc might possibly be explained as follows: On the acid side the colloid consists of positively charged particles of ferric hydroxide plus basic ferric sulfate or ferric chloride, surrounded by an envelope of sulfate or chloride ions. In the zone of slow coagulation on the acid side, the sulfate ion is far more effective than the chloride ion and both are effective in proportion to their concentrations. At a pH of about 6.5, at which point rapid coagulation takes place, both ions are equally effective. On the alkaline side of this point there is a second zone of slow coagulation in which the colloidal particles bear a negative charge due possibly to adsorption of hydroxide ions from the solution. In this zone (pH = 6.5 to 8.5), the bivalent calcium ion is far more effective than the monovalent sodium ion, and both are effective in proportion to their concentrations. At still higher pH-values, a second zone of rapid coagulation is approached in which zone both are equally effective. In order to establish definitely the sign of the charge carried by the colloidal floc at various pH-values on both sides of the neutral point, cataphoresis experiments have been begun.

If further work should confirm this apparent change in the sign of the colloidal floc on the alkaline side. it might serve to explain in part the difficulty that is often experienced in color removal in this pH-range, 6.5 to 8.5.

Color is usually present in natural waters in the form of a negative colloid, and it has been assumed that it is sufficiently acid to be appreciably soluble at the higher alkaline pH-values often used in coagulation. While this seems well established, yet the difficulties inherent in the removal of a color colloid by a colloidal floc of the same sign are obvious.

Residual Iron in Solution at Varying pH-Values.—Experiments were made to determine the quantity of iron remaining in solution at various pH-values. A series of runs was made in the usual manner with chlorinated copperas as coagulant. Sulfate ion (25 ppm) was added in the form of sodium sulfate and the hydrogen-ion concentration adjusted with sodium hydroxide at various pH-values from 3.5 to 9.4. The iron remaining in the solution (see Fig. 10), at various pH-values, correlates with the times of floc formation. There is a wide range on the acid side in which little or no residual iron is present. Beyond pH 9.0, when the floc again begins to form, the quantities of residual iron decrease rapidly with decreasing time of floc formation. Determinations were not made beyond pH 9.4 since Mr. Hopkins[21] has shown that the floc is highly insoluble in the pH-range, 9.4 to 13.0. The very high values which he obtained at lower pH-values (11.0 ppm at pH 6.0) are undoubtedly due not to solubility of the ferric hydroxide floc, but to the incomplete oxidation of the ferrous sulfate that he used as coagulant.

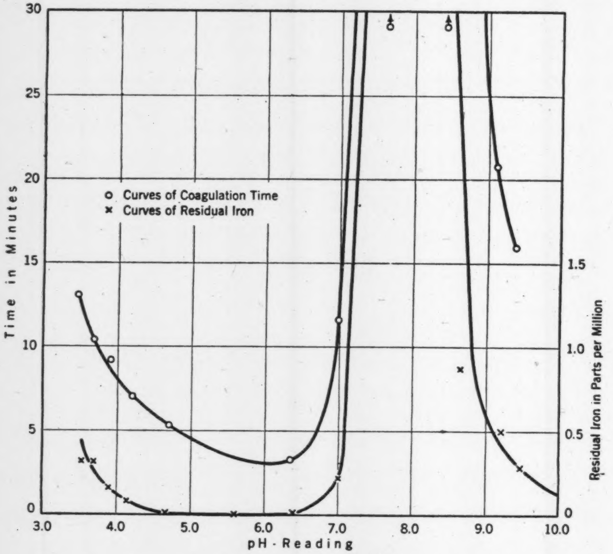

FIG. 10.—RESIDUAL IRON FROM FORMATION OF FERRIC FLOC AT VARYING pH-VALUES, USING 1.6 GRAINS OF CHLORINATED COPPERAS AND 25 PARTS PER MILLION ADDITIONAL SULFATE.

No attempt has been made to investigate the chemical composition of the floc formed at various pH-values, since Messrs. Miller[14] and Hopkins[21] showed rather definitely that the floc is a basic sulfate or chloride until three equivalents of alkali have been added. The molecular ratios, $\frac{SO_4}{Fe}$ and $\frac{Cl}{Fe}$, increase as the pH decreases. When three equivalents of alkali are present, the floc may be washed free of sulfate or chloride and appears to be true hydrated ferric oxide.

DISCUSSION

Edward S. Hopkins,[26] Esq. (by letter).—Practically applied, this paper shows the necessity of completely dispersing and oxidizing the iron salt before the addition of the alkali to produce floc. A fairly high velocity (1 ft to 2 ft per sec) of mixing must be maintained for complete dispersion, followed by a short period (5 min) of agitation to oxidize the iron by aeration. Upon the completion of this initial mixing the alkali should be added to form floc. Upon addition of the alkali a colloidal iron solution is immediately formed and by continued mixing at high velocity, coagulation occurs. A decreasing velocity through the basin beyond this point will produce a compact floc of greater tenacity than if uniform speed is maintained. Such a floc settles readily. This is an important factor in mixing-basin design and should be considered in future plans. It is believed that trouble with "pin-head" floc can be frequently traced to insufficient velocity or time of mixing. Microscopic examinations indicate that the physical properties of floc depend in a large measure on mixing conditions.

Coagulation of color in waters is a different problem chemically from that of turbidity. The sulfate ion, obtained from either alum or ferrous sulfate, is an important component of the floc and is of equal value to the iron or aluminum ion for coagulation of turbid waters. Color combines only with the aluminum or iron ion forming the flocculated organic particles of color floc. This coagulation is best at very low pH-values (4.0 to 5.0). When alum is used, it is becoming good operation practice to settle the color floc, then add coagulant and alkali, thereby raising the pH, with additional mixing to coagulate the turbidity followed by secondary sedimentation, the final effluent passing to the filters. The data presented in this paper, together with information from the Montebello Laboratory, indicate that if the color is coagulated by iron salts in the initial part of the mixing basin, alkali may be added in the latter part, necessitating only one sedimentation period. Analysis of floc thus obtained gives a formula of $Fe_2O_3 \cdot 3H_2O \cdot 2SiO_2 \cdot 4X$, when X represents the organic color material in combination. These results indicate that iron salts may be more advantageous for color coagulation than alum.

This study indicates that coagulation with iron salts reaches a maximum between pH-values of 6.0 to 6.8. As stated by the authors, it is at variance with previous work done in the Montebello Laboratory. Their assumption that insufficient oxidation of these salts explains this difference appears to be correct and should be accepted unless future work reverses it. Floc formation with chlorinated copperas showed clearly that when the iron was completely oxidized by chlorine, precipitation occurred at very low pH-values (4.0). Iron and lime coagulation is utilized in the Baltimore plant to remove manganese from the supply. This element is not adsorbed by this treatment below a pH-value of 9.0; therefore, no contemporary data are available relating to the effect of oxidation at lower values.

[26] Prin. San. Chemist, Montebello Filters, Baltimore, Md.

By presenting fundamental data of this type to a group of engineers, the authors have shown clearly the necessity of trained chemical personnel in charge of plant operation. This is particularly true for the small water plant; the large ones have such personnel. An excellent junior engineer in charge of plant construction is frequently given its operation after completion, with inefficient results. Under such circumstances the individual is not at fault; it is the wrong type of training that he possesses. Coagulation control is a highly complex problem in colloidal chemistry; therefore, operators should be fundamentally trained in this science thereby giving them a better understanding of the problems involved. Considerable improvement in operation would also result if a closer co-operation could be secured between the designing engineer and the chemical engineer. As is well known, the characteristics of every water are different and, therefore, each source of supply, apart from its engineering problem, is a chemical problem. The advice of the chemical engineer relating to details of plant design would be of mutual benefit and would assure a more smoothly operated plant than is now found in many localities. The architect is needed to provide a beautiful plant, the chemical engineer to minimize operating troubles.

W. D. HATFIELD,[27] ASSOC. M. AM. SOC. C. E. (by letter).—Until recently the coagulation of natural waters by means of iron, lime, and aluminum salts, before sedimentation and filtration, has been more of an art than a science. Although a well-trained chemist was best fitted to study the idiosyncracies of water treatment, even he had to use "cut-and-try" methods which, combined with hard-earned experience, would produce a satisfactory drinking water with a minimum of color, odor, and taste. Each water has been a distinct problem (some more than others) and will remain a distinct problem for some time to come. However, in recent years, material advances have been made in the knowledge and theory of inter-ionic activities. R. S. Weston, M. Am. Soc. C. E., first used pre-chlorination to aid in color removal. Soon afterward numerous investigators began studying the important action of the concentration of hydrogen ions on iron and aluminum flocs and color colloids. For a while the pH, or hydrogen-ion concentration, was believed to be the true governing factor in coagulation, but, later, this guide was found to vary with different types of water; in some cases the pH-zone of coagulation was narrow; in others, it was wide; in some cases, the optimum pH for coagulation was 6.3, in others it was 5.3, and in some water it was as low as 4. In the latter case iron had to be used as the coagulant because alum would not coagulate satisfactorily at a pH of 4.0. When one coagulant would not work another, and then another, was tried.

The individuality of a natural water is due to the compounds it contains in solution, and to the equilibrium between these compounds and the coagulant added. This phase of water treatment has been sadly neglected. The authors have made a real contribution to this field, by showing the effect of the chloride, sulfate, sodium, and calcium ions in conjunction with hydrogen and hydroxyl-ions on the coagulation of the ferric ion. Such contributions as these will soon completely remove water purification (coagulation) from an art to a science which is based on a definite knowledge of the part played by each individual component of the solution.

---

[27] Supt., Sewage Disposal Plant, Decatur, Ill.

The use of ferric salts in water treatment followed its use by Messrs. F. W. Mohlman and J. R. Palmer[7] in the coagulation of activated sludge in sewage treatment. The practical problems in water, sewage, and sludge treatment differ greatly, but fundamentally the theory on which coagulation of iron salts rests, must be basic and applicable in both fields. It is hoped that the authors will carry to a conclusion these ionic studies, using all the ions found in waters, sewages, and sludge liquors. Perhaps even the sewage field may some day rest on a firmer theoretical basis, due to a clearer knowledge of these ionic activities.

L. B. MILLER,[28] ESQ. (by letter).—In addition to summarizing clearly the pertinent work previously done on ferric coagulants for water clarification, its significance, and limitations, the authors have made a most significant contribution to the theory and practice of the use of ferric coagulants. The zone of non-floc formation between the pH-values of approximately 7.0 to 8.0 could not be anticipated; and, indeed, in some of the earlier work in which more concentrated solutions were used than those by the authors, it remained unnoted. The importance of this zone of non-floc formation in the practical application of ferric coagulants to water clarification cannot be over-estimated. It indicates clearly the conditions under which the water-works engineer must operate, in order to achieve optimum results.

The theory of the use of additional salts, such as those of alkali and lime, to control, partly, the formation of floc in the zones in which ferric coagulants exhibit a reluctance to floc formation, is interesting, and the practical significance of the application of this theory may be of considerable importance in certain cases.

The comparison of alum with ferric coagulants in the clarification of waters highly colored by organic matter, where clarification must be carried out at low pH-values, the advantages, and limitations of each of these types of coagulants, are likewise very opportunely emphasized.

LINN H. ENSLOW,[29] ASSOC. M. AM. SOC. C. E. (by letter).—In Nature a certain amount of natural coagulation is constantly going on, in which iron salts play an important rôle. Soluble iron is contributed through reducing reactions on iron compounds in the rocks and soil. Later, upon becoming oxidized, the iron thus brought into solution flocculates in running streams and at or near the surface of water bodies at rest. It is highly probable that such natural coagulation is responsible, to a considerable extent, for the gradual lessening of organic color in new reservoirs, more particularly the deep ones. In the latter the same iron is returned to the solution stage after having settled to the bottom and is released to the upper strata to flocculate anew.

Diffusion, wind action, and turnover of reservoir contents due to wind action and temperature changes, serve to complete the precipitation-solution-precipitation cycles.

Whenever the writer notes references in the literature that laud the work of Mr. L. B. Miller, who in 1923 to 1925 studied coagulation effects and the composition of the floc produced under varying conditions, he is always hopeful that some one will look a little farther back and give some of the deserved recognition to an earlier worker, Dr. Frank E. Hale, who did not have the new "constellation," pH, to serve as the remarkable tool that it is in coagulation studies and control. Hale, working with various waters, reached the conclusion that color removal was due primarily to the formation of a complex compound from the acidic color compound and the amphoteric hydrate of alumina. He explained why effective flocculation and precipitation did not necessitate the theoretical quantities of alkali in certain waters, and his paper[30] abounds in theoretical discussion and conclusions which have been substantiated in practice or confirmed by subsequent investigators—but rarely, if ever, with acknowledgment.

Early Work with Chlorinated Copperas.—The origin of chlorinated ferrous sulfate (chlorinated copperas) can be traced to the laboratories of the Chicago, Ill., Sanitary District. Ferric chloride had proved considerably superior to alum and other coagulants for conditioning sewage sludge for dewatering. Its "drug store" price was the chief obstacle to its use. The simple expedient of oxidizing ferrous sulfate solutions to produce a mixture of ferric sulfate and ferric chloride was the outgrowth of a search for the most inexpensive ferric coagulant obtainable. Its efficiency was lower than that of ferric chloride, but the over-all cost to obtain desired effects was sufficiently less to cause its adoption at Houston, Tex., for activated sludge dewatering. Shortly afterward, the City of Milwaukee, Wis., followed in quick order and although chlorinated copperas can still be used at a lower cost at Houston, Milwaukee found it less costly to purchase, on long-time contract, a supply of ferric chloride in solution which is shipped in rubber-lined tank cars. Since then several sewage plants—notably Gastonia, High Point, and Charlotte, N. C., and Pasadena, Calif.—have supplanted other conditioning agents with ferric chloride.

Coagulation of Water.—Following the successful adaptation of chlorinated copperas to sludge dewatering, the writer made several tests of its use as a coagulant for water and industrial wastes. It was soon apparent that it was a coagulant considerably superior to others in the low pH range (5.5 and less) and the pH range greater than 8.5. The outcome of this was its introduction at Elizabeth City, N. C., where studies were conducted on a plant scale by L. L. Hedgepeth, in co-operation with the writer.[18] Its use at Chickasaw, Ala., and at other points followed, notably its adoption at Providence, R. I.,[22] and Dallas, Tex. It can be stated with reasonable assurance that ferric iron salts are superior coagulants in dealing with color removal from water and with organic matter removal from other liquids, such as trade wastes and sewages. This statement applies in the matter of costs as well as efficiency.

---

[30] "The Relation Between Aluminum Sulphate and Color in Mechanical Filtration," by Dr. Frank E. Hale, *Journal of Industrial and Engineering Chemistry*, Vol. 6, August, 1914, p. 632.

In some instances, notably when oxygen is present to a sufficient extent and the pH is 9.0, or more, ferrous salts will serve. The chief drawback to the use of unoxidized iron is the fact that effective coagulation is slow, and frequently indifferent. The fact that ferrous hydroxide must first be produced and that thereafter it changes to the insoluble ferric hydroxide, or to some more complex compound, requires more time and longer mixing periods, than is the case where the iron is pre-oxidized, in part if not in whole, before introduction to the liquid being treated. In coagulating creamery wastes ferrous sulfate coagulates primarily as a light and feathery floc of ferrous hydroxide, and but little reaches the ferric state because of lack of oxygen.

Relationship Between pH-Values, Effectiveness of Coagulation, and Unprecipitated (Residual) Iron.—Of particular interest to the writer are the observations of the authors as illustrated in Fig. 10, revealing the pH-zone of quickest floc formation and the most perfect precipitation of the iron added in the form of chlorinated copperas. The curves, indicating that in the zone between pH 4.5 and pH 6.5 iron removal was complete and practically complete between pH 3.8 and pH 7.0, and, similarly, that floc formation was most rapid over the same range, might have been drawn by plotting actual operating data at the filter plant in Elizabeth City, N. C., during the periods of operation with which the writer is familiar.

Using colorless water fortified with calcium chloride the studies made in the laboratory of the University of Iowa show that the floc, if formed at all, was very poor between pH 7 and pH 9.5, but the residual iron was satisfactorily eliminated at pH 9.5 and beyond. Such high pH-values can not be considered as of practical use, in dealing with soft organic waters. Color removal would show a minus efficiency because alkalinization not only disperses color, but intensifies it, due to the fact that some of the organic compounds met with in water act as pH indicators to the extent of showing deeper color with increasing pH-values.

In practice, when coagulating with ferric salts at pH less than 7, the appearance of residual iron indicates the need for increased dosage of coagulant; and that is actually done in practice to meet the circumstance rather than reducing the iron applied or increasing the alkali, if the latter is used. It has been demonstrated in laundry waste treatment that acidification with sulfuric acid serves almost the same purpose, provided the necessary minimum of ferric iron is present to produce the floc effectively and give it the high gravity desired.

The authors made some reference to the fact that the quantity of ferric iron was the all-important consideration, regardless of the form in which it is used. In water treatment and sewage coagulation that appears to be approximately correct, but in sewage-sludge conditioning, to the acid side on the pH-scale, it does not hold. Ferric chloride remains superior to chlorinated copperas which probably has 66% of the iron present in the sulfate form, whereas only 33% is converted to the chloride during oxidation of the copperas with chlorine.

New Sources of Ferric Iron.—During the past year there have appeared on the market two ferric sulfate coagulants—one of which is being successfully used at Providence, R. I.[31] Both these products are dry and subject to handling and feeding in the same manner as pulverized sulfate of alumina—filter alum.

C. J. BROCKMAN,[32] ESQ. (by letter).—For too many years the purification of water through the use of chemicals has been thought to be merely the addition of alum, aluminum sulfate, or iron sulfate. Water-works operators in many cities and towns to-day believe that, when some of these chemicals have been added in the treatment process, nothing more can be done to improve the efficiency of the filtering process or the quality of the water.

It has not been many years since the term, pH, was introduced. The pioneer work of Messrs. W. M. Clark and E. J. Theriault, L. B. Miller, and others now too numerous to mention, have afforded an insight into the chemistry of the coagulating process in water-works control.

In the light of the work of these three pioneers, it appeared to be necessary to control the pH of the water within certain limits in order to coagulate the floc efficiently. Unfortunately, this simple procedure is not adequate as has been so ably shown by the authors. "Alkalinity determination" is no longer sufficient. It is now known that "alkalinity," pH, also chloride and sulfate content must be determined before efficient coagulation can be accomplished. It was indeed fortunate that the cheapest aluminum salt in the early days of water treatment was the sulfate and not the chloride, because the latter is more difficult to floc than the former. Consequently, water-treatment processes would have developed much more slowly.

Messrs. Bartow, Black, and Sansbury have shown that the iron floc formation in even such small concentrations as 25 ppm of sulfate ion takes only one-fifth the time as in an equivalent concentration of chloride ion when the pH is about 3.5 to 4.0, as will be the case with many colored waters. With larger values (8 to 9.5) for pH, the presence of sulfate ions also permits more rapid coagulation. They also show that, compared with previous knowledge, chlorinated copperas is more easily made than ferrous sulfate.

Over and above this, the most interesting phenomenon discovered is that the metal ion content of the water has a pronounced influence on the time of floc formation. This is a most outstanding fact of this contribution. In the range of pH of 7 to 9, it is shown that a solution of 5 ppm of chloride, as calcium chloride, is many times more satisfactory than 25 ppm of sodium chloride, and the coagulation range is wider. In the case of sodium sulfate as compared with calcium sulfate, the differences are not so marked; in the lower concentration ranges, the former permits more rapid coagulation and a wider band of floc formation on the acid side, but calcium sulfate allows a wider band on the alkaline side.

[31] "Advances in Iron Coagulation and Coagulants," by E. L. Bean, *Journal*, New England Water Works Assoc., Vol. 47, September, 1933, p. 273.

[32] Assoc. Prof. of Chemistry, Univ. of Georgia, Athens, Ga.

The implication which these facts have on water treatment is that the control of the process has developed into a complicated chemical problem. An efficiently operated water treatment plant must be in the care of a trained chemist, or, at least, under the not-too-distant supervision of some one capable of the necessary directive measures. Accurate control is now more than ever, of prime importance in the water-works.

Water-works chemists will await with interest a completion of this work which will establish definitely the sign of a change carried by the colloidal floc at various pH-values on both sides of the neutral point, because the treatment of colored water is still a serious problem.

MODIFYING THE PHYSIOGRAPHICAL BALANCE BY CONSERVATION MEASURES

By A. L. Sonderegger,[1] M. Am. Soc. C. E.

With Discussion by Messrs. H. H. Chapman, E. B. Debler, Frank E. Bonner, C. S. Jarvis, W. P. Rowe, J. C. Stevens, Gerard H. Matthes, J. B. Lippincott, Rhodes E. Rule, and A. L. Sonderegger.

Synopsis

In Nature, precipitation, erosion, and débris transportation and deposition by stream flow combine to produce, in some measure, a physiographical balance which, while not permanent, undergoes only gradual changes. This balance is expressed in the topography and cover of the mountain water-shed as well as in that of the flood-plain of a drainage area.

Interference with the natural processes of erosion, débris transportation, and disposal of flood waters of the stream of a water-shed by partial or complete regulation, may result in a modification of this physiographical balance to such an extent as to menace existing or future development. This modification of balance may be a slow process, apparent only after a considerable period of time and, for this reason, may be overlooked or considered as negligible; yet it may prove to be the undoing of otherwise well-laid plans.

The effect of interference with natural conditions is accentuated in the semi-arid regions because of the greater extremes of precipitation and other climatic factors which tend toward the accumulation of débris during dry periods. In the Southwestern United States, the regulation of water supply and the control of flood waters has brought about the erection of works of unprecedented size, which regulate large floods and permit the artificial disposal of the entire stream flow.

This paper is intended to call attention to the effect, on the physiographical balance, of the following conservation measures: (*a*) Changes in the water-shed cover; (*b*) effect of regulation on the natural balance of a

[1] Cons. Engr., Los Angeles, Calif.

stream system; and (*c*) effect of débris barriers on the stability of the stream bed on the débris cone.

In the examples presented, it was not so much the intention to discuss in great detail the phenomena which are affected by the modifying of the physiographical balance, but rather to illustrate the theory. For this reason, the problems arising in the mountain water-shed and those which arise in the transportation of débris are not discussed exhaustively.

1.—The Physiographical Balance

The physiographical appearance of a country is generally the combined result of orogenic (mountain-forming) movement and climatic conditions. Crustal movement is responsible for the basic physical features of a country. This basic relief is, however, gradually and continuously modified by climatic factors.

Of the climatic factors, precipitation and the processes accompanying its disposal, are principally responsible for the existing aspects of a country. Although the distribution of precipitation may vary in intensity with seasons and periods, past performance indicates, nevertheless, that over long periods its general characteristics and effects may be adjusted to a mean of conditions governing changes in terrestrial appearance which, to the human eye, is seemingly more or less permanent and unchanging. In other words, despite their erratic character, climatic factors in general, and precipitation in particular, produce in Nature what might be termed a state of equilibrium, or balance, expressed in a certain type and density of native vegetation, in more or less stable gradients of stream beds, in the disposal of débris, in the slopes of the plains, etc. It is a balance of natural forces which is seemingly maintained while, at the same time, the phenomenon of stream erosion gradually produces changes on land surfaces.

Any long-sustained change in the mean precipitation would naturally be followed by an adjustment to new conditions. A decrease in rainfall of 20% may transform habitable semi-arid areas into uninhabitable deserts. An increase in the mean precipitation by the same amount would result in less severe droughts, increased mean water supply, and in flood conditions of much greater severity. The vegetal cover of the water-shed would adapt itself gradually to the more abundant supply, becoming more profuse, but possibly less drought-resistant. Changed run-off conditions would gradually alter the regimen of the watercourses, including their gradients, stream beds, and character and volume of débris. Slopes of the plains, too, would be affected as well as the vegetation thereon; and ground-waters would rise above their former levels. In other words, the face of the country would alter gradually, but inevitably, until the new balance of geophysical forces becomes seemingly established, in conformity with the changed conditions.

The effect on human life of a long-sustained, substantial increase in wetness might be as far-reaching as that of greater prevalence of drought. In fact, it is conceivable that the disturbances during the period of transition may make human habitation in specific localities difficult, if not impossible, to be maintained.

If, then, there is a natural balance of physical effects, as the result of ages of adjustment to existing conditions, it is logical to infer that any interference therewith by human agencies is likely to result in disturbances. Those disturbances may, or may not, become apparent immediately, but are sure to follow and to remain as long as the cause exists. The very fact that such results are not immediate, or become felt only gradually, may be the reason why they are sometimes overlooked or under-estimated until they have assumed proportions that require heroic counter-measures, or may even have passed beyond control—comparable to the experience of the sorcerer's apprentice who conjured the spirits of witchcraft, but was unable to dismiss them.

A simple, every-day occurrence may serve to explain the continued and relatively far-reaching effect of interference with Nature's equilibrium. Under natural conditions, the gently sloping sides of the foothills are covered with certain types of vegetation which prevent the washing of soil and which are inducive to absorption of rainfall, producing a normal condition preventive of flood run-off, thus affording a physiographical balance on these foothills. If these slopes are cleared and cultivated, erosive action will immediately be noticeable, even if protection by cover crops is provided. It is not uncommon, therefore, that after some years the plow may strike an irrigation pipe line which originally had been buried the customary 2 ft under the surface.

Precipitation causes innumerable rivulets and barrancas on such slopes; flood waste is increased, while deep penetration is diminished, contrary to the opinion sometimes advanced that plowing favors larger absorption of rainfall. Where such slopes are devoted to residential settlement, rainfall penetration will be diminished further, augmenting erosion and flood waste to such proportions as to necessitate costly terracing and the construction of lined storm channels. The one effect which may not be immediately apparent, but may be the most far-reaching, in the long run, is accelerated erosion.

It is concluded that the physiographical condition of an area is the result of the activity and balance of natural processes of precipitation, erosion, and débris transportation and deposition by stream flow over a long period. A pronounced or protracted modification of these phenomena will initiate changes tending to establish a different physiographic balance. Although these changes may appear to be gradual and negligible, their effect, nevertheless, is irresistible and in due time will upset existing conditions.

2.—Changes in the Water-Shed Cover and Their Effect on Run-Off Conditions

Plans for the "improvement" of the water-shed for the purpose of increasing the water yield have been advanced of late years from many quarters. Radical changes in the water-shed cover have a more or less protracted effect on débris production, run-off, and the capacity of the stream to move its load. Aside from the timely agitation for the reforestation of cut-over or burnt-over timber lands, the proposals may generally be segregated into two classes:

First.—"Super-forestation"[3] to the effect of producing a denser growth of native or other vegetation on the water-shed; to "keep the water supply in the water-shed," as the saying goes; and to induce more copious precipitation.

Second.—"Light deforestation" to restrict the vegetation to a minimum compatible with effective prevention of erosion, with a view to reducing the evapo-transpiration requirements of the cover.

Super-forestation (and forestation for that matter) is analyzed as an effort to increase the storage of meteoric water in the water-shed by promoting profuse vegetation which naturally tends to absorb rainfall and diminish flood run-off. By this means surface soils may be better protected from washing, and débris production may be reduced. However, a dense vegetation may also be the cause of more intense forest fires and greater difficulties pertaining to fire protection and fire-fighting. Indirectly, the more complete destruction of plant life by fire, as a result of super-forestation, may be the cause of retarding re-growth and exposing the water-shed to a longer period of abnormal erosion.

Under the caption of reforestation comes the proposal of replacing chaparral by trees. However, since chaparral recovers naturally and more rapidly from fire than trees which would have to be replanted, the effect on the water-shed cover would be decidedly disadvantageous and would be most likely to protract the period of abnormal erosion after a fire.

Efforts at "super-forestation" on a large scale are not likely to meet with success. The general type of the forest cover of a region is indigenous to it and reflects its climatical conditions—mean temperatures, mean precipitation, and other climatic factors—while the range in precipitation and temperatures is reflected in the tolerance of the species, all to the effect that Nature has produced the vegetal cover which, both as to species and density, is best adapted to prevailing conditions. Any attempt, therefore, to induce denser growth is likely to fail, due to the great "weeding-out" process expressed in the law of the survival of the fittest.

Light deforestation is to be considered an effort to reduce underground storage in the water-shed and the evapo-transpiration losses of the cover, at the expense, however, of a more rapid, flashy, surface run-off and correspondingly increased erosive action. Under this category may be grouped: (*a*) The systematic burning of the water-shed; (*b*) the substitution of light water-using species for heavy water users; and (*c*) the cutting of trees which grow along the watercourses, such as alders, willows, sycamores, and the like. Similar results as to light deforestation would result from a diminished vigilance relative to forest fires.

The practicability of these proposals has never been put to a test. The most far-reaching plan in its effect on conditions of stream flow and débris production, and the one entailing the greatest risk, would be the systematic and periodic burning of the chaparral. This has been under discussion and advocated in some parts of California—first, with a view of increasing the water supply; and, second, to prevent the accumulation, over long periods, of masses of highly inflammable débris which results under the existing official policy of protection of the water-shed from fire. Burning is proposed to be done in checker-board fashion at the end of the wet season when humidity is relatively high and when soil moisture is sufficient to produce new sprouts of brush, grasses, and herbs.

---

[3] "Forests and Stream Flow," by W. G. Hoyt, M. Am. Soc. C. E., and H. C. Troxell, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1.

This proposal and others is of a highly controversial character. Although advocated in certain localities with considerable popular and political pressure, those in charge of water-sheds and responsible for damages, should the burning get beyond control, have been slow in yielding to the demand. In a report of the Ventura County (California) Farm Bureau[3] relative to the burning, it is stated:

> "The general consensus of opinion among those with great experience in fire-fighting is that when it is dry enough to burn, it is too dangerous to burn, and when it is safe to burn, the vegetation will not burn."

The effect of denudation by fire manifested in flashy, heavy flood flow and abnormal débris load, the possible destruction of surface storage, and the flooding of the plains, is too well understood to require discussion. A point sometimes overlooked is the sealing effect of ashes on the stream bed, which greatly reduces natural seepage, to the extent of more than offsetting the increase in the water yield of the burnt-over water-shed.

However, forest fires will be a factor as long as the public is allowed free access to the mountain areas. They will have to be reckoned with to an increasing degree in the planning of flood-control and conservation measures.

The forest cover unquestionably has an important constructive function in Nature, which may not be fully appreciated because it is not well understood. Its preservation should be uppermost in the minds of water conservationists because of the far-reaching and lasting effects that destruction or denudation of the water-shed will have on flood flow and on the production and movement of débris. It is not generally recognized that domestic water supply, irrigation, and hydro-electric enterprise have rights in the control of the water-shed. In settled regions, the value of the water-shed for natural storage and regulation of run-off may be superior to any other uses, such as grazing, recreation, or even the commercial exploitation of its timber and, therefore, should receive due consideration.

In the past there has been little or no co-operation between the forester, the engineer, and the water user, except to the extent of protection of the water-shed from fire hazard. A step toward a better understanding of the common problem was undertaken by the Committee on Water Conservation of the Irrigation Division of the Society, by calling a conference[4] of research workers, engineers, foresters, and agriculturists. This meeting resulted in the outlining of a program to correlate the work of the various groups relative to conservation of water supply.

---

[3] Mimeographed Rept., Conservation Committee, Ventura County Farm Bureau, April 8, 1931.

[4] Mimeographed Rept. on "Conference of Research Problems in Consumptive Use of Water and Conservation of Rainfall, Los Angeles, Calif., March 27, 28, and 29, 1930."

As yet, the function of the water-shed in its ramifications is not well understood. The United States Forest Service in late years has initiated a comprehensive program of research with a view of increasing the water yield and decreasing the fire hazard. When these investigations have progressed to the point where definite conclusions can be drawn as to the practicability of the proposed plans and their ultimate effect on the water yield, a logical solution may present itself. From the standpoint of general economics and efficiency of flood control and conservation, proper co-ordination of the improvements of the water-shed to those of the flood channel becomes a necessity.

3.—Effect of Regulation Upon the Natural Balance of a Stream System

The work performed by a stream or stream system may be segregated into three distinct functions: First, erosive action on the mountain water-shed; second, the transportation of débris; and, third, the building of débris slopes, or flood-plains.

With undisturbed conditions, each of these activities depends directly upon the combined effect of stream flow and available débris. Since both stream flow and volume of débris are subject to great and, sometimes, erratic fluctuations, it becomes apparent that the magnitude of these uncontrolled forces is forever variable, without attaining uniformity for any great length of time. However, available records indicate that, considering cycles of several years, these stream activities occur between limits that are defined by droughts and capital floods, so that in the intervals between such extremes there is a constant tendency to ‘iron out” the effects of individual floods or periods of drought. There results a state of balance which is characteristic for a stream, or stream system, termed its “regimen.” It finds expression in the gradient of the flood-plain and the character of its débris and alluvium.

Stream activity follows lines of least resistance and, therefore, will tend to establish the steepest gradient consistent with the basic factors—stream flow and débris. Only long-sustained climatic changes or the exposure of different geological formations, or a change in botanical cover over large areas of the water-shed, would materially affect the normal gradients and change the character of the débris of the flood-plain. The characteristics of a stream system, therefore, can be established by a study of its deposits and of its gradients.

Generally speaking, and in comparison with the time allotted individual human experience, water-shed erosion and the construction of the flood-plain are relatively slow, but ceaseless, processes.

Nevertheless, if, as a result of the construction of an impounding reservoir, the transportation of the débris is interrupted for a period of years, or if it is stopped, a permanent effect on the stream bed and flood-plain below is certain to follow.

If the stream bed is used for the diversion of the impounded water, the clarified effluent—having the capacity to load itself anew with sediment—will begin to scour and meander, reducing its gradient and changing its wetted perimeter. These new conditions, acting on the alluvium of the former natural stream, therefore, will establish a new state of equilibrium, in due time, expressed in flatter gradients. A further and vital change will occur at the point below the reservoir where the stream intercepts the first major tributary.

With a stream system functioning normally, there is a balance of forces between the flow of the main stream, its gradients, and the débris carried by it and those similar functions of its tributaries. The addition of a tributary brings about a flatter gradient in the main stream for some distance above the junction, while at and below the junction such steeper slope is established as may be required for the movement of the added débris. The tributary, as a rule, has a lesser run-off and steeper gradient than the main stream, its characteristics being reflected in its own flood-plain where it has established the most favorable conditions for the transportation of its own débris under its own conditions of flow.

If the main stream is regulated while the tributary remains unregulated, sooner or later conditions at the junction of the two will become critical because of the absence of the flood flow in the main stream, which formerly was available for the removal of the sediments and débris from the tributary. The tributary, now having to assume the rôle of the main stream, cannot cope with the wider stream bed and flatter grade of the latter, hence the deposition of sediments, a raising of both stream beds, and inundations at the junction.

A natural correction of these conditions cannot take place unless storage is released at intervals and in sufficient quantities to cause the movement of the excess sediment. However, since this remedy may not prove effective without serious infringement on storage, the only other solutions will be: (*a*) To improve conditions of flow in the main stream below the reservoir by straightening the alignment, to line the channel to meet the flow requirements of the tributary, or both; (*b*) to regulate the tributary itself by means of surface storage, as in the case of the main stream; and (*c*) to construct débris barriers on the tributary for the purpose of reducing its load.

In any event, if tributaries are of sufficient magnitude, the problem may prove to be a baffling one and not easily solved. If it can be solved at all, it may require the expenditure of relatively large sums, or the periodical removal of débris.

The depth of deposits when spread over a wide flood-plain even during a period of years, is relatively insignificant and its absence would not be noticeable or of material effect in a life time. From the geological standpoint, the volume of débris stored in the largest reservoirs is small.

Some observations pertinent to the foregoing discussion have been made in Southern California. During a series of dry years, the San Gabriel River with 218 sq miles of drainage area may have little or no flood run-off, because all the normal flow has been diverted, so that the stream bed remains dry over long distances below the mouth of the canyon. During the same period, the tributaries flowing in more or less trained channels and receiving the run-off from urban areas, have high, flashy silt-laden flows with every rain. At the point of junction with the river, this silt is deposited in the river bed, filling it enough so that inundation of adjacent lands during floods becomes a possibility.

In the Western States, the regulation, and, in some cases, the ultimate complete diversion of the flow, of large rivers form the bases of many reclamation and flood-control projects.

The regulation of a stream presents one problem and the effect of this regulation upon the tributaries becomes the cause of another problem. Although this effect may be gradual and over a period of normal stream flow create no menace, a new condition has been initiated which must be met sooner or later. In planning regulation works, this phase should receive the engineer's attention, as affecting either the quantity of storage that may become available for beneficial use, or requiring measures for the improvement of tributaries. The question arises in particular, as to whether it is feasible to regulate the capital flood run-off for irrigation or domestic use. In some cases this has been advocated regardless of costs when such flood flow might be wasted more profitably for the removal of débris.

Experience on the Rio Grande, in Texas, as a result of the construction of the Elephant Butte Dam, will serve to illustrate the foregoing analysis. In that case the problem is complicated by the use of the river channel below the reservoir for the conveyance of irrigation supplies.

4.—The Effect of Regulation of Rio Grande on Flood Conditions Below Elephant Butte Dam

The Rio Grande drainage basin above El Paso, Tex., occupies the south central part of Colorado and the central part of New Mexico. Drainage areas are divided as follows: Above San Marcial, N. Mex., 26 700 sq miles; above Elephant Butte Dam, 28 360 sq miles; and above El Paso, 30 460 sq miles. Fig. 1 shows the principal geographic and topographic features of Rio Grande Valley from San Marcial (Elevation 4 458), at the north end of Elephant Butte Reservoir, to Fabens, Tex. (Elevation 3 619) on the Rio Grande, 26 miles below El Paso.

Elephant Butte Dam is located across the bed of the stream about 125 miles above El Paso, and creates a reservoir of about 2 600 000 acre-ft capacity. The mean annual run-off at San Marcial, at the head of this reservoir, is roughly 1 200 000 acre-ft. The entire discharge of the Rio Grande has been retained in the reservoir (except as released for irrigation use) since storage operations started in 1915. The highest recorded discharge at San Marcial prior to 1930, was 33 000 sec-ft and the highest passing El Paso prior to the construction of Elephant Butte Dam was 24 000 sec-ft. The highest discharge at El Paso since the construction of Elephant Butte Dam is 13 500 sec-ft. The large floods which occurred at intervals of several

years, prior to the construction of the dam, covered the valley lands and often established new locations for the main river channel. In 1912, a peak of 16 000 sec-ft at El Paso flooded an area of 15 900 acres of land in the El Paso Valley. Except for overflow confinement by road and canal embankments the flooded area would have been much greater.

Prior to the construction of the dam the channel was shifting, due to its lengthening during years of low flood and to erosion and change in alignment during higher floods. Silt entering above the dam is 1.6% of the flow, by volume, the average annual silt burden being 20 000 acre-ft. The slope of the river below Elephant Butte Dam measured along the thread of the stream (as determined by a survey made in 1917) was about 4.00 ft per mile for the first 100 miles, or to the Mesilla Dam; 3.50 ft per mile from Mesilla Dam to Canutillo, Tex., 30 miles; and 2.8 ft per mile from Canutillo to El Paso, 15 miles. Below El Paso, the river had gradients as determined from the survey made in 1917 of from 2.45 ft per mile for the 6 miles immediately below the International Dam, to 1.45 ft per mile to the vicinity of Fabens, 50 river-miles below. River gradients through El Paso Valley, as determined from a survey made in 1907, varied from a slope of 1.83 ft per mile for the first 20 miles below the International Dam to 1.54 ft per mile near the 60-mile point. Other stretches had gradients of as much as 2.70 ft per mile.

River gradients as determined from the survey of 1932 show marked changes from the foregoing. In the reaches immediately below the dam heavy detritus from arroyos which the present river flow is unable to move, has formed rapids, resulting in a decrease in gradient. There is usually a decrease in gradient below the dam, although this is doubtless due to scour. Several artificial cut-offs have been made and these have caused scour above and filling below. Immediately below the International Dam, at El Paso, filling has taken place so that now the river bed is 12 ft higher than in 1907 and 6 ft higher than in 1917. This is in marked contrast to the action at the other diversion dams where scour below has resulted, this being approximately 6 ft at Percha Dam, 2 ft at Leasburg Dam; and 1 ft at Mesilla Dam; all as compared to the 1917 record.

The regulated discharge for irrigation demand as released from Elephant Butte Reservoir varies from 500 to 2 500 sec-ft. The Rio Grande is used as the main carriage channel of the Rio Grande Project with four diversion dams at the heads of as many irrigation divisions in the 200-mile length of the river through the project. In addition to the flow released at the dam, the river receives drainage water and run-off from arroyos, which drain the 2 100 sq miles between the dam and El Paso. This latter run-off is sporadic. In 1916, the flow from a combination of arroyos was 8 000 sec-ft. On September 1, 1925, rains on drainage areas of several arroyos caused a discharge of 13 500 sec-ft at El Paso. Large fans of eroded material from these arroyos now (1933) extend into the river or valley lands, according to topography. These materials were formerly carried away by the river. At points where they reach the river, the irrigation supply is now continuously loaded with fine sand by the action of the comparatively clear water from

Elephant Butte Reservoir on these accumulations. The concentrated discharge from one arroyo, resulting from an isolated cloudburst, has often equalled the discharge of all arroyos during a general rain. The drainage areas of these arroyos varying from a few square miles to 400 sq miles, are partly denuded of growth.

With the completion of the storage works, and the assurance of water supply throughout the irrigation season, the irrigated area was enlarged. Drainage canal embankments and lateral canals constructed near the river channel confined the flow to a more definite location and the deposition of sediment to a limited area. The former meandering river channel became the main canal for the project. Maximum flows were reduced more than 50%, the mean annual flows throughout the project were reduced 30%, and the run-off extended throughout the length of the irrigation season of nine months, rather than being concentrated in the spring or fall.

Project diversion works, as well as principal canal structures, were provided with skimming weirs and canal wasteways to the river, which are constructed and operated to return the sand sediment to the river and to prevent large maintenance costs. As these desilting devices were perfected and general sluicing operations became more effective, sand accumulations were concentrated in the river channel. River profiles show the effect of such deposits at diversion points and at the outlets of the wasteways.

Cross-sections of the river channel before and after construction of the storage unit are of interest in expressing the actual effect of the control and regulation of discharge on the former river channel. Table 1 gives the change in areas of cross-sections below a given elevation.

As may be expected, the decrease in flow at the lower end of the project, due to the consumption for irrigation purposes, has resulted in a closing in of the channel. This is shown in Table 1 for all sections below the International Dam. Furthermore, side fill is shown in many of the sections and immediately above the Mesilla Dam, "Line 30," bottom fill has resulted due probably to the checking effect at that dam. The absence of large destructive floods has afforded no opportunity for the former scouring action, and the river channel below El Paso has filled with sand sediment to a point where it is higher in many places than the adjoining farm area. As the channel thus conforms itself to the normal irrigation flow, floods from excess rainfall on the drainage area below the dam cause the overflow of the low-lying areas adjoining the river channel. The elevation of the river channel, of course, is no new condition. Practically all the valley lands were formed by river deposits of silt and sand from upper drainage areas.

Thus, the outstanding characteristics of the present regimen of the Rio Grande are: (1) The entire absence of large floods to scour the bottom of the river bed; (2) continuous flow in the river of a quantity sufficient to cover the necessities of irrigation, a flow that produces a continuous accumulation of sediment which is deposited in that part of the valley below El Paso, where the decrease of the flow and the reduction of the slope favor this deposit; (3) diminution of the flood area of the river in the lower parts of the valley, in consequence of this continuous deposit of sediments; (4) a river bed at present inadequate to permit the free passage of the waste waters of floods that may rise from the combination of the simultaneous discharge into the river from the various tributary arroyos below Elephant Butte Dam; and (5) greater actual danger of inundation of the lower river lands caused by the waste waters of the present smaller floods than those that occurred before the construction of the Elephant Butte Dam.

The proposed solution of the problem consists of shortening the river from 155 miles to 88 miles between El Paso and Quitman Canyon, by making cuts across bends. In this manner the slope of the channel is changed from 1.8 ft to 3.2 ft per mile.

As the silt content of the river at El Paso is only about 500 acre-ft per year, it is anticipated that following this rectification of the main channel, the flood and normal irrigation flow of tributaries will be of sufficient magnitude to produce scouring and to establish a new stable channel.

5.—Effect of Débris Barriers on the Stability of the Stream Bed on the Débris Cone

The stabilizing of stream courses on the cone has become a factor of importance in the semi-arid areas of the Southwest because the hillside and the cone have been proved to enjoy better protection from frosts than valley areas and, hence, to be better adapted to high-class residential development and to the culture of semi-tropical fruits. Furthermore, the availability of deep gravel deposits and the general commanding elevation above irrigable areas make the cone the most desirable location for the conservation of flood waste by water-spreading in contour ditches or ponds. Hence, the necessity of diverting flood waters on the cone by means of diversion dams into canals and ditches and of confining flood areas by levees for the protection of spreading grounds and residential areas.

Stream Action on the Cone.—The débris cone of a stream is defined herein as the alluvial deposit accumulated below the mouth of its canyon and over which the stream periodically meanders. When the flood stream emerges from the confining walls of the canyon, the path is clear for a lateral spreading. Velocities, therefore, will decrease and so will the transporting power of the stream; all to the effect that sediments and detritus will be deposited on the cone, more or less graded from the coarsest at the apex to fine materials at its base. This alluvial action constantly obstructs and tends to force the stream into other paths. The location of the stream bed on the cone is, therefore, inherently unstable, because there is no longer a balance between stream flow and the débris in traction.

As a rule, streams arrive at the base of the cone in broad sheets, which, having delivered themselves of their burden, then again collect into one, or possibly more, channels. As this concentration of flow takes place, velocities increase, scouring activity is again initiated, and, eventually, a single stream bed in cut is produced. Thus, a cycle of events is established: Erosive action in the mountain water-shed, the deposition of the débris on the cone, and the issuance from the cone of a stream delivered of its normal load and again capable of scouring its bed.

The apex of the cone being at the mouth of the canyon, shifting of the stream bed is likely to follow more or less along lines issuing radially from the apex, so that any structure or improvement on the cone is exposed to the danger of being flooded, washed out, or covered with débris. Little discussion is needed to show that any attempt to establish a balance on the cone between stream flow and débris by confining the stream between levees, can only be temporarily successful or, at best, will merely shift the location of deposit to lower areas.

It is generally accepted that a riparian owner may lawfully protect his property from the ravages of floods by means of levees, while diversion or other interference with natural conditions of stream flow is at the manipulator's risk. Considering then the instability of a stream on the cone, its manipulation will involve responsibilities which may assume unexpected proportions.

However, there are localities (and they are numerous in California) in which cones are among the choicest frost-free foothill lands, suitable for high-class agriculture or residences. Large areas have thus been improved, representing investments of thousands of dollars per acre and owners, therefore, demand protection from potential hazards, whether caused from natural or from artificial features.

Débris Barriers.—Débris deposition being the basic cause of the instability of stream courses on the cone, the apparent remedy is storage of the debris in the canyon above. A stream thus delivered of its burden has increased capacity for erosive action below, picking up its "normal load" on its course down the cone. In this manner, it may reverse its action from alluvial to erosive and automatically stabilize its alignment by deepening the bed.

A point to be given due consideration is the location of the barrier relative to the mouth of the canyon. If débris storage is accomplished at points only a short distance above the mouth, the stream will reach the cone practically free of débris. In heavy floods, such a stream would have the capacity to pick up and move even the largest type of débris. The general effect would be a deepening of the stream bed in the upper part of the cone, a re-grading of the materials removed, and their transport to points beyond the former margin of the cone. It is conceivable that this last-named activity might be the cause of property damage.

On the other hand, if the barrier is placed at some distance above the mouth of the canyon, the scouring action of the de-loaded stream would be primarily on the intervening section of the river bed, with the effect on the cone less accentuated. This result may be expected in cases where the stream intercepts below the barrier a number of tributaries which furnish a substantial supply of débris.

Over a period of moderate floods, the changes in the stream bed below the débris storage may be minor and gradual, while during capital floods they may be expected to become very marked and may be permanent. The essential fact remains that débris storage in the canyon involves a radical change of natural processes and hence will have its lasting effects on the action of the stream on the cone.

Practical Application of Débris Storage.—The practicability of débris storage behind dams was recognized and adopted years ago by the California Débris Commission to prevent devastation of valley lands by the waste from hydraulic mining operations. Numerous débris dams have been constructed and are being operated successfully in the western foothills of the Sierra Nevada. Of late years, débris barriers have also been used as flood-control measures in Los Angeles County, California, and in Utah.[5]

In the report of the Special Flood Commission[6] appointed by Governor George H. Dern, of Utah, it is stated that the present situation in Davis County is such as to call for steps: (*a*) To erect control works at the mouths of the canyons that have flooded, commensurate with the property values involved; (*b*) to control the débris that will be washed on to the farm lands and other property at the mouths of the canyons by high water in the spring, and by summer freshets; and (*c*) in so far as possible, to control summer floods that may occur until such time as adequate vegetation conditions have been restored on the water-sheds.

The essential requisite for débris storage is an economic dam site, since a reservoir site such as that for economic water storage, is not the governing requirement. The slope which débris will assume behind a barrier can be estimated from a study of canyons with alluvial fills. In such canyons, the gradient of the stream is the combined result of stream flow and débris. These two factors are not affected by the construction of a dam or barrier, which accounts for the tendency of the stream to re-establish the gradient it had before. As a matter of fact, the cone below the canyon mouth assumes the function of the barrier, above which the canyon fill has accumulated, and it is reasonable, therefore, to conclude that the slope ultimately produced above a barrier will not be materially different from that maintained by the old stream bed, except as modified by the greater width of the canyon. The effect of the latter would tend to produce a steeper slope because of less favorable channel properties.

---

[5] "Check Dams Control Débris Movements on Mountain Streams," by L. M. Winsor, M. Am. Soc. C. E., *Engineering News-Record*, August 20, 1931.

[6] "Torrential Floods in Northern Utah," *Bulletin*, Agricultural Experiment Station, Logan, Utah, 1930.

In selecting a site for a barrier, this fact has a bearing on the ultimate débris capacity in that a location below a wide section of the canyon would increase the available space, not only laterally but also vertically, because the new deposit would assume a steeper gradient. Fig. 2 shows the effect of a dam 6 ft high (built in 1921 across one of the active flood channels) on the cone of the Santa Ana River near San Bernardino, in Southern California, for the purpose of diverting water on to adjacent spreading grounds. The original gradient was approximately 3.2 per cent. The débris is exceptionally coarse, consisting mainly of large boulders. The survey of 1932 shows that the channel above the dam has been filled to a gradient of 3% for the first 1 000 ft.

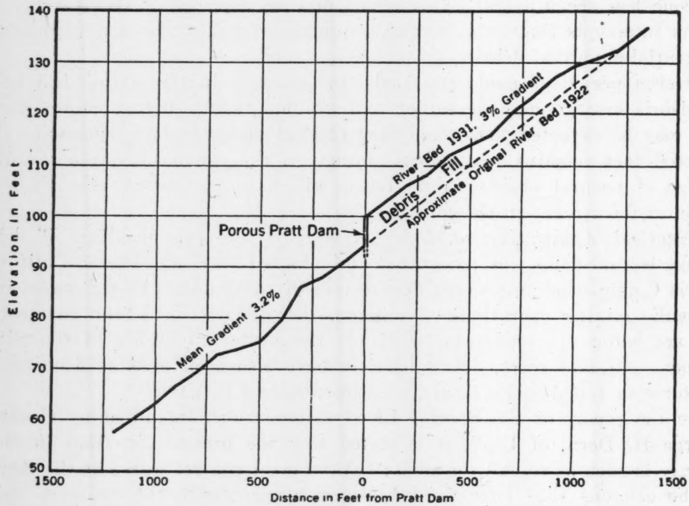

FIG. 2.—EFFECT OF INSTALLATION OF PRATT POROUS DAM ON CONE OF SANTA ANA RIVER, SOUTHERN CALIFORNIA.

The following examples will indicate what gradient may be expected. The Santa Ana River, above Mentone, in San Bernardino County, Southern California, has a well forested water-shed of 189 sq miles. Elevations range from 2 000 to 11 000 ft; and mean run-off is 75 000 acre-ft per annum, the estimated peak flood flow being 29 100 sec-ft, with a mean velocity of 13 ft. The width of the canyon varies for the first 4 miles from 500 to 700 ft. Bed-rock is at 70 ft, more or less. Débris is granitic and exceedingly coarse, with large boulders predominating. The stream gradients are as follows:

Location	Santa Ana River, Southern California: Elevation, in feet	Santa Ana River, Southern California: Gradient of stream bed (percentages)
Cone:		
Mile Two below canyon	1 550	3.8
Mile One below canyon	1 800	3.0
Canyon:		
Mouth of canyon	1 875	1.2
Mile One above mouth of canyon	1 960	2.2
Mile Two above mouth of canyon	2 100	3.8
Mile Three above mouth of canyon	2 320	5.6
Mile Four above mouth of canyon	2 570	4.7
Mile Five above mouth of canyon	2 750	3.4

The San Gabriel River above Azusa, in Southern California, has a water-shed of 220 sq miles, an average run-off of 135 000 acre-ft, and an estimated flood peak of 40 000 sec-ft. Its canyon above the mouth varies in width from 300 to 800 ft. Bed-rock is at 60 ft, or more. The water-shed is poorly forested and steep, rising in elevation to 10 000 ft. Débris is granitic, and less coarse than in Santa Ana Canyon, although boulders of several cubic yards may be found.

The gradients are, as follows:

Location	San Gabriel River, Southern California: Elevation, in feet	San Gabriel River, Southern California: Gradient of stream bed (percentages)
Cone:		
Four miles below canyon	500	1.4
Two miles below canyon	625	1.2
Canyon:		
Mouth of canyon	750	1.2
Mile Two, up stream	875	1.6
Mile Four, up stream	1 050	0.9
Mile Six, up stream	1 150	1.4
Mile Eight, up stream	1 300	1.6

Depending on the character of the débris, gradients as steep as 4% may ultimately be realized. The steep slopes of streams running on bed-rock cannot be maintained with alluvial fills. Where alluvial fills alternate with bed-rock exposures, the latter are characterized, as a rule, by steeper slopes.

The manner in which débris will be deposited above a dam is governed by the general laws of stream flow. In describing the process, the California Débris Commission states[7] that when the first of the débris arrives at the head of the (water) reservoir, where the current is relatively low, it will tend to pile up and thus flatten the slope. This will cause a progressive deposit up stream until the entire bed and slope of the river up stream from the reservior are raised. Thereafter, according to the Commission, feeding into the reservoir will come from material carried along or scoured from this bed.

---

[7] "Hydraulic Mining Investigations in California," Senate Doc. No. 90, 70th Cong., 1st Session, p. 20.

When the débris enters the reservoir, all the tractional load will settle immediately, assuming a steep natural slope down stream, with its top surface in prolongation of the surface of the débris bed in the river above. The suspended material will enter the reservoir with the initial velocity approaching that of the stream, and all but the lightest material will then begin to settle immediately, a portion on the slope of the tractional material and the remainder prolonging and flattening the toe of this slope on the bed of the reservoir to a distance depending on the fineness and specific gravity of the material. The reservoir will thus be filled from the upper end by an extension of the bed of the river into the reservoir, similar to the formation of a delta, with a relatively steep slope at its down-stream end. "The cross-section of the reservoir down stream from this slope," to quote the Commission directly, "will then be reduced only by the deposit of silt until the toe of the delta slope reaches the dam."

It is clear, without further explanation, that the final stable surface of the débris will be that assumed under maximum flood velocities. The foregoing discussion indicates that under suitable conditions, débris storage over a period of years may assume large proportions and that with a series of dams the stream may be stabilized on the cone proportionately as deposit areas are made available.

It is considered imperative that barriers be of a permanent type of dam construction. The sudden release of large quantities of alluvia, as a result of dam failure, might create conditions far worse than the natural meandering of streams on the cone.

As with all flood-control structures financed by public funds, the people assume, and possibly justly so, that the works are of a permanent type, that they do control floods, that they will afford effective protection (any intention of the planner or any publicity to the contrary notwithstanding), and that, therefore, the use of areas formerly menaced by floods may proceed with safety. This psychological effect is accentuated where structures are beyond the easy access by the general public, and it gains with time as minor floods are handled successfully. For this reason, temporary structures that are likely to fail during major floods may augment the dangers incident to the ravages of floods which occur only at long intervals. Débris barriers should be built to maximum heights consistent with funds, and should be provided with spillways and drain outlets. Economic dam sites are found in almost any canyon.

Rate of Débris Production.—Data on débris production in mountain water-sheds are meager. Table 2 was compiled from various sources.[8] Referring to Item No. 2, Column (7), the capacity of Castlewood Reservoir, which was originally 5 267 acre-ft, is said to have been greatly reduced after thirty-eight years. Had the reservoir been filled in this period, the rate of filling would have been 0.83 acre-ft per sq mile, annually.[9] Of the many streams mentioned in Table 2, all except Buckhorn Creek and Cherry Creek drain alluvial plains. Information on these two streams obtained by courtesy of Ralph I. Meeker, M. Am. Soc. C. E., is as follows:

---

[8] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1732, and Vol. 95 (1931), p. 1061.

TABLE 2.—SILT DEPOSITS IN RESERVOIRS

Item No. (1)	Reservoir (2)	Stream (3)	State (4)	Drainage area, in square miles (5)	Record, in years (6)	Silt deposit, in acre-feet per acre per square mile (7)	Silt by volume, in percentage of annual run-off (8)
1	Buckhorn	Buckhorn Creek	Colorado	130	18	0.24	....
2	Castlewood	Cherry Creek	Colorado	165	38	0.83	....
3	Elephant Butte	Rio Grande	New Mexico	30 000	11	0.665	1.66
4	Roosevelt	Salt	Arizona	5 760	20	0.875	....
5	White Rock	....	Texas	114	5	1.19	....
6	Zuni	Pecos	New Mexico	500	22	0.88	1.88
7	Lake Wichita	Holliday Creek	Texas	135	25	Very little	....
8	Lake Penick	Clark Fork, Brazos River	Texas	2 250	7	0.06	....
9	McMillan	Pecos River	New Mexico	22 000	10	0.06	0.8
10	Worth	Trinity River	Texas	1 870	13	0.57	....

Buckhorn (Item No. 1) is a channel reservoir on Buckhorn Creek, a tributary of the Big Thompson River. Its contributing drainage area extends from Elevation 10 500 to Elevation 5 300 at the water surface, but most of it is below Elevation 7 500. The annual precipitation is from 20.00 to 16.00 in. The foothills are grass-covered with some bushes, while the mountain area is covered with pines, spruces, and quaking aspen. Geologically, the foothills are characterized by sedimentaries, ranging from cretaceous to carboniferous material and the mountain area is composed of metamorphic rocks, granites, and predominant schists. The 10 miles of stream channel immediately above the Buckhorn Reservoir traverses sedimentaries that are the chief source of erosion. There are no measured records of flow, the average of 5-year estimates by the Water Commissioner ranging from 2 000 to 51 000 acre-ft per year. The yearly average run-off may be accepted at 19 000 acre-ft.

Castlewood (Item No. 2) is a channel reservoir on Cherry Creek, a tributary of South Platte River. Its contributing drainage area extends from Elevation 7 600 to Elevation 6 500 at the water surface. The annual precipitation is ± 18 in. The cover is mostly grass, with small areas of oak brush and some pines. The surface geology is characterized by sedimentaries in the tertiary group, with loam soil and some rock outcrops. There are no measured records of flow, but it has been estimated by Mr. Meeker at 5 000 to 10 000 acre-ft, with an average of 7 500 acre-ft. Some lands in the basin are dry-farmed.

As to McMillan Reservoir, the period available for the determination of the silt load may not be representative, because the reservoir has been in operation more than 40 years; it has been enlarged twice and loss in capacity may not have been in direct relation to run-off at all times.

---

[9] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1732.

Water Storage in Débris.—The material deposited in reservoirs draining alluvial plains may consist largely of silt and clay with initial porosity that may run as high as 60 or 70 per cent. It is quite different from that produced in mountain water-sheds of crystalline formation and composed of sand, gravel, and boulders, the pore space of which may vary from 8% for materials in which large boulders are predominant to 35% for sand deposits. The following values were determined experimentally for the San Gabriel Wash, in San Gabriel Valley, Southern California,[10] mentioned previously:

Miles below mouth of canyon	Material	Percentage of voids
2	Boulders, gravel, and sand	12
7	Coarse gravel and sand	17
10	Medium gravel and sand	20
12	Fine gravel and sand	28

A reservoir intercepting a stream such as the San Gabriel River would also receive small quantities of silt that otherwise would be deposited in the plains below the cone. The percentage of fine materials might increase considerably if the reservoir should intercept the débris of burnt-over areas, which as a rule deliver large quantities of silt and ashes, depending on the severity of the rain storm.

In semi-arid regions, the water storage in the débris above the barrier may assume commercial value. The tendency of the water-table is to assume a slope approximately parallel to the surface of the débris fill and, for this reason, an appreciable increment of ground-water over and above free-water storage is available. Even with relatively high rates of percolation, a retarding effect is produced and eventually seasonal water storage takes place. Provision for controlled drainage of the débris mass, therefore, should be made at the time the works are planned.

It is interesting to note that, offsetting a diminished water storage in reservoirs resulting from débris deposition, water storage in accumulated débris behind barriers increases in proportion to the quantity of débris.

It is concluded that a feasible method of stabilizing the course of the stream on the débris cone is available in the construction of suitable débris storage above the cone. In planning the location of such storage, it should be borne in mind that the débris plain is the combined result of stream flow and available débris. The complete elimination of débris will reverse stream activity from alluvial to erosive. The effect may turn out to be more radical and far-reaching than expected because of the steep gradients generally encountered and the large volume of the periodic floods. A location at some distance up stream from the head of the cone, which will intercept a part of the débris produced by the water-shed without completely eliminating it, may be worth consideration.

---

6.—CONCLUSIONS

(1).—*Physiographical Balance.*—The great constructive processes of Nature expressed in the functions of the water-shed cover, the stream, the débris cone, and the flood-plain, combine in maintaining a physiographical balance. Any attempt to modify, or reverse, these processes by flood-control or conservation measures will re-act, in due time, in disturbing this balance. Although the effect may be slow, and although it may appear to a fast-moving world as imperceptible or negligible, the change of natural forces thus initiated by permanent improvements may be lasting and irresistible; hence, they present new problems to solve.

(2).—*Physiographical Inter-Relation of Mountain Water-Shed and Flood-Plain.*—In the development of flood control or conservation programs, the agency undertaking the control of streams should be in a position to consider improvements in the mountain water-shed as well as on the flood-plain and to treat the stream system of a drainage area as a unit, because interference with natural conditions at one point on the stream may have its reaction on the physiographical balance at points below and eventually create a new menace which, sooner or later, must be met.

(3).—*Co-Operation of Governmental Agencies Necessary to Attainment of Maximum Yield of Water-Sheds.*—The demand for additional water supplies is responsible for numerous plans advanced from many quarters for the improvement of the water-shed, with a view to increasing its water yield. Some of these plans are considered impracticable, while others entail a risk tending to unbalance débris production and removal. The United States Forest Service and affiliated State agencies, while not approving some of these projects, have initiated systematic studies of the water-shed, however, with a view to increasing run-off and decreasing fire hazard. It is also noted that engineers, investigators, and agriculturists have come to realize that the water-shed is their common problem and that co-operation will lead to a rational solution of water conservation in the water-shed.

(4).—*Storage Regulation May Produce Flood Menace.*—The regulation by storage of a major stream, in time, may become the cause of new inundation problems at the point of junction of tributaries below the reservoir, because the regulated flow may lack the power to move the load which an uncontrolled tributary may carry to the point of junction. This problem may present itself particularly in cases where storage of the capital flood flow is proposed. The effect of the Elephant Butte Dam on flood conditions of the Lower Rio Grande is an example.

(5).—*Effectiveness of Débris Barriers.*—The checking of débris transportation by a débris barrier will change stream activity below until a new load and a modified stream bed and gradients balance the carrying capacity of the stream. This principle may be applied to the stabilization of stream courses on débris cones and on the flood-plain, in that alluvial stream action may be lessened, stopped, or changed to erosive action.

Single barriers built to considerable height (50 ft, or more) are far more effective in intercepting abnormal débris loads which may result from denudation or other causes, than large numbers of check dams built to nominal heights of about 6 ft.

(6).—*Temporary Structures to Check Débris Not Advisable.*—The checking of débris by temporary structures in the mountain water-shed is adverse to best public policy:

(*a*) For the physical reason that an abnormal débris load caused by failure of structures may unbalance stream activity and cause a shifting of the course of the stream, for which the agency erecting the barrier would be responsible.

(*b*) For the psychological reason that the people assume flood-control structures to be permanent and effective for any magnitude of flood. They take for granted that the natural flood channel below such works may be encroached upon and improved without risk.

ACKNOWLEDGMENTS

For the statement, "(4) The Effect of Regulation of Rio Grande on Flood Conditions Below Elephant Butte Dam," the writer is indebted to L. M. Lawson, M. Am. Soc. C. E., for many years Project Superintendent of the Rio Grande Project of the United States Bureau of Reclamation, and, at present (1933), Engineer of the United States Department of the Interior, and United States Boundary Commissioner.

The writer is indebted to S. T. Harding and Charles H. Lee, Members, Am. Soc. C. E., and Harry F. Blaney, Assoc. M. Am. Soc. C. E., members of the Water Conservation Committee of the Irrigation Division, and to L. M. Winsor, Assoc. M. Am. Soc. C. E., for critical review of this paper and constructive suggestions; also to R. L. Egenhoff, Assoc. M. Am. Soc. C. E., for valuable suggestions and for information relative to the operation of mining débris barriers.

DISCUSSION

H. H. CHAPMAN,[11] ESQ. (by letter).—That changes in the water-shed cover upset the state of equilibrium or balance expressed in a certain type and density of vegetation, and that the one effect which may not be immediately apparent, but may be the most far-reaching in the long run is accelerated erosion, as stated by Mr. Sonderegger, are facts worthy of closest scrutiny in their far-reaching effect on irrigation, storage reservoirs, and water control. This balance is maintained over huge areas in the West by grasses and herbage. Profound disturbance of this equilibrium has taken place through excessive over-grazing. Extensive channel cutting has accompanied this phenomenon in the Southwest and intermountain region. That over-grazing is the principal cause of this arroyo formation is proved by the fact, attested by Dr. Earl Morris, Division of Historical Research, Carnegie Institute, Washington, D. C., that the cycle of degradation now operating is of recent origin. Throughout the occupation of the San Juan Area, in Colorado, by agricultural aborigines, the valley floors were rising instead of being cut away. The recent cuttings have laid bare stratified exposures recapitulating in reverse order the entire culture series as it is known to have existed in the area in question. Other outstanding areas showing the same series are Chaco Canyon and Canyon de Chelly. The destruction of all vegetation by grazing animals, the consequent prevention of reseeding, and the beating out of the roots of grass and other plants, are given as the dominant causes of arroyo cutting in this region by this authority on aboriginal American history.

An exceptionally valuable piece of historical evidence as to the condition of the Southwestern rivers in the period preceding the coming of white civilization is found in the diary[12] of the noted explorer, James M. Pattie. Of the Gila River in Arizona, now transformed into a typical sandy wash, he says, on December 14, 1824, "we started early and crossed the river, here a beautiful clear stream about 30 yards in width, running over a rocky bottom and filled with fish"; and "on the morning of February 1, 1826, we began to ascend the Black River. It is a most beautiful stream to the point where it forks in the mountains, that is to say, about 80 miles from its mouth." During January, Pattie trapped the Gila to its junction with the Red, or Colorado River, and on February 2, 1826, says,

> "At twelve, we started up the Red River, which is between 200 and 300 yards wide, a deep bold stream, and the water at this point is entirely clear. The bottoms are a mile in general width. The timber of the bottoms is very heavy and the grass rank and high."

On April 15, 1826, after passing the Grand Canyon, he says, "we returned to the banks of the Red River, which is here a clear beautiful stream."

---

[11] Prof. of Forest Management, School of Forestry, Yale Univ., New Haven, Conn.

[12] "Early Western Travels," by Reuben Gold Thwaites, Vol. XVIII, pp. 87, 131-132.

The cumulative effects of erosion following disturbance of vegetative equilibrium have been discussed[13] in great detail. B. P. Fleming, M. Am. Soc. C. E., has discussed the problem of water erosion in New Mexico, on the Rio Grande area covered by Mr. Sonderegger's paper, and attributes disastrous changes in stream conditions and erosion to overgrazing.[14]

There are incalculable quantities of loose or unconsolidated soils on all water-sheds, capable of being eroded at an accelerated pace once the vegetative balance is destroyed, and of upsetting the calculations of engineers on storage capacity and life of reservoirs.

E. B. DEBLER,[15] M. AM. SOC. C. E. (by letter).—The author has devoted not a little space to forestation and rightly so. It is noted that the Forest Service is stated to be engaged upon a program of research with a view, among other objects, of increasing the water yield. Such research, if conducted without prejudice and with due regard to all interests involved, should receive every possible encouragement. Dogmatic propaganda for tree planting without regard to results other than the growing of trees will injure the cause of reforestation. The effects on grazing, recreation, and water production must be given full consideration.

Silt problems arising from accentuated erosion and from stream depletion merit careful consideration by every one. The mining of soils and their wholesale erosion with or without the aid of Man should not be viewed complacently. As with forestation there must be careful consideration of the attendant risks. Silt barriers are being erected or promoted, wholesale, throughout the United States. Many of these erosion checks or barriers are being built of short-lived materials. Who will maintain these barriers? Are they not likely to lead to even greater damage than now occurring when some future flood sweeps through a series of such structures weakened by age and overwhelms an area built up on a false sense of security? Permanent construction and watchful maintenance are essential to the success of such structures with the latter particularly difficult to secure. The efforts of the author and others to arouse interest in the erosion problem are no longer falling on deaf ears; the public is awakening to this menace, but more remains to be done before the selfish interests of the cattle owner, the sheep herder, the agriculturist, and the miner give way to an enlightened public policy.

The writer cannot fully agree with the conclusions presented in the case of the Rio Grande Project. From the Elephant Butte Dam almost to El Paso, Tex., the author's data show increases in river sections, except only where the sections were formerly much greater than the average. The increase in area is by means of bottom scour, occurring even in some of the sections, which show a net loss. The only area that did not show such a scour was one with a total area fully three times the average, and so unnatural in size that the adjustment of river sections and gradients naturally resulted in a reduction under conditions of regulated flow. Section changes have resulted in increased capacities.

---

[13] Sen. Doc. No. 12, 73d Cong., pp. 298-462 (Copeland Rept.).

[14] "The Southwestern Conservation League," *Bulletin No. 1*, Conservation Series, Univ. of New Mexico, December 1, 1933.

[15] Hydr. Engr., U. S. Bureau of Reclamation, Denver, Colo.

The statement that arroyo fans have formed rapids, is also open to question. Bottom scour with the usual increase in section and the lowering of the stream bed at the dams, supports a conclusion that the rapids are the remains of older fans of coarse materials which have resisted recent removal, whereas the softer bottom material between these rapids has been removed. The writer is unaware of data showing the relative silt deposition in the valley above El Paso before and after the construction of the Elephant Butte Reservoir. It is likely that less silt is being carried away from the project than formerly, but he doubts whether the difference is equal to the amount being deposited in the reservoir.

At the International Dam, near El Paso, a silt plug is in constant process of formation through the desilting of diverted waters, little water normally passing this point. Each flood carries away a part of the silt plug. For lack of such floods for a number of years, this plug reached menacing levels prior to 1925 when two floods of local origin restored favorable conditions. The favorable river-bed level of 1907, mentioned by the author, was probably due to severe scouring resulting from the heavy run-off then current, and particularly the high floods of the latter part of 1905.

The stabilized river channel has gradually approached El Paso and should reach there in the near future, with anticipated improvement in local conditions. Thereafter, local floods and surplus waters entering Elephant Butte Reservoir, which have been missing in recent years of sub-normal run-off, no doubt, will clear the river channel at El Paso with sufficient frequency to avoid the extreme high levels of 1925.

Below El Paso, there has been a loss of capacity such as is to be expected in a channel carrying little water for a number of years. This situation will shortly be improved by channel rectification. Unavoidable waste and surplus waters should have little difficulty in maintaining the new channel free of silt accretions provided meandering is prevented.

A feature of stream development not mentioned by the author, and which may warrant much consideration, is the concentration of salts through re-diversion. Rarely is the quality of waters improved in passing through the soils. There is usually a marked increase in deleterious salts, with drain waters in some cases carrying several times the agricultural tolerance limit for ordinary crops. This feature must receive increasing attention as the utilization of Western streams progresses toward complete consumption of all ordinary flows.

Frank E. Bonner,[16] M. Am. Soc. C. E. (by letter).—An excellent review of problems involved in water-shed development and control is presented in this paper. Although relating primarily to the special conditions of the arid Southwest, some features have more or less general application. The meagerness of data bearing on the rates of débris production has been pointed out by the author. It is unfortunate that published information on the subject is so fragmentary in character. In an endeavor to provide a basis for general estimates, the writer has been compiling, for some time, such records as have been made available for representative drainage basins of the United States. The results thus far are presented in Table 3, which has been compiled from information supplied by the U. S. Department of Agriculture,[17] the U. S. Army Engineer Corps,[18] U. S. Geological Survey,[19] American Society of Civil Engineers,[20] *Engineering News-Record,*[21] U. S. Reclamation Service,[22] the late A. J. Wiley M. Am. Soc. C. E.,[23] and R. V. Meikle, M. Am. Soc. C. E.[24] Wide variation is evident, but the unit values exhibit reasonable consistency with the different climatical and surface geological factors which constitute the basic influences on erosin.

---

[16] Cons. Engr., Piedmont, Calif.

Some uncertainty is involved in the correlation of the results of the various investigations because of different methods adopted for silt measurements. Many have used the dry-weight basis, while others have recorded determinations in the less certain terms of volume. The weight-volume ratio varies considerably because of the wide range of density in alluvial deposits. The variation is due not only to the size and grading of the particles, depending on the manner of deposition, but also on the degree of consolidation resulting from exposure to the atmosphere. Coarse débris, consisting of a mixture of boulders, gravel, sand, and silt, characteristic of the load laid down at the head of débris cones of swift mountain streams, will have high density. On the other hand, fine particles of sand or silt carried long distances in suspension and finally dropped in slowly moving water form relatively porous deposits. Between these two extremes endless combinations are represented. On exposure to the atmosphere and loss of the moisture contant, deposits of finely divided silt undergo substantial shrinkage of volume. Visible evidence of this process of consolidation is found everywhere in the pattern of wide cracks developed in drying mud-banks. Renewal of saturation fails to produce corresponding expansion. Tests show that the specific gravity of the solid material in alluvial deposits generally ranges from 2.6 to 2.7, depending largely on variation in the small proportion of organic material ordinarily present. Obviously, the deviation of specific gravity is too small to affect the weight-volume ratio to any extent.

The dry weight of material ordinarily found in silt deposits ranges from 30 to 106 lb per cu ft. This corresponds to a range in place (saturated) of 81 to 128 lb per cu ft. Sometimes even these wide limits are exceeded. Harold Conkling, M. Am. Soc. C. E., reports some coarse detrital material in San Gabriel Wash, California, with only 12% voids[25] which corresponds to a

* Measured by deposit volume. † Exclusive of Salt River Basin tributary to Roovevelt Reservoir. ‡ Exclusive of area tributary to upper lakes and reservoirs. § Exclusive of hydraulic mining débris. ‖ Computed on basis of 85 lb per cu ft.

weight of 144 lb per cu ft. Orville A. Faris, M. Am. Soc. C. E., found several samples from Lake Worth, Texas, to weigh only 18.7 to 22.6 lb. (dry weight) per cu ft.[26] On the basis of his comprehensive study of conditions in Texas, Mr. Faris concluded that the density of silt in that locality would be controlled primarily by the degree of exposure, and he estimated[27] the average dry weight per cubic foot of reservoir deposits, as follows: (*a*) 30 lb when continuously submerged; (*b*) 70 lb in reservoirs emptied occasionally; and (*c*) 90 lb in reservoirs standing empty most of the time.

As a result of their detailed investigation of the Colorado River silt problem the late Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, Assoc. M. Am. Soc. C. E., concluded[28] that 85 lb per cu ft would represent a fair average for the combination of suspended and bed-load sediment deposited in a reservoir near the lower end of the Canyon Section of the river.

From the foregoing it will be apparent that selection of a value to represent average conditions is subject to no small degree of conjecture. Considering, however, that most deposits occur along river channels and in storage reservoirs with fluctuating levels it is believed that 85 lb per cu ft offers a fair estimate, and this ratio has been adopted for conversion in those cases listed in Table 3 where the investigations failed to establish a relation between the weight and volume of the ultimate deposit. Accumulations of the coarse débris carried by mountain streams will be heavier on the average, while the fine silt deposited in lakes, bays, and reservoirs with constant level will be considerably lighter.

Some of the determinations recorded in Table 3 are derived from measurements of accumulations in reservoirs over long periods, while others are based on systematic sampling and calculation of the amount of solids carried in suspension at different river stages. In connection with the latter there is no feasible method of measuring the bed load which in certain situations is known to be a substantial fraction of the total load. Messrs. Fortier and Blaney estimated[29] the bed load of the Colorado River at Yuma, Ariz., to be about 20% of the total load. Mr. Faris cites[30] a similar estimate relating to the Rio Grande and an estimate that the bed load of the Mississippi River amounts to 11% of the suspended load. Determinations relating to the movement of coarse débris from the mountain water-sheds of the Sierra Nevada, in California, give somewhat higher results.

It might be assumed, therefore, that reservoir measurement would provide more accurate appraisal than river sampling. This will depend, however, on the effectiveness of the reservoir as a desilting agency which, in turn, depends largely on the relation between the dimensions of the reservoir and the extent of the tributary water-shed. Mr. Faris shows[31] that the average annual silt accumulation (20-year period) in the small Lake Austin Reservoir, on the Colorado River of Texas, amounted to less than one-fourth the average suspended load of the stream. In that case, the reservoir capacity was comparatively small in proportion to the area of the drainage basin above. That estimates by river sampling provide reliable indices to the probable siltation of large reservoirs is well demonstrated by the work of the late W. W. Follett, M. Am. Soc. C. E., on the Rio Grande. On the basis of stream sampling at San Marcial, from 1905 to 1912, he estimated the average annual suspended load of the river at 19 739 acre-ft,[32] whereas measurement by the U. S. Bureau of Reclamation of the siltation of Elephant Butte Reservoir from 1916 to 1925 indicates an average annual accumulation of 20 470 acre-ft.[33]

Comparison of the values in Column (10), Table 3, show plainly the regional variations of soil erosion. It is least active in the permeable soils of the northern part of the United States and reaches a maximum on the soft sandstone and friable shale formations of the arid Southwest. In the Rio Grande and Lower Colorado Basins the removal of material progresses at an annual rate in excess of 1 000 tons per sq mile and over certain areas it is evident that the rates are much higher. As may be observed from the tabulation, investigations show an average of about 1 600 tons per sq mile for the Salt River and Zuni River water-sheds. Herman Stabler, M. Am. Soc. C. E.,[34] estimates an average annual removal of 3 000 tons per sq mile from the barren desert region of 60 000 sq miles drained by the San Juan and Little Colorado Rivers.

These high rates of débris removal over large areas are exceeded only by those for several basins of the Sierra Nevada in California where hydraulic mining of auriferous gravel was practiced extensively. Although this form of gold mining was brought to a sudden halt by Federal Court decree in 1884 the rivers of that section are still struggling to rid themselves of the enormous load of alluvial débris dumped into the channels during the thirty years previous. The hydraulic mining operations were carried out extensively on all the streams from Feather River south to Tuolumne River, but the greatest activity centered in the Yuba Basin, where a total of about 700 000 000 cu yd of material, or nearly one-half the total for the entire region, was dislodged. This great disturbance of natural conditions and the progressive movement of the huge load of detritus down the river channels to eventual deposit in the tidal bays, supplied a most unusual opportunity for observation and study of river hydraulics in relation to débris transportation, but the results are beyond the bounds of the present discussion, except for certain features. Through the notable investigation by Dr. G. K. Gilbert[35] it was demonstrated that "the apex of the débris flood, leaving the mines in 1883, passed the mouth of the canyon in about the year 1900 and the mouth of the Yuba River in about 1905." Dr. Gilbert's comprehensive measurements showed that the detrital load carried past the mouth of the canyon in 1905 amounted to 7 200 000 cu yd. Nearly 70% of the total consisted of bed load. The tributary area of the Yuba, exclusive of that part which drains to head-water lakes and reservoirs, amounts to 1 042 sq miles, thus, the 1905 load (at 85 lb per cu ft) was equivalent to 7 930 tons per sq mile. Recent investigations by the writer in connection with plans for a dam in the Lower Yuba Canyon indicate that the normal load of the river has now (1934) decreased to approximately 1 700 000 cu yd, or about 1 870 tons per sq mile. Natural erosion accounts for only 30% of the total, the remainder coming from the diminishing remnants of the old mining deposits scattered throughout the water-shed.

Comparison of the heavy detrital load carried from the Sierra Nevada mining water-sheds with the débris produced by natural erosion elsewhere serves to emphasize the possible acceleration of surface degradation through violent disturbance of the natural processes by human agencies. Of course, the hydraulic mining areas offer a highly exaggerated illustration, since no other possible activity by Man could result in comparable removal of surface material. Under certain conditions agricultural activities contribute measurably to soil waste. Farming on comparatively level land or on coarse permeable soils probably has but little influence; but instances have been cited of excessive erosion from cultivation of light soils on moderate slopes. On the other hand, some farming operations may serve to build up the soil. This is true of irrigation enterprises in which the sediment of the diverted waters is carried through the canals and deposited on the fields. In California, for example, it is estimated that total soil accretion through irrigation exceeds the erosion losses from all the unirrigated land in cultivation.

Native vegetation constitutes an important control on erosion and its destruction naturally increases the normal rate of soil removal. Various destructive agencies arise from human activity. Smelter fumes have destroyed the vegetation of certain areas in Tennessee, California, and Montana, with consequent increase of erosion. Fires and over-grazing are also destructive in some localities. The latter is probably more serious from an erosion standpoint since the effect is likely to be more widespread and continuous. The scars left by fire are quickly healed by volunteer growth of brush, grass, or weeds, and excessive erosion results only when the burned area is subjected to torrential downpours before new growth is well started. Such occurrences are infrequent and mainly of local significance. The construction of improvements, such as railroads, canals, highways, etc., serve to increase erosion along their course, but the regional result is relatively slight. In the broad view, human activity can have but little effect either to accelerate or to retard the slow but inevitable weathering of the earth's surface.

Depletion of reservoir storage capacity through siltation comprises one of the effects of surface erosion that in some cases may be of economic importance. Instances have occurred in which small reservoirs were rapidly filled with silt and lost their usefulness. Even in the case of some larger reservoirs, the depletion of storage capacity through siltation has reached such proportions as to interfere with the purpose for which the reservoir was intended. Studies demonstrate that silt removal is more costly than provision of additional storage capacity, and thus it is obvious that original designs that fail to take into consideration and provide for the progressive silt accumulation are defective. It is not difficult for the engineer to estimate the effects of silting within reasonable limits, and to overlook this feature may not only jeopardize the economic success of the enterprise through early loss of capacity, but also the stability of the dam itself may be threatened by improper appraisal of the up-stream pressures. The horizontal forces acting against a dam through combination of the silt and water load may amount to 50% more than those from the water load alone.

Instances of excessive silting are chiefly in connection with reservoirs disproportionately small as compared with the area of the tributary basins. Lake Austin, Texas,[36] is an outstanding example. Naturally, also, if the formations of the water-shed are of such character as to yield extraordinarily large amounts of débris like at Zuni Reservoir, New Mexico,[37] rapid depletion is unavoidable. Effective preventive measures cost more as a rule than the construction of new storage capacity. The problem of rapid depletion seems to be confined largely to the Southwest. In California, several small reservoirs (used primarily for diversion purposes) have filled with silt at a rapid rate but, in general, the water storage reservoirs, have been proportioned to their respective drainage basins so that the percentage of depletion through siltation will be negligible for at least a century to come. The situation is illustrated by Table 4 which shows the siltation rates of representative South-

[36] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1681.

[37] *Loc. cit.*, p. 1695.

western reservoirs as compared with twenty of the main storage reservoirs in California. The latter group is shown to have more enduring usefulness. Only one of the twenty has an indicated life of less than 1 000 yr. This means that during the first 100 yr of use the decrease of effective storage capacity will not exceed 10 per cent. Under the circumstances, it is clear that in the operation of these reservoirs the siltation problem will be of no consequence.

It probably should be pointed out that none of these reservoirs is in Southern California. A number of reservoirs have been constructed in that section for flood control, irrigation, and domestic supply purposes, but the water-shed conditions are essentially different from those of the remainder of the State. The area of the South Pacific slope (south of San Luis Obispo) amounts to 13 600 sq miles, about evenly divided between mountain water-sheds and coastal plains. Although comprising less than 9% of the State area and yielding less than 5% of the run-off of California's streams, the water-shed problems are important because of the dense population and intensive water utilization. Rainfall is erratic and occasional severe storms produce flood flows carrying heavy loads of débris from the steep mountain water-sheds. Considerable damage results to limited areas where human habitation has crowded upon active débris cones, but over the locality as a whole the erosion rate is not exceptional.

* Computed on the basis of 106 lb per cu ft in place.

Consideration of rates of débris production in various sections naturally leads to speculation as to regional comparisons and quantitative estimates for the country as a whole. Available data can scarcely be considered adequate for accurate determinations, but the values in Table 3 are sufficiently well distributed to serve as a basis for general approximation. Study of the data permits an estimate of the average annual waste per unit of area for each of the main drainage basins and in combination with the tributary areas, the total weight of material removed and the depth of degradation have been computed. The results are presented in Table 5.

The estimated annual total of 933 000 000 tons for the United States as a whole amounts to an average of 308 tons per sq mile. Assuming a weight of 106 lb per cu ft for the material in original place, the average wearing off would be 0.0025 in. per yr. It thus appears that the elements are planing down the surface of the country at an average rate of 1 in. in about 400 yr.

It should be understood, however, that this material is not lost. Very little escapes to the oceans. Dr. Gilbert found[38] that of the 2 375 000 000 cu yd of alluvial débris originating from lands tributary to San Francisco Bay, during the 65 yr, from 1849 to 1914, only 50 000 000 cu yd were carried through the Golden Gate and deposited in the ocean. For the most part eroded material is re-deposited along river channels, on flooded bottom-lands, and in lakes, reservoirs, and bays. New land is thereby formed in the same way that the fertile low lands have been built up through countless geologic ages. The foregoing estimate fails to consider the constant building up of soil through the decay of vegetation. Over large areas this agency probably more than offsets the degrading effects of erosion. On the other hand, no consideration has been given to material carried away in solution. Investigations disclose that, on some streams,[39] the amount of dissolved solids exceeds the weight of the suspended matter. As a rough approximation, it seems reasonable to assume that the losses of dissolved solids are balanced by the gains from vegetation decay, and the estimate based on silt movement provides a fair measure of the general rate of surface leveling.

C. S. Jarvis,[40] M. Am. Soc. C. E. (by letter).—The author has undertaken a calm, methodical analysis of the natural forces as related to run-off and erosion, together with the influence manifest by works of Man in altering the definite balance that presumably existed under long-established natural conditions. Engineers need more of such serious consideration, before committing themselves to policies that have a decided trend against both public welfare and individual security. A great service has been rendered to the profession, and thereby to communities at large, by bringing the subject and its ramifications into such relief at this time, when it is most needed. Although the writer is in accord generally with the views and conclusions in this paper, he must take exception to some of the minor details.

When long records are studied—especially graphic charts of rainfall and run-off—the most impressive feature seems to be the wide variety of precipitation and stream flow that may occur in a locality. With long-term records, such as 50-yr periods, the mean annual rainfall at stations of most dependable supply in the United States may represent about 1.4 times the minimum yearly; and a like ratio is approached by the maximum in comparison with the mean. A wider disparity exists between minimum and mean or maximum seasonal rainfall; and a still wider disparity, if compared on a monthly basis. Furthermore, these ranges are greatly increased in the field of run-off, the minimum annual yield from a water-shed being perhaps one-tenth of the long-term maximum, while the variation among monthly or daily discharges may exceed 100 as a ratio, even in humid areas. In arid regions, both precipitation and stream flow are still more erratic and flashy.

[40] Senior Hydr. Engr., U. S. Geological Survey, Washington, D. C.

Man's main efforts with respect to altering conditions of natural stream flow and erosion may be symbolized by his treatment of rough land: He reduces the knolls and fills in the gullies, striving to obtain a more nearly even and dependable profile. Taking the example of the Rio Grande immediately below the Elephant Butte Dam as representative of thorough regulation, it is difficult to find any serious up-setting of the physiographic balance. The data of Table 1, relating to comparative scour and fill of the Rio Grande channel below the dam are enlightening, particularly when expressed as totals or sub-totals. Thus, the changes therein noted between the years 1915, or 1918, and 1932, in the cross-sections of the river channel selected at the first ten of the tabulated stations, amount to totals of 2 628 sq ft of scouring as compared with 2 332 sq ft of fill. Therefore, in the 143 miles between the Elephant Butte Dam and International Dam, near El Paso, Tex., the regulated stream, devoid of the customary silt burden that had prevailed during the natural and primitive conditions, was actually deepening its channel. It is not surprising, however, that the inclusion of the final five stations for this comparison would have shown an increase of fill amounting to 1 493 sq ft, or nearly 300 sq ft per station, far below the main canal diversions. This silting of the channel is small in comparison with what has been observed near San Marcial, N. Mex., as a result of back-water influence from the reservoir. Moreover, it was demonstrated early in August, 1925, that destructive floods could form as run-off from the usually arid region between Elephant Butte and El Paso, representing more than one-half the peak flow of record from the unregulated stream.[41]

The writer's observations do not uphold the idea expressed in Article 1, to the effect that a decrease of 20% in rainfall may "transform habitable semi-arid areas into uninhabitable deserts"; and that, an increase by the same amount would necessarily result in "flood conditions of much greater severity." The proof lies largely in the record of variations previously mentioned herein. The sub-normal precipitation occasionally ranges to a minor part of the mean annual, and the excessive rainfall ranges to more than double the mean. Even a succession of several years with rainfall far removed from the ordinary either above or below normal, has not apparently wrought the corresponding changes. Neglecting those years during which the excess or the deficiency occurred in the winter or non-growing season, and centering attention on those growing seasons with either sub-normal or excessive rainfall to the amount of only 20% of the mean, intensive cultivation and mulching to conserve the soil moisture may compensate fully for such a deficiency; and the increased capillary action of the soil during periods of abundant rainfall seems to increase the permeability thereof, thus allowing larger percentages to enter underground storage than if the surface were bone dry. Under such conditions, floods of greater severity do not always follow. They are more likely to occur from a torrential downpour on baked, drought-hardened soil than on moderately moist earth, supporting a luxuriant seasonal growth of vegetation to retard surface flow and to encourage or facilitate absorption, and transpiration thereafter.

[41] "Flood Flow Characteristics," by C. S. Jarvis, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1098.

Granting that débris barriers of moderate height, 50 ft, or more, are more effective for intercepting abnormal débris loads than a large number of 6-ft check dams would be, the writer's experience and observation would justify the adoption of numerous small structures rather than single high dams, for the majority of conservation projects. The potential hazards are so much less with the smaller barriers; their construction is much simpler; they are drowned out and cease to cause intensive local erosion when the flood volume increases greatly; and the failure of one or more need not greatly disturb the others of a series, nor damage the property which they are intended to protect. In many cases, they are better investments; they may be undermined or overturned, yet they remain obstacles, better adapted for maintaining the physiographic balance than the higher structures.

W. P. ROWE,[43] ASSOC. M. AM. SOC. C. E. (by letter).—The subject of this paper is timely for Southern California, because of the extensive flood-control and water-conservation works being built under the Federal Unemployment Relief Administration in this area. The author sub-divides the effect on the physiographical balance of conservation measures, under three headings: (*a*) Changes in the water-shed cover; (*b*) effect of regulation on the natural balance of a stream system; and (*c*) effect of débris barriers on the stability of the stream bed on the débris cone. He assumes that these three effects are the work of Man. The water-shed cover is the work of Nature, and it is axiomatic that Nature is never static. Climatic conditions are a governing factor in water-shed cover and one over which Man has no control.

The disaster in the La Crescenta-Montrose area of Southern California (New Year's Day, 1934), resulting from an intense rain (averaging more than 12 in. for the 2-day storm, and with a fairly uniform maximum intensity of about 1 in. per hr for 3 hr over the entire area), on a small water-shed which had been recently denuded by fire, has concentrated attention on water-shed cover. All the measures for fire prevention, advocated by the Forest Service in dealing with brush-covered areas, such as paved highways, motor-ways, fire trails, fire breaks, fire apparatus, and hundreds of men from near-by unemployment relief camps were available, and still the fire burned unchecked until the area was burned over. The fire was held at the crest of the drainage area by back-firing, which is nothing more nor less than controlled burning. When a torrential rain fell on this area, the catastrophe resulted. The natural phenomena accompanying this disaster offer the clearest examples as to how the many enormous débris fans have been formed at the mouths of Southern California streams. The occurrence of these fans is evidence of similar but heavier floods in the past.

---

[43] Cons. Engr., San Bernardino, Calif.

Segregating proposals for improving the water-shed cover Mr. Sonderegger, in Article 2, suggests two classes. Regarding the first of these (as it relates to the capacity of the water-shed cover to "induce more copious precipitation"), the rain in the La Crescenta-Montrose area, where there was apparently as much rainfall on deforested areas as on those which were heavily forested with brush, would seem to disprove this theory; at least, as regards local conditions in Southern California.

In treating the second class it should be emphasized that reduction of evapo-transpiration loss is not the primary reason for the advocation of light deforestation or controlled burning. The fire in the La Crescenta-Montrose area demonstrates the advisability of some method of light deforestation in the brush-covered areas, which would permit no more than 50% of the water-shed cover to be denuded at any one time. Where the entire water-shed cover was destroyed, the resulting damage was heavy, but in the adjacent areas, where less than 50% of the water-shed area was burned over, there was little material damage. The fact that this area was denuded, in the face of all the preventive measures recommended and used by the Forest Service, would indicate that the present policy is wrong. If light deforestation were advocated simply as a means of decreasing evapo-transpiration losses and thereby increasing the water supply, the present Forest Service policy of fostering a fire hazard, which eventually results in the temporary destruction of the entire water-shed cover when the inevitable fire occurs, offers the best medium. The inevitable needs no advocate.

That the effect of ashes is to seal the stream bed, is a moot question. The presence of ashes in an absorptive stream bed, after a forest fire, is an indication that the water has percolated through and left the ashes behind. Any flood will stir up the stream bed and carry away the transportable material, the size of which will depend on the severity of the flood. When the peak of a flood has passed, lighter and still lighter materials will be dropped as the flow decreases, until, eventually, only the finer materials are left to be deposited when the water sinks. The argument relating to ashes has been used in the past as regards the presence of silt in a stream bed after a flood. The present methods of maintaining silt-suspending velocities in the spreading ditches have solved this problem. It is significant that no large deposits of ashes or silt have ever been found, as far as the writer knows, in excavations made in active stream channels on Southern California débris cones.

In connection with the acts of Man on the effects of over-balancing the regimen of the stream, Mr. Sonderegger has pointed out the effects of the deposition of débris resulting from the construction of dams or barriers across the channels. The Government's activities for unemployment relief in Southern California have resulted in large sums of money being spent on water conservation works on the débris cones at the mouths of Southern California streams. Dams have been built across them without any regard for the future effects of deposition of additional débris.

In 1926, a spreading dam, 2 000 ft long, was constructed across the mouth of Lytle Creek. This dam raised the bed of the active channel at least 10 ft. In succeeding years, floods re-graded the stream to such an extent that it has been raised at least 2 ft at the U. S. Geological Survey gauging station 1.5 miles up stream. The future effect of this dam would have been a shifting of the stream to a highly improved area on its débris cone west of the old active channel, if an expensive training levee confining the stream to its former active channel, had not been constructed. This reconstruction resulted in the abandonment of about 1 750 ft of the original dam.

In 1920, a spreading dam, 3 000 ft long, was constructed on the débris cone of the Whitewater River. This dam was built on an approximate contour to a height of 5 ft, but with the maximum height limited to 3.5 ft above any of the active channels traversing the cone. The other 1.5 ft of height was buried. Floods which followed the construction of the dam resulted in the re-grading of the stream beds up stream, until the water was forced out of its former channels and spread over an area which the stream had not occupied for at least twenty years. Precise profile lines run across the cone from this dam in 1920, 1924, and 1927, show that each flood gradually raised the bed up stream until, after the capital flood of 1927, the re-grading effect was noticed at least 1 mile up stream. This was one of the primary reasons for the construction of this dam, as no danger could result from such additional overflow of adjacent lands.

A careful survey of the débris cone was made in 1927 by running an axial line down the center of the cone and parallel radial lines on the arcs of circles having their apexes at a common point where the stream first begins to fan out. This survey showed that there was a true cone between the confining banks of the wash. Future dams are planned to take advantage of this condition by installing movable crests so that the stream bed may be raised or scoured at will. In addition to the re-grading effect up stream, there was a scour down stream due to the erosion of the 1.5 ft of material between the original stream bed and the spillway mat 5 ft below the crest of the dam. This scouring effect extended down stream for a distance of 700 ft.

The author has shown correctly that the effect of the construction of bridges, culverts, dikes, and roadway dips across débris-laden streams is not a simple matter, but one that should receive careful study, so that the various structures along the same stream shall be co-ordinated in their effect on the deposition and scouring of the débris.

Another factor in the deposition from débris-laden streams is the elimination of artesian areas through which such streams may flow. In the San Bernardino Basin, the artesian rim in 1916 extended to a point 5 miles, or more, above the Bunker Hill dike, and no deposition took place in this stretch of the stream while the artesian rim remained at this limit. However, with increasing use of water and years of sub-normal stream flow, the artesian area shrank until, in 1934, there are more than 3 miles of absorptive channel where there was formerly a rising stream. This has resulted in deposition of débris by the diminution of the stream flow due to absorption. At the Gage Canal intake, 2 miles above the Bunker Hill dike, there is a sand-trap in the canal which formerly drained water and sand back to the stream level. One can now stand in this sand-trap, and his head will be below the level of the present stream channel.

In designing barriers across such streams, the effect of scouring during flood periods has not been considered in many cases. The writer has found tin cans and other signs of recent origin at a depth of 5 ft below the active stream bed, indicating scouring to at least this depth during flood. A sawed plank was found during the excavation for Boulder Dam at a depth of 50 ft below the present bed of the Colorado River.[43] Stream gaugings at Yuma, Ariz., indicate that the Colorado River scours to a depth of more than 30 ft during capital floods.[44] When a permanent barrier is placed across such a stream, the flow that was formerly transported through a scoured section is forced to pass over the barrier, thus increasing the wetted area above that barrier. In many cases the only way in which this increased flow can be accommodated is by overflowing adjacent lands which were formerly in no danger from floods.

Another active phenomenon that influences the physiographical balance of streams in Southern California is the effect of changing climatic conditions. The Whitewater River flows into the Salton Sea, which in recent years (but not within the memory of Man), extended to an elevation 40 ft above sea level. The present level of the Salton Sea is about 250 ft below sea level. While it was at its former level of + 40 ft, the stream bed of the Whitewater River was graded to fit this condition; since the lowering of the sea level, the stream is accommodating itself to the changed condition by scouring its bed. This scouring is an almost imperceptible process because of the long intervals between capital floods. Whenever such a capital flood occurs the erosion proceeds up stream as a series of cataracts.

In former years the Mojave River adapted its bed to fit the conditions created by the ancient Manix Lake into which it flowed. This lake had a surface area large enough to evaporate more than five times the present mean annual flow of the river. After the barrier that formed one side of the lake was washed away, the water in the lake escaped and scoured a deep outlet. The stream is still adapting its grade to this new condition, and in this case, also, it is slow because of the infrequency of capital floods.

The physiographical balance on débris cones is a delicate one. There is ample proof that slow climatic changes (imperceptible from year to year, but apparent over long periods of time) are modifying this balance. Annual precipitation data are misleading. A year of well-distributed rainfall will move a certain quantity of débris and will deposit it as the water sinks into the cone. Another year of equal rainfall, but torrential in character for a few days or hours, will have a far more devastating effect.

Professor Ellsworth Huntington has given a vivid description of alluvial terraces as proof of climatic changes.[45] Similar evidences of change are to be noted on the various coastal streams of Southern California. Changes of stream-channel conditions, that can not be attributed to over-grazing, forest fires, or any act of Man, have occurred within the memory of man.

[45] "The Climatic Factor," by Ellsworth Huntington, *Publication No. 192,* Carnegie Institution, pp. 23–36.

The New Year's Day, 1934, flood in Pickens Canyon in the La Crescenta-Montrose area exposed evidence of similar floods and canyon-side slumping in previous years. At one place, a log about 12 in. in diameter, that had been buried long enough to rot through, is exposed. At another place, a flood had carried down an oak tree and buried it in a horizontal position. Its roots were buried and several sprouts came up from the trunk. These sprouts had developed into trees as large as 4 in. in diameter before the last flood exposed their origin. The fact that some agency was instrumental in building more than a hundred check dams in this narrow bed-rock canyon would also indicate that some one with previous experience had recognized the danger from débris or mud flows.

The carrying capacity of a stream loaded with sand, gravel, and boulders may be calculated, but when a large quantity of mud increases the specific gravity of the conveying fluid, the carrying capacity is tremendously increased. A flood of clear water of sufficient force to move some of the boulders found on the local débris cones is inconceivable, but when there is a flow of mud accompanying the flood one can easily account for the presence of these boulders.

Mr. Sonderegger has mentioned débris barriers above the canyon mouths as a means for preventing the débris from reaching the cone. The Haines Canyon débris basin, which was credited with such miraculous powers during the La Crescenta-Montrose disaster, was simply a gravel-pit in the stream channel. Its lower end was closed with the waste sand from the screening plant. The confining wall had been lined with wire and rock protection and equipped with a shallow flat spillway lined with concrete. All the storage capacity was below the original stream bed at the outlet end. The excavation of rock and gravel at the upper end of the pit had created a drop of more than 30 ft at the entrance of the stream channel. When the flood occurred, the water that flowed over this loose alluvial bank soon cut a new grade and deposited the eroded material in the basin. This recession of grade worked up stream through several wire and rock check dams and was stopped just below the gauging station about $\frac{1}{2}$ mile up stream. At this point the grade was lowered about 5 ft. The material eroded in this section of the stream accounted for most of the débris deposited in the basin. Had the barrier been erected above the stream bed, most of this scouring would not have occurred, and there would have been more storage space for débris from the upper water-shed. In such a case, the dam and spillway would have to be of the safest and most permanent construction. It would probably be cheaper to re-excavate the débris after each flood than to construct such expensive works. This would depend on the frequency of débris-carrying floods.

The high peak flow of 4 000 or 5 000 sec-ft per sq mile credited to Haines Canyon[46] was undoubtedly caused by log jams in the canyon backing up the water and suddenly giving way. That this flow was of short duration is proved by the outflow through the spillway of the débris basin. The area of the Haines Canyon water-shed above the débris basin is approximately 1.2 sq miles, about one-half of which was burned over. At the critical section of the spillway, the average depth of water was 2.2 ft and the average width was 45 ft. The concrete approach channel is level, but just below the critical section at the crest there is a drop of about 1 ft in 10 ft. Computations based on these data indicate that the outflow did not exceed 400 sec-ft.

---

[46] "Notes on the Recent Flood," by E. C. Eaton, M. Am. Soc. C. E. (Not published.)

The area of the Haines Canyon débris basin below the spillway level was not greater than 2.5 acres before the flood. During the flood a débris cone was built at the upper end of the basin by inflowing débris. The present area (1934) at the high-water mark is 1.9 acres. According to an eye witness, the water level in the basin was 3.5 ft below the spillway level at the time the peak flow arrived, so that there was a capacity of about 9 acre-ft for storage before overflow began. The float-well at the U. S. Geological Survey gauging station silted up during the peak flow. A total of 7 acre-ft passed the gauging station during the three days preceding the peak. This value, less seepage losses, is an indication of the original storage below the aforementioned 3.5-ft mark. Between the spillway level and the high-water mark there would have been about 5 acre-ft of storage while the peak outflow was occurring. If the inflow was assumed to be 4 000 sec-ft for only 3 min. and the outflow was 400 sec-ft for the same period, the available storage would balance the flows.

The same witness stated that the outflow continued for 2.5 hr. The inflow during this period could not have exceeded the outflow as there was no available storage for regulation. If all the rain, falling on a burned-over area of 300 acres, at a rate of 1 in. per hr, became available as run-off and one-fourth of the same amount of rain falling on 400 acres of brush-covered area joined it, one would have a run-off figure consistent with the peak outflow as computed previously herein. It is evident that the high peaks were caused by the sudden release of dammed water and that steps should be taken to prevent the recurrence of such a condition in the future.

The approach to the spillway of the Haines Canyon débris basin is crossed by a railroad trestle for the operation of the gravel pit. The trees carried down by the flood partly blocked the approach and it is conceivable that the outlet might have been blocked completely by trees and other drift, in which case the débris barrier would have failed, resulting in an enormous damage. The elimination of similar hazards to the proposed small débris basins will be expensive unless the hazard is eliminated at the source. The saving of evapo-transpiration losses from trees removed from stream bottoms would pay the cost of removal. It would not be necessary to remove all the trees. A selection could be made and the trees with deep root systems and least water requirements, preserved for recreational purposes. Under the present policy of the Forest Service in closing most of these similar areas to recreational uses, in direct contradiction of the policy on which this Service was established, it would not be necessary to save even these few trees.

The maximum depth of débris deposition in the basin amounted to about 18 ft and was of such a mixture of mud, sand, gravel, and boulders that there would have been little drainable void space for underground storage, especially near the outlet. If the débris deposited behind a barrier is to be utilized for underground water storage it would be advisable to provide some means of passing mud during the flood.

In Article 5, the author gives two examples of the major débris-carrying streams in Southern California. A study of these data and those of other local streams would indicate that the grade of the débris cone just below the mouth of the canyon is an indication of the flow, the steeper cones being below the mouths of the streams of lesser flow. These examples could be used as a substantiation of the argument of Professor Huntington relating to profiles of débris cones in relation to stream flow.[47]

Mr. Sonderegger is clairvoyant in describing the results of dam failures on a débris cone (see paragraphs in Article 5 preceding "Rate of Débris Production"). These paragraphs, written as they were several months before the La Crescenta-Montrose flood, are prophetic. Pickens Canyon, having the major water-shed (1.6 sq miles) of the streams causing the damage, traverses a region of faulted and easily eroded rock. It has built a large débris cone below its mouth from previously eroded material.

The main branch of Pickens Canyon flows in a narrow trough, ranging from 50 to 100 ft deep. Before the flood it was crossed with a multitude of wire and rock check dams averaging 6 ft high. Most of these dams were founded on bed-rock bottom, or very near to it. The sides of the canyon, for a distance of at least ½ mile above its mouth, are very precipitous, and the soil is held in place by the large masses of roots of the oaks and other vegetation. The trees in the canyon bottom were not burned by the fire preceding the flood. About ½ mile above the mouth of the canyon there are typical slides which accompany faulting along such streams in Southern California. The bank material is loose rock with large masses of clayey earth. The rainfall of more than 12 in. for the storm, saturated this material, causing it to slump into the stream, carrying trees, rocks, and earth into the canyon bottom, where the trees lodged and formed temporary dams, behind which the heavier débris lodged. There would have been a débris flow from Pickens Canyon even if the water-shed cover had not been burned.

The check dams were washed out as soon as the confining wires were broken by the erosive action of the material in the stream. The débris accumulated behind these check dams was added to the slumped material and carried down the canyon. There was very little scouring of the channel below the original canyon bottom because of the shallow fill above bed-rock. At the mouth of the canyon, the stream debouches on a steep débris cone built up by previous floods. The stream channel across this cone above the highway was also crossed by numerous check dams. These dams accumulated large masses of débris before their failure, but when they failed, the channel was scoured to depths ranging from 5 to 10 ft below the original bed. The hugh boulders deposited in the residential area below the State highway were carried down from this débris cone and their presence on the cone is evidence of similar but heavier floods in the past, before there was any over-grazing or forest reserve.

---

[47] "The Climatic Theory," by Ellsworth Huntington, *Publication No. 192*, Carnegie Institution, p. 33.

The check dams that withstood the flood in Haines Canyon, offer an example of what must have happened to the check dams on the various débris cones above La Crescenta and Montrose. Unlike Pickens Canyon, Haines Canyon has a broad flat débris-filled bed. The flood passing over the check dams in Haines Canyon scoured the channel below the toe of the dams and deposited the eroded material behind the next dam down stream.

The check dams on the Pickens Canyon débris cone remained intact long enough to raise the stream bed and cause overflow of the banks. Vast amounts of débris were then diverted out of the original channel. The culvert at the State highway was so well constructed that it did not wash out. Its capacity, however, was so reduced by a 6-ft boulder lodging at its entrance, that most of the débris coming down the channel passed over the highway, which acted as a spreading dam and spread the débris over a broad area.

The latest spreading works on the Upper Santa Ana River are designed to by-pass the silt back into the active channel, where the stream will have a flow diminished by the amount of absorption above. This action will tend to increase the silt load beyond normal conditions. When the stream reaches the absorptive area in the lower river any further absorption will raise the stream bed by the deposition of this silt. It is necessary, if spreading works are to be maintained at their maximum efficiency in such stream channels, that large flows be permitted to pass through them at intervals, in order that the silt may be scoured out, even if large flows may escape into the ocean. Professional conservationists, in their desire to impress the taxpayer with the importance of their endeavors, frequently cite this "large waste of water into the ocean" as the argument for more extensive works to preserve this water, even if the cost of the works outweighs the value of the water thus escaping. They fail to take account of Nature's laws and unwittingly accelerate the overthrowing of the physiographical balance.

J. C. STEVENS,[48] M. AM. SOC. C. E. (by letter).—The author postulates his thesis on the theory that the physiographical factors combine to produce a balance. Such a general statement may well be challenged.

Nature herself seldom remains quiescent long enough to permit the establishment of anything like a permanent or even a gradually changing balance of these factors. She builds consistently for a few years and then with wild abandon utterly wrecks her handiwork. Man's efforts are puny in comparison, yet so conceited is he that he likes to believe that his is the mighty hand.

One factor at man's command is the construction of dams. Another is the straightening of stream channels. He may remove timber, cultivate lands, divert water for power and irrigation, and graze stock. Beyond these, his efforts are futile. Even his control is haphazard and uncertain, because his highest dams fail and his diversions get out of control, as witness the St. Francis Dam failure and the flooding of the Imperial Valley by the Colorado River. He cannot control, in the slightest degree, rains, frost, winds, tides, landslides, earthquakes, fire, and vulcanism. Nature buffets him mercilessly with these forces.

---

[48] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

Man's works are temporary. Left without persistent and painstaking maintenance and repair, they soon become mere ruins, failing utterly in their intended purpose. Nature's forces never rest. These are such platitudes, it is almost a waste of space to recount them; yet, in the face of these facts, how can any one conceive of a physiographical balance "that undergoes only gradual changes"?

Was the Gros Ventre landslide (Wyoming), that put a dam in Gros Ventre River 1 000 ft high and, later, wrecked the entire landscape below it, a gradual change? Are the rather frequent Southern California floods caused by a foot or more of rainfall in a day factors for gradual changes? Is it fair or consistent, or rational, to assign the burning of a scattered growth of chaparral as the cause? If so, what about the recent unprecedented floods in the Pacific Northwest from the most heavily forested areas in this country? The changes effected were not gradual, but sudden and mighty. What about the Yellow River of China that, during the flood of 1851, suddenly left its channel, inundated an empire in spite of elaborate works of man, snuffed out a million lives, and found a new outlet to the sea 500 miles to the north? The entire physiographical complexion of China is thus suddenly changed every few generations. There is no balance.

A protracted wind storm a few years ago laid low thousands of acres of standing timber in Oregon. A more ruthless destruction, man, with all his machinery and ingenuity, has not equalled. In the summer of 1933 a forest fire on the west slope of the Coast Range in Oregon destroyed an enormous area of heavy virgin timber. That fire was carelessly set by man; yet, throughout the Northwest are untold acres similarly destroyed by fire from lightning before man's occupancy.

These few examples illustrate the impotency of man's control and raise a serious doubt as to whether any permanent relief can be predicated on a theory that there is a physiographical balance of Nature's factors. It seems that the author's physiographical balance is only Nature's quiescence between upheavals.

Erosion has come to claim the attention of scientists, pseudo-scientists, "yes men," and politicians. A struggle for the control of the grazing areas of the public domain has invaded Congress. Who gets that control has funds, personnel, jobs, influence. Propaganda in waves, broadcast by speeches, radio, articles in scientific and lay journals, and by newspapers, points to the same thing, "unprecedented and accelerated erosion due to over-grazing."

The writer believes in a National control of grazing and forested areas, but not for the reasons often assigned. Control of forest areas to perpetuate a timber supply and for recreational purposes is reason enough. The water-conserving properties are insignificant, unimportant, and enormously exaggerated. Control of grazing areas for maintenance of stock feed affords abundant reasons why it should be exercised. If grazing areas are so controlled for that purpose the erosion feature will be cared for automatically.

Erosion does not result from the mere removal of timber or the mere grazing of animals. It results from the cultural works of man. Roads, trails, and logways, are incipient causes of erosion. Field cultivation is another. On grazing areas erosion occurs at places of animal concentrations, such as waterholes, trails, and feeding and bedding grounds. On both forested and grazing areas such incipient erosion can be eliminated only in so far as these cultural activities can be eliminated or effectively controlled.

The writer agrees heartily with the author that temporary débris barriers, silt dams, flood channels, and works for erosion control of non-permanent materials are almost worse than none. When they fail, as they surely will, without well planned and well financed maintenance expenditures, the results are more disastrous than if they had never been constructed.

GERARD H. MATTHES,[49] M. AM. SOC. C. E. (by letter).—The author has focused attention on a much neglected phase of water conservation in the United States. In Europe, the evils resulting from disturbing the physiographic balance which exists in any water-shed between erosion, run-off, and the débris-carrying capacity of streams, have attracted considerable attention. The situation on the Rio Grande, described by the author, shows clearly that the time has come for American engineers to look ahead and profit from European experience. This is the more important in view of the large number of flood-control and water conservation projects now under consideration. As far as the writer is informed, little thought appears to have been given, in any of these projects, regarding the ultimate effect of their operation on the stream channels below them.

Channel deterioration is of two distinct kinds:

(*a*) Excessive bed scour in the reach immediately below a reservoir, caused by lack of sufficient débris load to absorb the energy of the released water normally available for débris transportation; this assumes all the bed load and, at least, part of the suspended load to lodge in the reservoir.

(*b*) Loss of cross-sectional area in the lower reaches due to the inability of the reduced stream flow to remove débris accumulations contributed by uncontrolled tributaries emptying below the reservoir. As illustrated by the Rio Grande case, both forms of deterioration, although of opposite types, may occur in the same stream. In fact, the conditions cited under Class (*a*) operate to aggravate those under Class (*b*). In either case, the hydraulic gradient eventually becomes affected, after which restoration to normal carrying capacities for both water and débris cannot be accomplished except at considerable cost. It is to be noted that the conditions under Class (*a*) are readily checked by providing suitable sill dams, whereas conditions under Class (*b*) are not easily rectified; and if they are not checked at the start they lead to serious losses of channel capacity.

---

[49] Prin. Engr., Office of Pres., Mississippi River Comm., Vicksburg, Miss.

In most projects interference with the physiographic balance, as described, can be minimized if not completely eliminated by careful *a priori* evaluation of soil erosion and run-off conditions on the one hand, and by the débris-carrying capacities of streams on the other hand. The principle involved is that any stream, viewed as a débris carrier, requires for its channel maintenance the flushing action of bank-full, or nearly bank-full, discharges at appropriate times. Furthermore, intelligent operation of reservoirs can provide such discharge if included as an essential feature in project design and operation. The reason why comparatively little channel deterioration has resulted in the Eastern United States from failure to observe these requirements, is that water utilization there is still in its infancy. Most reservoirs are not large enough to prevent major floods from spilling large volumes into the river below, and, therefore, do not materially curtail the flushing action of flood flows. In the arid Western States where for economic reasons water conservation has been extended farther, reservoirs large enough to absorb most of the flood flow are found on many streams. It is in such cases that the effects of channel deterioration are most noticeable. The author has given a clear portrayal of the problem as it affects these Western conditions.

One factor enters into the problem, which heretofore has received little attention. This is the resistance to scour and transportation by water on the part of débris accumulations which have aged and become compacted. Compaction of this kind is much more pronounced in Eastern than in Western streams, a circumstance which tends to mitigate channel deterioration in the latter. While bank-full flow is practically a necessity for removing débris accumulations in Eastern streams, it is probable that much less than bank-full discharge does effect such removal from streams in the arid West. Accurate data on this latter aspect are greatly needed. Certain it is, that the physiographic balance in Eastern streams is dependent on more frequent high rates of discharge than in the arid West, and that the streams of the latter during high stages carry a vastly greater débris load than Eastern rivers in flood.

An important difference appears to lie in the relative degrees of compaction of the débris. In the East, stream flow is perennial, and any materials left to lie undisturbed under water compact at a rapid rate, especially during the summer and fall when organic matter of all kinds is very active, and bed-load movement practically ceases. Agglutination of the sediment particles results, and this, added to the mechanical bond brought about by the puddling action of water which tends to fill the voids between large particles with smaller ones, enhances cohesion to a marked degree. The finer silts and clays compact more firmly than the coarser sands and gravels. In the arid regions, stream beds are dry or partly dry for many months each year. Oxidation of organic matter, sunlight, and wind then operate to reduce compaction. As flood flow in such streams usually subsides rapidly, débris deposits do not lie submerged long enough for compaction to reach a high stage of development; and this will account for the notoriously mobile character of the materials composing the dry beds of Western arroyos and rivers. This mobility facilitates their transportation when flow resumes.

Deforestation, over-grazing, and soil erosion have received increasing attention of late years, but the necessity of maintaining unimpaired débris-carrying capacity in streams has not come in for the attention that is due it. Evidently, it has not forced itself sufficiently on the attention of those who have the power to correct it. Impairment of natural channels in its incipient stages, is not easily recognized and, like an insidious disease, its symptoms are not manifest until an advanced stage is reached. This makes it all the more important for the Engineering Profession to be alert in this matter.

J. B. Lippincott,[60] M. Am. Soc. C. E. (by letter).—The effect of structures on the natural channels in the streams in the southwestern part of the United States, is well described in this paper. The deductions are of interest and value.

Temporary check dams composed of stones wrapped in wire netting and placed on the débris in the canyons or cones, to catch detritus and reduce stream gradients, are a menace rather than a benefit. Following the severe storm on New Year's Day, 1934, in the drainage basin of Verdugo Creek, 12 miles north of Los Angeles, Calif., all such structures inspected, which had not been built on bed-rock, failed, releasing impounded material. They are likely to mislead the public into believing in false safety.

In Article 2 the author states that "the forest cover unquestionably has an important constructive function in Nature which may not be fully appreciated because it is not well understood." The beneficial effect of forests in regulating floods has been generally accepted, but its profound extent has not been appreciated until recent investigations by foresters in California have made available its quantitative effect. A review of some of these determinations appears to be justified. The general conclusion of field tests has been sustained and emphasized by the startling results of the New Year's flood disaster in the drainage basin of Verdugo Creek.

In Southern California stream gradients of the mountain drainage basins are steep and the prevailing crystalline rocks are of a fragmentary and friable nature subject to rapid erosion. The sedimentary formations of the foothill areas also are rapidly cut by floods. When exposed to violent storms, floods are projected through the canyons on to the valleys, carrying with them surprisingly large quantities of débris which are deposited as delta cones below the mouths of the canyons. The depth of the valley fills is often in excess of 1 000 ft. Floods travel over these deltas in changing and uncertain channels. Communities located in the plains are menaced both by the floods and also, to a greater extent, by the débris. Occasionally, these violent floods contain surprisingly large percentages of mud, sand, and gravel as a thick emulsion, their high flow marks indicating a discharge too great to appear rational, if they were considered as composed of water only. For instance, in the summer of 1931, a flood occurred in Lone Tree Canyon, in the Tehachepi Mountains, discharging into the Mojave Desert, 14 miles northeast of the Town of Mojave. This was computed from high-water marks, to have been 51 500 cu ft per sec from a drainage basin of 35 sq miles as estimated by engineers of the Department of Water and Power of the City of Los Angeles. This drainage basin rises from 3 000 to 6 708 ft in elevation. The lower half is practically bare. Above 4 500 ft it is sparsely timbered and has little brush cover. Floods exceeding 2 000 sec-ft per sq mile were indicated for certain neighboring basins of from 2 to 4 sq miles. Fig. 3 shows the character of the lower part of the drainage basin and the flood channel of Lone Tree Canyon.

---

[60] Cons. Hydr. Engr., Los Angeles, Calif.

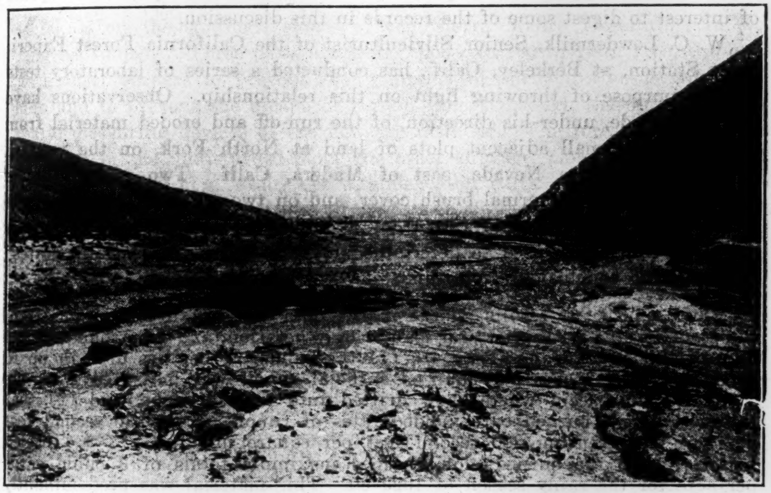

FIG. 3.—LONE TREE CANYON, SHOWING CHARACTER OF CHANNEL FOLLOWING FLOOD OF AUGUST, 1931, WHERE SECTIONS AND GRADES WERE TAKEN. NOTE BARE CHARACTER OF DRAINAGE BASIN.

Another flood on September 30, 1932, in the Tehachepi Pass left marks of indicated flows of 19 200 cu ft per sec from 33.8 sq miles on the headwaters of Tehachepi Creek. This basin is from 3 000 to 5 000 ft in elevation and is about one-half bare of cover. The remaining part has a few scattered oak and pine trees and little brush cover. A flow of 43 500 cu ft per sec was estimated from 20.2 sq miles on Oak Creek.[51] This basin is 10 miles west of Mojave. It rises from 3 600 to 7 950 ft in elevation, and is about three-fourths bare of cover. These three drainage basins are relatively smooth mountain areas. The floods were flashy, resulting from so-called cloudbursts.

During the past few years, the State and National Forest Services have been making intensive studies both in the laboratory and in the field, to find the relationship between water and débris discharge from brush-covered and burned areas.

---

[51] Estimates for Tehachepi and Oak Creeks by the California Div. of Water Resources Rept. (January, 1933), on Flood of September 30, 1932, on Tehachepi Creek.

The storm of December 30 and 31, 1933, and January 1, 1934, which occurred in the Los Angeles area, produced large floods of water and débris from the upper parts of Verdugo Creek. These floods were projected from the steep slopes of the Sierra Madre Range on to the Canada Valley, 12 miles north of Central Los Angeles, causing the death of 34 people, the demolition of 200 homes, and damage to much other property. The results from this storm, accentuated the importance of the study of the foresters of the relation between flows from denuded and forested areas. The data that have been compiled are of such impressive nature to the writer, that it appears of interest to digest some of the records in this discussion.

W. C. Lowdermilk, Senior Silviculturist of the California Forest Experiment Station, at Berkeley, Calif., has conducted a series of laboratory tests for the purpose of throwing light on this relationship. Observations have also been made, under his direction, of the run-off and eroded material from two duplicate small adjacent plots of land at North Fork, on the western slope of the Sierra Nevada, east of Madera, Calif. Two of these plots ($\frac{1}{40}$ acre, each) had normal brush cover, and on two of them this cover was burned. The ground slopes were from 30 to 60 per cent. Recording gauges and sand-traps were used to determine quantities. Dr. Lowdermilk states[52] the following conclusions from this test:

> "Two significant results appear in the data of rainfall and runoff from the plots covered with a natural mantle of vegetation, and from plots burned bare of this vegetation. They are (1) that under intensities of rain up to as much as 2.4 inches per hour no surficial runoff was measured from the covered plots, except where snow drifted into baffle troughs, and (2) that the soil surface burned bare yielded rates of runoff up to 0.30 second feet per acre, representing 200 second feet per square mile. * * * Eroded material from the burned plots reached maximum totals of 3 cubic yards per acre for the rainy season of 1929–30. This material was predominantly mineral soil, whereas material from the covered plots was essentially the organic material of litter."

TABLE 6.—RUN-OFF AND EROSION, IN CUBIC FEET PER ACRE, FROM NORTH FORK EXPERIMENTAL PLOTS; STORM OF DECEMBER 30 AND 31, 1933, AND JANUARY 1, 1934

Area	Unburned	Burned once, 1930	Burned annually 1929–31–32–33
Run-off	4	56	1 854
Ratio	1	14	463
Erosion	0	0.1	100
Ratio	0	1	1 000

The eroded material from the burned plots was 241 times as much as from the covered area. One pair of plots is in undisturbed natural forest-brush cover characteristics of the Sierra foothills. Two of the plots are on an area on which all cover was cut and burned completely in the fall of 1929.

---

[52] *Agricultural Engineering*, April, 1931.

Table 6 gives the results of the test for the storm of December 30 and 31, 1933, and January 1, 1934, on these North Fork plots.[53] The total rainfall for the storm was 2.92 in. Its maximum intensities for 10-min and 60-min periods were 0.18 and 0.58 in., respectively. It will be noted that the ratio of run-off for the period of the storm for the area that was burned once, was 14 times that from the unburned area and 463 times that from the area burned annually four times. The eroded material was zero from the unburned area and 100 cu ft per acre for the area that was burned four times.

Similar observations were made from small plots in San Dimas Canyon, which is on the southern slopes of the Sierra Madre Mountains, in Los Angeles County. These plots are from 1 000 to 1 200 sq ft in area, equipped with inset borders to prevent the incursion of surficial run-off from each side and to prevent the escape of run-off except through the outlets. Automatic measuring devices of the flow are installed. The forest cover consists of brush in the undisturbed plots, the other adjacent plots being burned off. The plots (0.022 acre, each) are established in pairs. The results obtained from observations on the storm of December 30 and 31, 1933, to January 1, 1934, are shown in Table 7. The total rainfall for this storm was 11.68 in.

TABLE 7.—SAN DIMAS RUN-OFF AND EROSION PLOTS; SUMMARY OF STORM, DECEMBER 30, 1933, TO JANUARY 1, 1934

Description	Covered plots		Burned plots	
Plot No.	301	302	303	304
Precipitation per plot, in cubic feet	932.5	932.5	932.5	932.5
Run-off per plot, in cubic feet	1.055	0.702	34.65	37.26
Run-off as percentage of precipitation	0.11	0.08	3.72	3.99
Ratio of run-off	1		40.9	
Maximum rate of run-off expressed as second-feet per square mile	10.2	11.4	223.4	200.7
Eroded material (dry weight, in grams)*	935	446	8 367	16 595
Eroded material (average)	690		12 481	
Eroded material expressed in moisture-free weight, in pounds per acre	68		1 250	
Ratio of erosion	1		18.4	

* Material was dried at 110° C for 40 hr.

Its maximum intensities for 5-min, 60-min, and 1 440-min periods were 0.12, 0.97, and 9.55 in., respectively.

The cover in the unburned area consists of a dense growth of brush approximately 10 ft in height. It will be noted that the ratio of run-off from the burned plots was 40.9 times that of the unburned plots, and that the ratio or erosion from the burned plots was 18.4 times the erosion from the unburned plots. These measurements were made by the California Forest Experiment Station.

Table 8 shows the rain that occurred during the storm of December 30, 1933, to January 1, 1934, along the southerly face of the Sierra Madre Range.

---

[53] From paper by Charles J. Kraebel, Senior Silviculturist, California Experiment Station, before a Conservation Conference in Los Angeles, Calif., March 23, 1934.

TABLE 8.—MAXIMUM RAINFALL INTENSITIES

Station	Inches of Rainfall		Location	Total for storm, in inches
	10-min. period	1-hr. period		
Mt. Lukens	0.30	0.88	Summit of burn	11.04
Haines Canyon	0.27	0.94	West edge of burn	12.08
Flintridge	0.34	1.33	1 mile southeast of burn	14.03
San Dimas Water-Shed	0.25	0.97	25 miles east of burn	10.8
Pomona City	0.28	1.29	30 miles southeast of burn	10.56

While quite uniform it was somewhat unusual in that there was no marked increase in precipitation with rise in elevation. The first station, Mt. Lukens, is at the crest of the Verdugo Water-Shed, Haines Canyon adjoins it on the west and Flintridge to the east. San Dimas is near the base of the range, 26 miles to the east.

TABLE 9.—RESULTS OF NEW YEAR'S STORM; RUN-OFF AND EROSION FROM SOUTHERN SLOPES OF THE SIERRA MADRE RANGE, LOS ANGELES COUNTY, CALIFORNIA

Water-Shed	Rainfall, in inches	Area, in square miles	Percentage of Water-Shed		Peak run-off, in cubic feet per second per square mile	Erosion, in cubic yards per square mile
			Burned	Unburned		
Burned Water-Sheds						
Verdugo *	12.5	19.3	33	67	350	30 700
Pickens †	12.5	0.48	100	0	1 000	50 000
Unburned Water-Sheds						
Arroyo Seco	12.3	16.24	0§	99.4	58	(No record)
San Dimas	10.8	16.85	0	100	53	56
Fern and Bell ‡	12.4	0.30	0	100	25	52

* Area and run-off computed at Wabasso Way. † Area, etc., computed above junction with east fork. This is a mountainous part of the Verdugo Water-Shed. ‡ Average of four experimental water-sheds, except area, which is total. § The area burned, 58 acres, in backfiring was too small and too lightly burned to affect the run-off from more than 16 sq. miles.

Table 9, taken from Mr. Kraebel's paper,[53] gives run-off and erosion figures from five small neighboring drainage basins. It also shows the extent of burning that occurred in the Verdugo Basin in the fall of 1934.

The increase in stream run-off and eroded material from the burned range as compared to the unburned areas is startling. The comparison from the small Pickens (burned) Mountain area of 0.48 sq miles and the Fern and Bell (unburned) area is illuminating. The Bell Canyon figures are actual measurements, but the Pickens Canyon quantities are estimated. The estimates by the engineers of the Los Angeles County Flood Control of peak flows from some adjacent small canyons in the burned area were much larger. The rainfall on the different basins was quite similar. The Arroyo Seco Basin adjoins the Verdugo Basin to the east. The San Dimas Basin is 26 miles east of the Verdugo Basin. Their topography and exposure are quite similar except that about 6 sq miles of the Verdugo Basin is the steep absorbent canyon floor. Probably the greater damage to life and property in the Verdugo area was caused by the débris that was projected from the burned areas more than by the water.

The volume of the flows in the Verdugo Basin is not possible of close estimation because of the high percentage of débris carried by the water and the erosion of the channels. It is also difficult to make accurate estimates of the quantity of débris discharged on to the valley floor. It has been computed from surveys as more than 500 000 cu yd, mostly from the burned part of the Verdugo Basin.

On the Arroyo Seco, which adjoins the Verdugo Canyon on the east, the peak run-off of which was caught in a reservoir, there occurred only one-sixth the quantity per square mile of the 19.3 sq miles of the Verdugo, the higher mountainous portion of which had been burned over in the fall of 1933. There is no record of the eroded material from the Arroyo Seco, but it was relatively insignificant. The violence of the flood in the headwaters of the Verdugo Canyon is demonstrated by the size of some of the boulders that were left standing by the storm on concrete street pavements, the largest of these boulders being estimated at 59.5 tons (see Fig. 4). It probably was pushed or rolled along by a mud flow.

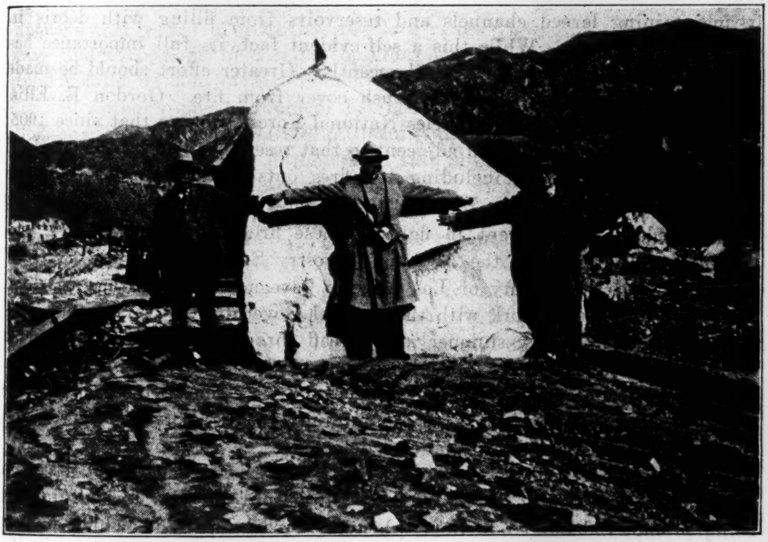

FIG. 4.—FLOOD DAMAGE, MONTROSE DISTRICT, LARGE BOULDER DISPLACED NEAR MOUTH OF DUNSMUIR CANYON. THIS BOULDER IS RESTING ON STREET PAVEMENT.

It will be noted that only one-third of the Verdugo water-shed was burned over, but this was in a high mountain part of the basin. It will be observed also that La Canada Valley, which has been filled by previous storms with steep sloping débris cones, constitutes another third of the Verdugo Basin. The remainder and unburned part consists of the Verdugo brush-covered mountains and hills. It would be more reasonable to expect less peak run-off per square mile from the Verdugo water-shed had it been brush-covered than from the Arroyo Seco, or other basins to the east, both because of its topography and exposure.

Many "check dams" which consist of rock covered with wire netting, built in the beds of the canyons, to heights of from 6 to 10 ft in the Verdugo water-shed, were destroyed by this flood, demonstrating that such structures, which have been advocated by many, are failures as retarding elements for such floods. If these dams were built on bed-rock and of masonry to heights of 25 to 50 ft, they would have beneficial effect.

Efforts at afforestation in the Sierra Madre Mountains have been failures except on high crests and northern slopes. The brush cover has proved efficient for flood and débris control. It has the advantage of reproducing itself by sprouting from its roots after fires, which is not true of large trees. The so-called "forest reserves" are not used for, and have little value as, a source of lumber.

The lesson to be learned from these floods demonstrates the value of brush cover in controlling floods, preventing erosions, and indirectly aiding in maintaining leveed channels and reservoirs from filling with débris in Southern California. While this a self-evident fact, its full importance has not been quantitatively shown until recently. Greater effort should be made than in the past to preserve the brush cover from fire. Gordon E. Ellis, Assistant Supervisor of the Angeles National Forest, reports that since 1905, 448 fires have occurred in and adjacent to that reserve, which have burned off a total of 227 710 acres, including 102 fires outside the boundaries of the National Forest, the latter totaling 18 704 acres burned. The expenditure by the Federal Government in fighting these fires has been $448 277. In addition to the work of the National Forestry Service, both the State of California and the County of Los Angeles have active organizations which co-operate in forestry work with the Federal Government. Fires occur during the heat of the dry summer and spread through the dense brush with rapidity. It is extremely difficult, if not impossible to extinguish them unless the effort is made at their incipiency. It is essential to reach the fire quickly. Permanent outlooks are maintained in the Forest Reserves and they are also patrolled by airplane to detect fires.

The most effective way of fighting fire is by the construction of a system of roads in the Forest Reserves that will permit of men and equipment being promptly delivered to them when the fire is reported. This can best be accomplished by building trunk roads through the Reserves, which may be used as public highways, from which branch forest roads may be constructed to strategic points, which laterals may be kept closed except in times of emergency. Such road systems are now (1934) being constructed in most of the Southern California Forest Reserves.

The adopted policy of building substantial masonry dams on the principal stream lines for the purpose of flood control and conservation is desirable but very expensive. They have demonstrated their effectiveness. Usually, the capacities of the reservoirs are small and unless their drainage basins are protected by forest or brush cover so as to prevent large erosion in their tributary basins, the duration of their usefulness is rapidly reduced.

The author has properly called attention to the necessity of careful consideration of stream gradients in relation to constructive conservation works. The protection of the forest cover is a still more basic requirement for the maintenance of permanent flood control.

In Conclusion (3) the author states that "engineers, investigators, and agriculturists have come to realize that the water-shed is their common problem and that co-operation will lead to a rational solution of water conservation in the water-shed." The writer heartily concurs in these sentiments which were endorsed at a large meeting of conservationists, including engineers, foresters, and civic organizations, held in Los Angeles on March 23, 1934.

RHODES E. RULE.[54] ASSOC. M. AM. SOC. C. E. (by letter).—The result of mature deliberation on an important but usually neglected phase of conservation engineering is presented in this paper. In so doing the author displays that rarest of qualities, the long-range viewpoint. Although many may find exceptions to detailed opinions expressed, none can question the fundamental wisdom of Mr. Sonderegger's proposition.

The author's physiographical balance is not a condition of true equilibrium; it is rather a relative uniformity in the time rate of change of the physiographic condition. As he states, this uniformity is of long-term trend rather than short. However, this uniformity may be over-stressed. Within human experience rivers have made major changes in their courses. Mountains have actually "fallen", forming gigantic natural dams. Other exceptions to the rule that geologic processes are in general non-cataclysmic are abundant. There is a common tendency to exaggerate the importance of normal geologic processes when they occur infrequently.

When going to extremes Nature has a habit of doing a thorough job of it. The late Allen Hazen, M. Am. Soc. C. E., has stated;[55]

> "In considering the whole flood problem there is the remarkable condition that a few very large floods are so high in comparison with all the rest that the question is raised as to whether they belong in the same class or whether they are outside and follow some law of their own which comes into operation only at very long intervals and with extraordinary floods."

Recent statistical studies made by the writer tend to bear out this hypothesis that extreme storms—and, hence, floods—follow a law of their own. The tentative conclusion is that great floods are more probable of occurrence than is indicated by ordinary probability studies.

---

[54] Civ. Engr., (Rule & Rule), Los Angeles, Calif.

[55] "Flood Flows", by Allen Hazen, p. 53, John Wiley & Sons, New York, N. Y.

Of recent years it has become the vogue to credit many extreme floods to human interference in the form of fires, timber removal, and over-grazing. The conclusion that removal of this interference will reduce materially the possible maximum flood must be treated cautiously. On the other hand, there is no doubt that these human activities have a marked effect on flood conditions and, in some cases, are the controlling factors.

In the case of the destructive floods of 1923 and 1930, at the westerly base of the Wasatch Range, between Salt Lake City and Ogden, Utah, there is strong geologic evidence to support the theory that the rate of erosion resulting from these floods was much greater than at any time since the passing of Lake Bonneville, a matter of tens of thousands of years. This excessive erosion rate is probably properly attributed to denudation by fire and over-grazing.

Similarly, the La Crescenta-Montrose mud flow in Southern California, on January 1, 1934, was the result of a severe precipitation concentrated on a relatively small but almost completely fire-denuded area of steep watershed. Undoubtedly, some human hand was responsible for setting this fire and was, therefore, responsible for upsetting the physiographic balance which resulted in destructive floods and mud flows, and loss of life and property. It is significant, however, that this took place despite a most elaborate and highly organized system of fire-patrol. This raises the question as to how far human effort can go toward stemming the tide of natural forces.

Before civilized man came on the scene detrital flows of the same nature as those occurring in the La Crescenta-Montrose area were of frequent happenings. In no other way is it possible to account for the alluvial fans at the bases of the Southern California mountain ranges. Detritus hundreds of feet in depth has been deposited in the space of relatively short geologic time. To have accomplished this vast task of transportation required many great floods because it is only in major floods that coarse material, such as that comprising these fans, can be transported in any appreciable quantity. It is doubtful whether works of Man can do much in an economic manner toward controlling such floods to the point that occupation of these alluvial fans can be made safe. Granting that débris dams may be built to accomplish the purpose for a term of years, is the cost balanced by the benefits? Should an entire county be taxed for protecting the property of a small special class of property owners? The major portion of the damage in the La Crescenta-Montrose area was done to improvements lying in the direct paths of countless previous floods.

The author's treatment of the effect of regulation upon the natural balance of a stream system deserves serious consideration. In Southern California the equilibrium between aggradation and degradation is accomplished by many seasons of the former and few of the latter. When storage is provided on a stream for all but the capital floods the burden of establishing a new gradient is imposed upon the stream below the storage. The periods of degradation become much fewer and of less ability to do work of transportation. Add to this the continually growing flood discharges from paved streets in the metropolitan area, and the situation becomes acute. The effect of this discharge from improved areas is to increase the discharge and carrying power of the tributary streams without adding much to that of the main stream. It seems that unless proper precautions are taken the arrival of the rare capital floods will find conditions right for overflow of much highly improved real estate.

A. L. SONDEREGGER,[56] M. AM. SOC. C. E. (by letter).—More than gratifying have been the discussions in that they have brought out many points of interest and importance in stream control and conservation. Like the subject of the paper, the discussions have covered a large range of thought and observation. Most of the discussers appreciate the necessity of a correct evaluation of the effect of modern works on natural processes and the physiographical balance. Engineering science has made great strides in the theoretical analysis of strains, stresses, and forces, and has succeeded in clothing important results of research in convenient formulas for the ready use of a learned and busy profession. On the other hand, the study of natural phenomena and a correct appraisal thereof proves to be a matter of experience rather than of learning and, as a rule, is not acquired without reprimand by failure. Hence, it would not be astonishing if subjects like the disturbance of the physiographical balance would find more appreciation with the older members of the profession than with the recent graduate who is justly proud of his newly acquired knowledge.

The importance of the water-shed cover and its effect on run-off and débris production is touched upon by several discussers. Mr. Lippincott's discussion is particularly illuminating in this respect, in that it is supported by comparative data relative to the effect of the vegetal cover in its natural condition and after one or more burnings. He concludes that "greater effort should be made than in the past to preserve the brush cover from fire." While this is a desirable objective, it must be borne in mind that the preservation of the brush cover over a long period of years promotes the accumulation of highly inflammable materials which, when set on fire, are difficult of control. Fires will continue to occur; in fact, with an ever growing population and greater facilities of access to the water-shed, the odds are in favor of an increasing fire hazard.

These considerations may have induced Mr. Rowe's point of view, namely, that of periodical controlled burning. Possibly the solution to this perplexing problem is already found in the present policy of the responsible authorities, of maintaining efficient fire-fighting organizations and completing the network of mountain roads which will permit the rapid conveyance of crews and apparatus to strategical points while fires are in their incipiency. While the number of fires may continue to increase, the probabilities are that, with improved methods and perfected organizations, damages will be confined to smaller areas. Thus, a system of rotation of burning may evolve which will eliminate major conflagrations, at the same time relieving authorities of the risks and responsibilities that attend controlled burning.

---

[56] Cons. Engr., Los Angeles, Calif.

The La Crescenta-Montrose flood discussed by Messrs. Lippincott and Rowe, and referred to by others, has brought out several distinct facts bearing on the flood-control problem of Southern California: (1) That brush fires are a permanent menace at any point; (2) that run-off from tributaries may assume such proportions as to overtax existing flood channels of main streams; (3) that débris production from burnt-over areas may be of such magnitude as to be a menace to foothill areas and to the storage space of flood-control detention reservoirs; and (4) that a material increase in the peak discharge of both water and débris may result from the failure of temporary check dams.

Mr. Jarvis takes exception to the writer's statement that a permanent decrease or increase of 20% of the mean rainfall of semi-arid areas might result in far-reaching climatological or physiographic changes, while Mr. Stevens challenges the general statement that physiographical factors combine to produce a balance, even under existing conditions. The viewpoints are distinctly at variance.

It is admitted that, in the Southwest, cyclic fluctuations of seasonal rainfall in the past, which resulted in wet and dry periods of 10 to 15 yr each, seemingly had no effect on the development of the country, or on the earth's surface. As far as farm husbandry is concerned this is explained, in part, by the utilization of underground storage which, over large areas, yielded abundant supplementary supplies for the relatively short period of droughts. With a permanent reduction of 20% in the mean seasonal rainfall, the periods of relatively low water supply would necessarily be extended and periods of recharge correspondingly shortened, leaving no doubt as to the ultimate effect on the safe water yield of large areas.

The natural vegetal cover of the water-shed, as a rule, is a fair index of the mean seasonal rainfall, expressed in the prevailing species, as well as in the vigor and size of individual plants. In fact, with some experience in these matters, it is feasible to estimate with a fair degree of accuracy, the seasonal rainfall by the character of the vegetal cover. The difference in appearance of water-sheds receiving 12 in., 15 in., and 18 in. of mean seasonal rainfall is striking enough to leave no doubt as to Nature's adjustment to mean climatic conditions. Similarly, general topographic conditions must be the result of some combination of the effect of the controlling causes. If the latter undergo permanent changes, a reflection in effect is inevitable. Nature, like the "mills of the Gods", may grind slowly, yet it grinds exceedingly fine.

Mr. Stevens' standpoint is scarcely justified. Nature's adjustments must be to some mean condition which undergoes only gradual changes; otherwise, human settlement would be forced to make way to a nomadic existence. Exceptions to this rule, due to local disturbances by reason of floods, wind storms, fires, etc., no doubt take place, and may result in radical changes of physiographical features — often temporary, sometimes permanent — but they effect a relatively insignificant portion of the inhabitable areas.

Professor Chapman makes some rather startling assertions in that he claims (1) that the physiographical balance is maintained over large areas in the West by grasses and herbage; (2) that profound disturbances of the equilibrium have taken place through extensive over-grazing; (3) that over-grazing is the principal cause of modern arroyo formation and that the cycle of degradation now operating is of recent origin; and (4) that historical evidence shows that both the Gila and the Colorado were clear streams near Yuma, Ariz., in 1824.

It is not disputed that over-grazing within the water-shed of the Colorado River has reduced the grass carpet over large areas, thus promoting erosion and denudation. This phase has been discussed by Ralph I. Meeker,[57] M. Am. Soc. C. E., and by F. H. Olmstead,[58] M. Am. Soc. C. E. However, it is questioned whether over-grazing is a major phenomenon affecting the physiographic balance of the West. On the subject of the origin of silt the following quotation from the comprehensive study of silt production in the Colorado River water-shed is submitted:[59]

> "The aridity of the climate and the consequent lack of vegetation is one of the main causes. Because the territory is sparsely settled, relatively few climatic records have been kept, and in many parts the precipitation is not known accurately. Roughly estimated, 40% of the total area of the basin has a precipitation of less than 10 inches a year, in 50 per cent the precipitation ranges from 10 to 17 inches, and in the remaining 10 per cent it is from 17 to 25 inches and higher in the high mountains. Fully one-half of the basin is either bare or but scantily covered with desert shrubs and grasses."

Relative to the silt production of the Green River and Upper Colorado, where the major grazing areas are located, as compared with that of the Little Colorado and San Juan Rivers, data given in the report[60] reveal a much greater proportion of silt in the water of the lower tributaries which drain desert areas.

Professor Chapman's reference to the diary of the explorer, James M. Pattie, in which the Gila and Colorado Rivers are described as clear streams, can scarcely be accepted as conclusive historical evidence that the muddy appearance of these streams is a modern phenomenon. Other historians have left records which emphasize conditions to the contrary. Quoting from F. S. Dellembaugh[61] who was a member of the Second Powell Expedition through the Colorado River Canyon, in 1872:

> "In 1539, the Spanish explorer, Francisco de Ulloa, leaving from Acapulo, sailed to the head of the Gulf of California where he made this observation—'and thus sailing we always found more shallow water and the sea thick, black and very muddy'.

* * * * * * * * * *

> "In 1609, Don Juan de Onate, traveling west from San Juan on the Rio Grande *via* Zuni, '10 leagues beyond Moki, they crossed a stream flowing

"On Powell's first trip down the Colorado, the tributary Fremont River, in Southeastern Utah, was given the name 'Dirty Devil' from the character of its water.

* * * * * * * * * *

"In 1869, Powell's party found the Little Colorado at its mouth 'small, muddy and saline'."

Lieut. R. S. Williamson[63] writes:

"The water [in the Colorado River, at Yuma, in 1853] was highly charged with fine red mud which gave it a decided red color and opacity. * * * The amount thus annually transported to the Gulf of California by this river must be very large, and very considerable additions to and alterations of its delta must result."

Last, but not least, the statement is here presented that the Grand Canyon of the Colorado, cut to a depth of 1 mile into the plateau during past ages, has been the basic cause for the degradation of the tributaries and their water-sheds during the same period, with the great Colorado Delta a silent but potent witness to a process in which the works of Man had no part.

The discussion by Mr. Bonner of the rate of débris production of representative streams, storage depletion through siltation, and annual silt production in the United States, illustrated in Tables 3, 4, and 5, is of general interest and no doubt is widely appreciated by engineers occupied with problems of water supply, conservation, and flood control. Table 3, in particular, has filled a long-felt want relative to the silt load of streams in that it covers a wide range of drainage areas, both as to size and geographical location. The assumption of a mean weight of 85 lb per cu ft for alluvial deposits furnishes a convenient justifiable ratio for the establishment of the relation between weight and volume and for comparison of data when different methods of measurement have been adopted. The compilation of records of storage reserve depletion is gratifying in that it demonstrates for a large majority of cases a remarkably low rate of depletion.

Reference has been made to the conditions on the South Pacific slope which form rather the exception to this rule. Because of steep gradients of streams and, in many cases, unsuitable foundations, economic reservoir sites are few, and the available storage capacity, almost without exception, is deficient for flood control. Flood regulation, therefore, remains imperfect, being circumscribed by available detention storage. On many streams, the one practical reservoir site has been utilized and the channel capacity below it has been adjusted to the resulting peak flow. Although, under normal conditions of the water-shed cover, débris production may not be a disturbing factor, there remains the ever-present danger of abnormal erosion from burned areas. Under such conditions, a preconceived plan of débris storage for the protection of water storage becomes imperative.

[63] Report of Explorations in California, 1853, Senate Doc. No. 78, 33d Cong., 2d Session, p. 112.

Check Dams.—Mr. Jarvis comments on the relative merits of high débris barriers and check dams for conservation projects. Check dams were an important feature in the La Crescenta-Montrose flood discussed by Messrs. Rowe, Lippincott, and Rule.

These check dams were of a temporary type of construction. Many had been placed in the small canyons of the La Crescenta-Montrose area by the Los Angeles County Flood Control District several years prior to the fire. Immediately after the fire of November, 1933, other agencies in the vicinity were engaged to build additional checks, both in the canyons and on the débris cones. In Pickens Canyon, checks had been placed on the cone from the State Highway to the mouth of the canyon and from there in the rock formation to upper reaches of the creek. This work was of such magnitude as to be generally known and to create in the local population the conviction that the problem of flood control had been satisfactorily solved. As an added precaution, the Forestry Service had sowed a large part of the burned-over area with a variety of mustard used in Southern California for cover crops. The criticism has been advanced that a widespread use of temporary structures in the mountain areas tends to create a false sense of security on the part of the population of the area below. This unfortunate psychological effect, and the dangers inherent in temporary types of structures have also been brought out by Mr. Debler.

In this particular case, the checks undoubtedly released a considerable quantity of débris which, with permanent structures, might have remained in the mountains. However, with a subsequent flood, their efficiency would have been negligible in any case because they would have been either completely back-filled or buried. The latter effect was observed in 1924 in Sawpit Canyon where the stream bed, raised by a series of checks, assumed its original gradient.

Check dams have been an element in the flood protection and conservation program of Southern California. Thousands have been built and although those subjected to severe tests have failed, the popular faith in and demand for this type of structure has not abated.

The conception has been that check dams "hold the water in the mountains" for future release, affecting not only conservation, but also regulation of flood flow. So firmly has this idea been entrenched in the public mind that check dams have lost their technical significance and in Southern California have become a political issue. For this reason, it is considered justifiable to devote some space to an analysis of the function of this type of structure.

As a flood-control feature check dams were proposed in Southern California after the capital floods of 1914 and 1916, the idea being to regulate the flow of the mountain streams at the source. The prototype of the check-dam system was the débris barrier of the Swiss Alps. Unfortunately, in applying the Swiss system to conditions in Southern California, the true functions of the structures were misunderstood, and the guiding principles of construction disregarded. In the Alps, the barrier systems were utilized to control abnormal débris production in regions where the formation consists of soft slates, marls, and chalks, which are easily erodible. The Alpine barriers were built of massive dry masonry, as a rule, with the two top courses of pointed rock laid in cement mortar, and were from 20 to 100 ft in height. Particular care was exercised to secure the foundation by building on bed-rock, or by providing one or more stilling-basins as a protection.

The purpose of these barriers is first to stop erosion of the stream bed and then to cause the back-fill of the barrier and thereby protect the adjacent slopes from undercutting and slides. After the slopes are stabilized, they are further consolidated by planting. The massive type of dry masonry is well demonstrated in reports of Swiss engineers on the improvement of mountain streams.[63]

In the application of checks to Southern California conditions, the intention was primarily to regulate the flow of water during flood peaks and to effect conservation by holding water temporarily in the back-fill of the dams. This was to be accomplished by the erection of systems of check dams of a nominal height of 6 ft, distributed throughout the length of the stream bed. In some canyons several hundred checks were erected. Débris control, or storage, has not been considered the major objective.

The original plan contemplated the construction of dry masonry arches, built carefully to bring the arch action into play. However, lack of skilled labor, unsuitable materials, and the absence of proper foundations soon caused a modification in design. Arches were abandoned, and the dry masonry degenerated into dry rock walls, built by unskilled labor. Cases are known in which, in the absence of suitable quarry rock, boulders from the bed of the creek were used. After numerous failures, the practice of wrapping the structures with triangular wire netting was adopted, so that, to-day, the strength of the rock wall rests with the strength of the wire mesh. Large numbers of such dams have been built in Southern California. The contention has always been made that these dams can be built for from $25 to $50, although experience has shown that they cost more and that the cost of wire-bound rock check dams may be as high as $500, depending on the length. It is a feature of this check system that the dams are built approximately the same height regardless of the size of the water-shed and the depth of the stream flow, and that the spacing is more or less arbitrary. The systems, as constructed deviate further from the theoretical plan in that, in many canyons, dams cannot be built in the uppermost and steep parts where the slopes may be from 40 to 60 per cent.

It is apparent that the function of the barrier systems in Southern California is fundamentally different from that in the Swiss Alps and, furthermore, that the rugged construction of the latter has been abandoned for a comparatively fragile and unstable type.

Flood Regulation by Check Dams.—The popular view that "check dams hold the water in the rocky formation of mountains" may be explained by the erroneous concept that the time consumed in transit of the water from the water-shed to the valley is materially increased. It should be clear that checks do not affect the rate at which water collects from the canyon slopes so that the period of retardation is determined mainly by the amount of possible channel storage within the checked area.

Conditions are conceivable in which the construction of a proper number of correctly proportioned small checks may reduce the velocities of a mountain stream to such an extent that a temporary storage in the channel will result and, hence, a material reduction of the peak flow. A first requirement is that the height of check dams is in correct proportion to the depth of overflow (see Fig. 5(*a*)). Next, comes the spacing of check dams which is determined theoretically by the point of intersection of the original slope (20%) with the slope of the back-fill of the check (5%). In other words, the spacing must be a function (*a*) of the height of the check; (*b*) of the original gradient of the stream; and (*c*) of the gradient normally assumed by the back-fill material. This proportioning holds for a depth of overflow which will produce a free fall and a destruction of the energy by fall and turbulence. However, if the depth of overflow is such as to cause the check to act as a submerged weir, the effect of the drop is largely lost. This, for example, was the case with some of the check dams in the La Crescenta-Montrose area (see Fig. 5(*b*)).

FIG. 5.

Aside from any question of design, regulation is a function of the total reduction in velocity during peak periods. This reduction results from decrease in gradient, greater width of channel, and loss of energy at the various drops. Theoretically, the reduction of the gradient from 20% to 5% would reduce the mean velocity by about one-third; the flat section above checks tends further to retard the flow, while the increased depth of water in the narrower parts of the channel below the check increases the theoretical gradient. The resulting channel storage will be in proportion to the length of the checked section and the reduction of velocity.

Apparently, the most efficient reduction in gradient compatible with economy would result from high barriers spaced correspondingly, for the reason that the narrow section of the channel would be only a small part of the total length between checks, leaving a large stretch for the adjustment of velocities. With barriers of a height of 20 ft, or more, the width of channel at the check would probably be in excess of 50 ft. Under such conditions, channel storage would attain a maximum.

Assume the theoretical case of a canyon being visited by a rain of maximum intensity. In such an event, the hydrograph of an unchecked canyon would assume the line, *A-B*, shown in Fig. 6, with a peak discharge represented by Line *B-C* and the run out by Line *C-D*, the period of the storm being indicated by the distance, *T*. If, as a result of proper checking, peak velocities have been reduced, the time represented by Curve *A-B* becomes longer and if the peak is delayed beyond Point *C*, it will also be reduced as indicated by Curve A-B_1-C_1. In other words, factors remaining equal, the shorter the time represented by Line *T* (that is, the duration of the storm), the greater the probability that checking would be effective. On the other hand, if the duration of the storm represented by the distance, *T*, and the peak flow, *B-C*, are extended beyond B_1, checking would have no effect on the size of the peak; the effect would be a delayed peak of shorter duration. In any case, the delay could not be longer than the difference in time of transit for the water from the upper end of the canyon to the mouth.

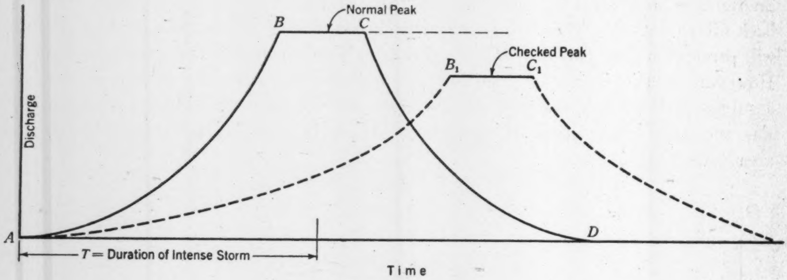

FIG. 6.

The effect of checking can best be explained by an example. Assume a mountain stream with hydraulic properties, as given in Table 10. While the total difference in channel storage is 100 000 cu ft, the proportion of this extra storage which affects the peak flow depends on the depth of stream flow prior to the period of intense rainfall and, consequently, can be only a portion of the 100 000 cu ft. Furthermore, if the time of the peak discharge exceeds 833 sec, the maximum flow at the canyon mouth remains the same in both instances.

In Southern California, the small tributary canyons, in which checks are placed, are short, ranging in length from ½ mile to 1½ miles, with gradients of from 10 to 40%; hence, velocities are high and time of transit relatively short—probably less than 30 min for severe storms. Cases are recorded where two periods of intense rainfall occurred at short intervals. Under such conditions the second peak might catch up with the delayed first peak of a checked canyon, resulting in a greater flood than would happen under natural stream flow.

TABLE 10.—HYDRAULIC PROPERTIES OF AN ASSUMED MOUNTAIN STREAM

Description	Unchecked stream	Checked stream
Length of bed, in feet	5 000	5 000
Peak flow, in Cubic Feet per Second:		
Upper end	100	100
Lower end	500	500
Mean velocity, in feet per second	10	6
Mean Wetted Area, in Square Feet:		
Upper end	10	16⅔
Lower end	50	83⅓
Channel storage, in cubic feet	150 000	250 000
Time of transit, in seconds	500	833

The difficulty in estimating the effect of check dams lies in the lack of reliable data as to the intensity and duration of storms. It is unwise, therefore, to place too much, if any, reliance on the effective flood protection by systems of checks, even if properly designed and constructed. In fact, it is the writer's opinion that, during capital floods, conditions may be such as to render regulation by check dams ineffective.

Water Conservation by Check Dams.—In an appraisal of the efficiency of check dams for purposes of water conservation, differentiation must be made between streams flowing on bed-rock and those flowing on an alluvial fill.

Mountain streams issuing from bed-rock canyons act essentially as drains, intercepting the water which percolates down the slopes in fissures, cracks, and in the soil cover. If the creek bed is crossed by deep-seated fissures, the stream will be carrying the unabsorbed water. This function of the stream as a drain is not changed by the construction of a series of check dams, except that the débris behind the checks will hold some of the water temporarily, which then will be exposed to evaporation from the saturated mass, or will promote plant growth. Absorption into deep-seated fissures is assisted by this process only to a small extent.

A stream flowing on porous alluvium, with a water-table at effective depths, is naturally a losing stream. If checked by a system of dams, absorption will increase in proportion to the additional width of the wetted perimeter. In both cases checks should be credited with the storage in the débris which, although small, nevertheless remains an element to be considered. However, the débris storage and its water capacity increase more than the square of the height of the dam; hence, conservation favors the higher dams.

Summarizing on the relative merits of low and high check dams, it is concluded that for the consolidation of the stream bed in an erodible formation, low checks or fixed sills offer a satisfactory solution; that for débris storage, the consolidation of slopes, and, for conservation, high barriers may be found to be more efficient; and that for purposes of regulation, barriers with negligible water storage cannot be relied upon at times of critical discharge.

Unfortunately, the popular conception may attribute flood regulation to a system of checks designed for conservation, or débris control, and induce encroachment on the over-flow areas of a stream. Unless such areas are definitely zoned as dangerous for habitation, destruction of human life and property is inevitable.

Design of Check Dams.—To be effective check dams must have a height in proper relation: (*a*) To the depth of overflow; (*b*) to the gradient assumed by the stored débris; and (*c*) to the distance between checks. These matters would be taken into consideration were the problem one of designing a small number of high barriers; yet they are equally important with small checks.

Another feature of the design would be the correct thickness of the dam relative to the overflow wherein must be considered such forces or combined forces as extreme high water, débris, and mud flow, resulting in an extremely high specific gravity for the material passing over the dam and the impact of large rocks. Depending on the magnitude of slides, the stream may become temporarily blocked or dammed until a small lake is formed. When such slides are topped they may be released suddenly, advancing down the canyon as a mud-flow or débris wave. Such conditions were observed in the La Crescenta-Montrose flood. To withstand such forces in steep mountain canyons will require structures quite different from a dam consisting of loosely piled rock wrapped with triangular wire netting.

The conclusion is reached that in order to be permanent a 6-ft check dam must be constructed to withstand strains and forces out of proportion to its size, and, therefore, if properly built, will prove likely to be the most expensive type of control works instead of the cheapest, as has often been claimed.

The discussions of the paper necessarily centered on conditions in the arid Southwest. The writer is indebted to Mr. Matthes for his comparison of the problem in Eastern and Western streams. Attention is called to a paper by Mr. Matthes, which bears on certain phases of the physiographical balance manifested in stream dynamics.[64]

It was the purpose of this paper to awaken the consciousness of the Engineering Profession to the dangers accompanying the disturbance of the physiographic balance. The interest thus aroused is gratifying.

AN APPROACH TO DETERMINATE STREAM FLOW

By Merrill M. Bernard,[1] M. Am. Soc. C. E.

With Discussion by Messrs. C. S. Jarvis, LeRoy K. Sherman, W. W. Horner, C. H. Eiffert, Charles S. Bennett, R. L. Gregory and C. E. Arnold, Gordon R. Williams, W. G. Hoyt, L. L. Harrold, and F. F. Snyder, and Merrill M. Bernard.

Synopsis

In a paper on the determination of stream flow from rainfall records, LeRoy K. Sherman, M. Am. Soc. C. E.[2] undertook, through the summation of daily increments of run-off, not only to establish the maximum flow resulting from a recorded rainfall, but to produce the stream hydrograph, a process that to a remarkable degree parallels the phenomenon of stream flow produced from storm run-off.

The results of a study, the outgrowth of an interest in Mr. Sherman's paper, is presented herewith. It treats of other aspects of the problem and offers a procedure that is believed to be an approach to determinate stream flow. The transition from rainfall to stream flow is accomplished through the medium of a "distribution graph," which is found to be a function of water-shed characteristics. The possibility of developing the distribution graph without resorting to the stream-flow records is shown. The "pluviagraph," or maximum hydrograph, is discussed, and its value to design in the field of hydraulic engineering is demonstrated.

The study utilizes six water-sheds of from 500 to 6 000 sq miles and embraces practically the entire State of Ohio. These water-sheds were selected from the unregulated streams served by the United States Geological Survey, and represent an acceptable range in area and water-shed characteristics.

Note.—Published in January, 1934, *Proceedings*.

INTRODUCTION

A general interest in the flow of a stream divides itself into: (1) The conservation of water for such useful purposes as irrigation and power development; and (2) the disposal of flood-waters without loss or damage. In the latter case the objective will be the determination of maximum values of flood volume or stream stage, depending on the nature of the problem and the degree of protection sought.

The ideal situation is that of finding a long-term flow record applicable to the location of the structure to be designed. If the project is one of flood protection, however, or of channel improvement, that disturbs the regimen of the stream; or if the water-shed is subject to further development, even this record must be modified to meet the new conditions of delivery and concentration of flood-water.

As is more generally the case, the designer is forced to deal with a short-term record on the stream itself, must extrapolate a record of a neighboring stream having similar water-shed characteristics, or must attempt to establish the magnitude and frequency of various flood flows by analyzing the factors that produce them. In dealing with such problems, complexities have discouraged all except a comparatively superficial treatment of the problem.

The evolution of this science is interesting. The best of the older empirical formulas expressed flood flow as a function of area only; others introduced rainfall rate and slope factors. More recent studies are to be divided into two groups. One group, utilizing recorded stream flow, relates flood flow to area by means of coefficients and exponents which tend to become constant for localities of considerable extent. The other group attempts to express flood flow as a function of storm intensity, more recently giving values to such factors as storm frequency and duration, and water-shed characteristics. Further development of the former method is restricted by a data source rendered inadequate through poor distribution and short-record period. The latter group, advocating the rational method, or some modification of it, must develop, through research, values for several important factors now indeterminate.

The objective in this field may be stated thus: A method of determining flood flow in terms of magnitude, duration, and frequency, at any point on any stream, within a region having the same range in climatological, topographical, hydrological, and geological conditions. The method must give determinate values to all principal factors affecting run-off and must group the minor influences into coefficients that approach constant values of regional application. It must utilize available data only, which, in this country, are limited to the published records of the United States Weather Bureau and the United States Geological Survey. The method must meet the test of reproducing the stream hydrograph accurately.

BASIC DATA

The foregoing "specification" has stipulated that the proposed method must be capable of utilizing published Weather Bureau and Geological Survey records. This assumes their application to the larger water-sheds on which the time unit for the unit graph or for the distribution graph is one day or more. The advantages of general availability and distribution far outweigh the disadvantages and objections which are set forth, with suggested remedies, in a recent Committee report.[3] Other improvements in this service, admittedly not easy of accomplishment, would be: (1) All stations to take readings on the same hour; (2) notation of hour and depth at end of period of continuous downpour, within the 24-hr interval; and (3) improved typography and arrangement in the monthly publication of climatological data.

The Unit Graph.—Defining the theory of the unit graph, LeRoy K. Sherman, M. Am. Soc. C. E., states[4] that, for the same drainage area, there is a definite total flood period corresponding to a given rainfall, and that the length of the base of the hydrograph will be the same for all 1-day rainfalls, regardless of intensity.

According to Mr. Sherman, "if a given one-day rainfall produces a 1-in. depth of run-off over the given drainage area, the hydrograph showing the rates at which the run-off occurred can be considered a unit-graph for that water-shed."

The unit graph is constructed by segregating the daily stream flow resulting from a single downpour of 1 day (or the other time unit), from the flow occasioned by previous and subsequent rainfall. This, by proportion, is converted into run-off, in feet per second, equivalent to a depth of 1 in. over the area, and becomes the unit graph of the water-shed.

The hydrograph is developed through the following procedure: (*a*) Daily rainfall, properly weighted, is listed by date; (*b*) a coefficient is applied, reducing rainfall to run-off, in inches of depth; (*c*) the unit-graph value for each day, multiplied by the run-off depth, gives the increment of stream flow attributable on that day to the daily rainfall so affected; and (*d*) the horizontal summation of the run-off increments, day by day, produces the total flow and becomes the ordinates of the hydrograph.

The Distribution Graph.—The writer's conception of the theory on which the unit graph is based, is as follows: For a particular water-shed, two storm periods confined to the same time interval and uninfluenced by preceding and subsequent rainfall will become effective to stream flow at the same proportional rate, expressed as a percentage of the area contributing its run-off to the flow of the stream, at the point of observation, day by day. This is to be conceived as a time contour, which, having developed around the point of concentration, recedes to the outer limits of the water-shed, progressively enveloping the various portions as they contribute to the flow, reaching the extremities when all parts have contributed and the area under the distribution graph is equal to 100 per cent.

---

[3] Progress Rept. of Special Committee on Meteorological Data, *Proceedings*, Am. Soc. C. E., January, 1933, p. 153.

[4] "Streamflow from Rainfall by Unit-Graph Method," *Engineering News-Record*, April 7, 1932, p. 50.

Here, as in the unit-graph method, the concentration period may be defined as a time interval, at the end of which all parts of the water-shed are contributing to the flow at the point of observation. This definition should apply, as well, to the time interval used in the rational method to establish the critical average rainfall intensity; but it will be found that the concentration period, as usually estimated or calculated, is much shorter. The calculated time in transit of flood-waters from head-water to outlet on the Tuscarawas River, at Newcomerstown, Ohio, is between 3 000 and 4 000 min, while its distribution graph shows that only about one-half its area has become effective to the stream flow in that period. The error lies in a misconception of the meaning of "remote area." It is usual to consider that part of the water-shed in the vicinity of the head-waters as establishing concentration time because of its distance from the outlet. As a matter of fact, the efficiency of the main channel, through higher velocities, places head-water areas much closer to the outlet in terms of time than extensive areas nearer but less advantageously located.

It is difficult to select from the rainfall record, a storm of the type which will produce a hydrograph suited to the construction of the distribution graph of the water-shed. The task requires boundless patience and the application of unusual care and judgment. Upon first attempt one is convinced that any result can be obtained. A storm period, to produce the distribution graph of the water-shed, must have the following characteristics: (1) The rain must have fallen within the recording time interval, or the time unit, as the day (or hour); (2) the storm must have been well distributed over the water-shed, all stations showing an appreciable depth of rainfall; (3) the run-off following the storm must have been uninterrupted by the effects of low temperatures and unaccompanied by melting snow and ice; and (4) the storm period must occupy a place of comparative isolation in the record. It should follow a period of low stream flow and there should be no further rainfall until the flood peak is well passed.

Certain unavoidable sources of error and inaccuracy must be recognized and accepted in dealing with Weather Bureau data. At some rainfall stations readings are made at 8:00 A. M.; at others, at 5:00 P. M. It is highly probable that at many of the co-operative stations readings are taken at irregular intervals, the record going in as a forenoon or an afternoon observation. A continuous storm of 24 hr, or less, may be divided by the recording hour, appearing in the record as a 2-day storm. Particularly on small water-sheds it is possible that the entire rainfall may have fallen in the first hour, the flood peak on the twelfth hour, and the flow, officially recorded on the twenty-fourth hour, may be only a small fraction of the maximum. Stream flow is recorded as a 24-hr average, obscuring true maximum values, particularly on small water-sheds.

Table 1 includes all data used in developing the distribution graphs for the six water-sheds embraced by this paper. In every case but one at least three storm periods were found which gave acceptable graphs, the average being taken as the distribution graph for the water-shed.

* Day record abandoned.

The daily value of the distribution graph is given a proportional value instead of a quantitative value as in the unit graph. In developing it, the rainfall record is only necessary to check the isolation, duration, and distribution of the storm period and to determine the date on which subsequent rainfall affected the flow of the stream, at which point the record is to be abandoned and the further recession of the flood flow estimated.

By taking a number of storm periods followed by intervals of no rainfall, a composite "recession curve" can be prepared which gives a dependable idea of how the base flow would have fallen and the flood flow would have receded had no subsequent rainfall occurred.

THE WATER-SHED FACTOR

As the area under all distribution graphs is equal to 100%, the differences between water-sheds are reflected in the respective shapes of their distribution graphs. It is apparent, too, that the distribution graph demonstrates the inadequacy of area as the basis of comparison between water-sheds, as illustrated by Fig. 1. Here, arises the need for some means of evaluating the characteristics of a water-shed which so markedly change the shape of the distribution graph on water-sheds of approximately the same area.

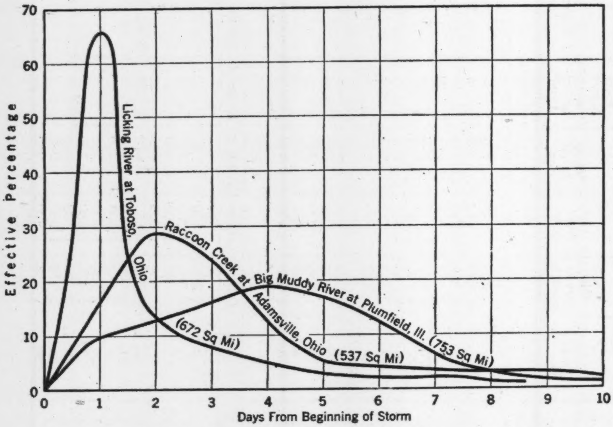

FIG. 1.—DISTRIBUTION GRAPHS OF THREE WATER-SHEDS.

Elsewhere[5] the writer has segregated from the general expression of run-off[6] the factors representing water-shed characteristics into the expression:

$$U = \left(\frac{60\,P}{L}\right)^{4eg} F^{8eg}\,\frac{S^{1.5eg}}{1\,000^{2eg}} \qquad \text{(1)}$$

in which, P is a constant, depending on the shape of the area of the water-shed and its manner of concentration; L, the length, in feet, which water must traverse in running from the most remote portion of the water-shed to its outlet; *F*, a constant, depending on the shape and condition of the main channel of flow; *S*, the fall, in feet per 1 000 ft of main channel of flow; and *e*, a positive fractional exponent of *t*, the duration of rainfall intensity for the locality.

---

[5] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1154.

[6] *Loc. cit.*, p. 1059.

Table 2 gives the values of the various factors entering into the determination of *U* in Equation (1). In its further use on large water-sheds the factor, *P*, should be re-tabulated and its range of values checked. The values given for the factor, *F*, in Table 2 are known to be inaccurate, the writer having no direct data at hand regarding channel shape and condition. The values of *L* and *S* were taken from the topographic maps of the U. S. Geological Survey.

TABLE 2.—Computation Data

Description	Raccoon Creek	Licking River	Hocking River	Walhonding River	Tuscarawas River	Muskingum River
M, in square miles	537	672	944	1 490	2 430	5 980
L, in feet	380 000	234 300	401 200	475 000	486 000	706 000
P (a constant)	0.543	0.469	0.513	0.510	0.480	0.470
F (a constant)	4.85	4.79	4.69	4.56	4.41	4.30
S, in feet per 1 000 ft	0.89	2.22	1.05	0.64	0.65	0.62
U (a constant)	0.0000610	0.0001570	0.0000540	0.000042	0.0000320	0.0000195

If the influences of the water-shed upon run-off can be separated from the influences of the storm, and if these water-shed influences are given a determinate value such as *U*, then it is possible to prepare a chart, as shown in Fig. 2, applicable to any region over which geological and climatological conditions are, in general, the same. This enables the designer, after having determined the value of *U*, to select, at any point on any stream within the region, a distribution graph for its water-shed. The value of this procedure to stream-flow problems, at points where no flow records are available, can be appreciated.

The relationships between the value of *U*, the daily value of the distribution graph, and the progressive duration of the storm period, for the region embraced by the study, can be stated as follows: For any particular day within the storm period the daily value of the distribution graph increases directly as the five-thirds power of *U* to a maximum daily value; then it recedes inversely as the two-thirds power of *U*. Furthermore, for a particular value of *U*, the daily value of the distribution graph increases directly as the square of the storm duration, in days, to a maximum value, then it recedes inversely as the square of the storm duration, in days.

Consistent results from the use of the chart are shown in Table 1, the last column in the table giving a distribution graph for each water-shed, the values being taken from the curves of the chart.

Reproducing the Hydrograph

The reproduced hydrograph serves the principal purpose of demonstrating the utility of the method proposed and is the means of developing coefficients.

Table 3 demonstrates the arrangement of the computation sheet for the Tuscarawas River, at Newcomerstown. The procedure is, as follows:

1.—Daily rainfall is taken from the monthly climatological record, weighted[7] according to station-area distribution and listed opposite the proper date in Column (2).

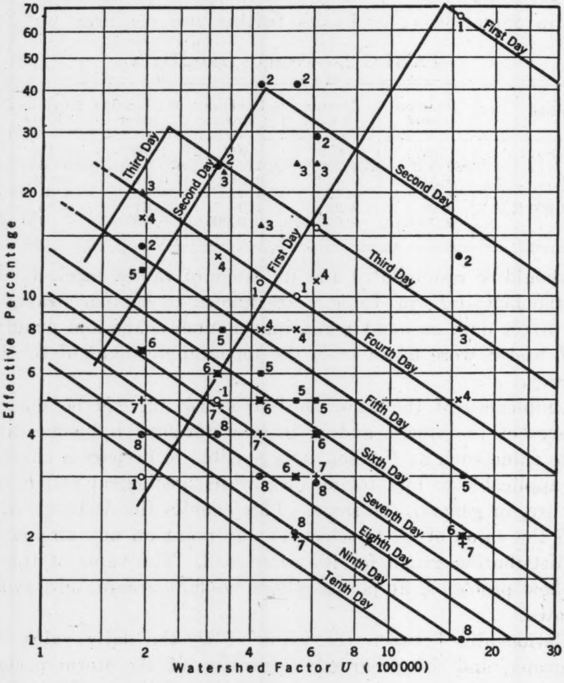

FIG. 2.—RELATION OF WATER-SHED FACTOR U, TO DAILY INCREMENTS OF THE VARIOUS DISTRIBUTION GRAPHS.

2.—The distribution graph is applied to the weighted daily rainfall and listed in Columns (3) to (13), inclusive, beginning the distribution opposite the date on which the rainfall occurred.

3.—The rainfall increments are added horizontally and the summation, the effective rainfall depth, D, is listed in Column (14).

4.—The 24-hr average observed stream flow is taken from the Geological Survey record and listed according to date in Column (15).

5.—Stream flow, in second-feet-days, is converted into depth of run-off, in inches, by the conversion equation,

$$D = \frac{0.03718\,Q}{M} \qquad \text{.......................(2)}$$

in which, Q is the average 24-hr discharge and M, the area of the water-shed, in square miles. These values are listed in Column (16).

6.—The tabulation is divided into storm or peak periods, the divisions being easily identified in the column (Column (14)) of effective rainfall depths.

7.—Both rainfall and run-off are expressed in the same terms (that is, inches of depth). Within the storm period they bear a straight-line relationship to each other, and the coefficient is the ratio of their storm-period averages. These are to be found in Column (17).

8.—The coefficients are applied to the effective rainfall depths, I, computed values of D being obtained and recorded in Column (18).

9.—The computed values of D are converted into stream flow, in second-feet-days, and listed in Column (19).

10.—A graphic comparison of daily rainfall, effective rainfall depth, the observed hydrograph, and the computed hydrograph for the six water-sheds is finally plotted, as illustrated by Fig. 3 for the Licking River Water-Shed, and Fig. 4 for the Tuscarawas River Water-Shed.

Coefficients

The distribution graph is, in reality, a distribution coefficient, fulfilling that function in a manner much more in accord with the actual phenomenon than is the application of a single coefficient to the rainfall depth on the day in which it falls. The distribution coefficient breaks down rainfall depth and re-assembles it as it becomes effective to the flow of the stream. In this form there is a straight-line relationship between rainfall and run-off within the storm period, the slope of the curve becoming a coefficient that might be termed the "retention coefficient," because it is now called on to express the value of the losses to run-off only.

It will be seen that the retention coefficient marks the seasonal change in soil absorption. In addition, it is influenced by the degree of saturation immediately preceding the storm period and by the intensity of the storm itself. Beginning with a high value, throughout the storage period, January to March, it drops to a value of less than 0.10 through the growing season, May to September, increasing into the fall and winter months and reaching, in November, a value of approximately 0.50. When melting snow and ice are added to run-off, the value may exceed unity.

The seasonal fluctuation in the coefficient value shows marked stability over the entire region embraced by the study. It would seem that the way is opened for further refinement of the method by possible correlation of the coefficient with soil saturation in terms of previous rainfall, evaporation in terms of temperature, and with the average intensity of the storm which obviously affects the value of the coefficient.

The Pluviagraph

If the factor that is used to convert depth over the water-shed to stream flow, in second-feet-days, is applied to the effective rainfall depths, I, a

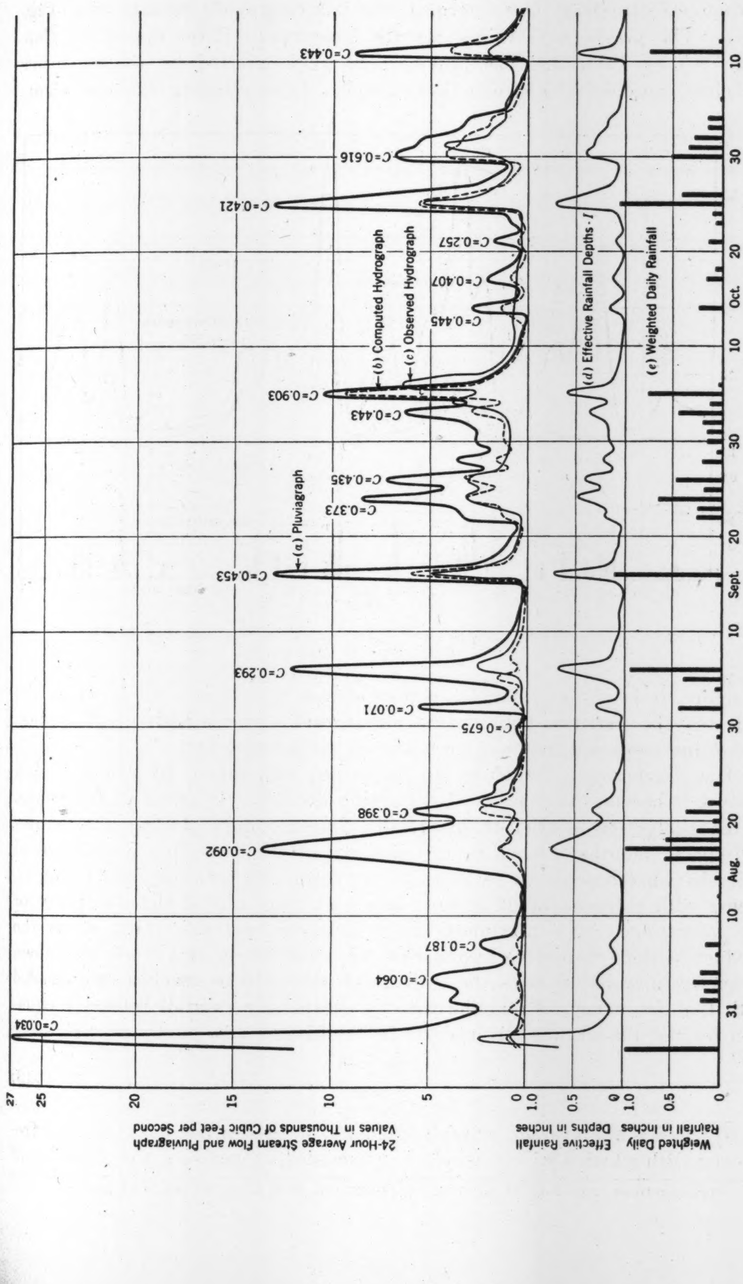

FIG. 3.—RAINFALL-STREAM-FLOW CHARACTERISTICS, LICKING RIVER, AT TOBOSO, OHIO.

maximum hydrograph (here termed the "pluviagraph") results (see Fig. 3(*a*)). The pluviagraph values for the Tuscarawas River appear in Column (20) of Table 3. The pluviagraph, when affected by the retention coefficient, becomes the stream hydrograph. In developing the coefficient, therefore, it is not necessary to reduce stream flow to run-off depth as the ratio may be stated as between the pluviagraph and the hydrograph values, both being expressed in the same unit—the second-foot-day.

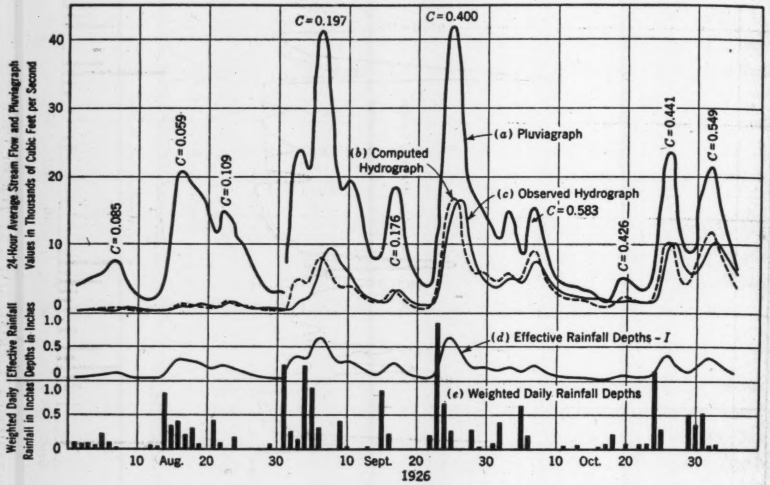

FIG. 4.—RAINFALL-STREAM-FLOW CHARACTERISTICS, TUSCARAWAS RIVER, NEWCOMERSTOWN, OHIO.

The pluviagraph should be an important adjunct to hydraulic design because it becomes the means of expressing flood flow in terms of frequency.

The retention coefficient practically reaches unity during the winter and spring months of each year, and north of the snow line it will exceed unity by what appears to be 10 to 20 per cent. If, therefore, the unity, *C*, occurs with a frequency of at least once each year, and if the possibility of the concurrence of a maximum storm intensity and the unity, *C*, is the product of their respective frequencies, the pluviagraph of a storm of known frequency may be taken as the hydrograph that will be reached or exceeded with that frequency. From the writer's charts,[8] the rainfall intensity equation for the Tuscarawas River above Newcomerstown is,

$$i = \frac{30\ T^{0.21}}{t^{0.80}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which, *i* is the average rainfall intensity, in inches per hour; *T*, the frequency with which *i* will be reached or exceeded, in years; *t*, the duration of rainfall, exceeding 1 hr, in minutes; K, a coefficient depending for value on locality; and x and n are exponents depending for value on locality.

---

[8] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 618, Figs. 18, 19, and 20.

When reduced by an area factor,[9] $(1 - 0.015 \sqrt[3]{A_m})$, Equation (3) becomes,

$$i = \frac{24\ T^{0.21}}{t^{0.80}} \qquad (4)$$

Reducing the average intensities of known frequency to daily rainfall depth and applying the distribution graph of the water-shed, results in the frequency-pluviagraph group shown in Fig. 5(a). These graphs are based on the assumption that the storm will parallel the rainfall intensity curve group, coming to a peak on the first day. That the storm curve may take any shape without materially affecting the pluviagraph is shown in Fig. 5(b), with Table 4, in which the peak is shifted to various positions in the storm period, without disturbing the average intensity or frequency of the storm. The effect is to increase the maximum pluviagraph values about 10 per cent.

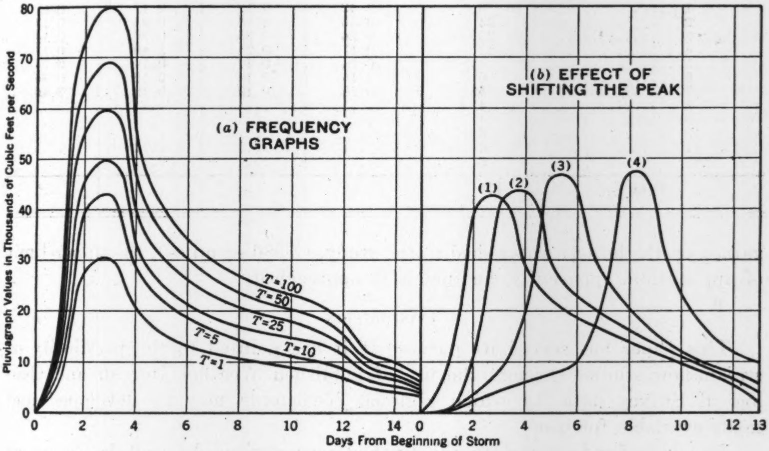

FIG. 5—PLUVIAGRAPHS, TUSCARAWAS RIVER, AT NEWCOMERSTOWN, OHIO

LIMITATIONS OF THE METHOD

While the theory of the unit and distribution graphs appears to be generally applicable, the units used, and, therefore, the Weather Bureau and Geological Survey data, have their limits of application.

That the writer's study approaches the upper limit of value of U, and the lower limit of area, is shown in Fig. 3, the rainfall-stream-flow characteristics of Licking River at Toboso, Ohio. The relatively poor agreement of the computed and observed hydrographs and the erratic relationship of the peak coefficients, show that the 24-hr interval is too great to measure unit changes in stream discharge and storm intensity. For the smaller areas, particularly where the shape and slope of the water-shed are conducive to the prompt delivery of run-off waters, the hour should become the unit interval of the rainfall and stream-flow record. From the satisfactory results gained on the largest water-shed in the study, (5 980 sq miles), the upper limit of application, apparently, has not been approached.

CONCLUSION

This paper has served its purpose if it has pointed to the possibility of stream-flow studies through the use of published Weather Bureau and Geological Survey data, by which regional coefficients may be developed and made available for use.

The idea fundamental to the method proposed might well be taken as common ground upon which to unify engineering thought in the important field of stream-flow determination.

DISCUSSION

C. S. Jarvis,[10] M. Am. Soc. C. E. (by letter).—This paper embodies several forward steps in a scientific field of much promise. The author has made practical application of some of the most recent developments toward logical and fairly dependable estimates of stream flow that should follow rainfall of given intensities and duration.

The assignment of proper and consistent values for the various constants seems to demand special skill or experience for guidance. The values of U in Table 2, ranging from 0.0000195 to 0.0001570 (or to eight times the smaller), need some kind of fundamental co-relation. Obviously, the factors in Table 2 most directly related are the length, L, and some function of the slope of the main channel, designated as S. Furthermore, they vary inversely, as shown by Equation (1). By inspection and trial, it was found that a fair approximation to the tabulated values of U for the six streams, as there listed, may be computed from the following expression,

$$20 \frac{\sqrt{S}}{L} = U \text{ (approx.)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (5)$$

Slide-rule computations brought the results shown in Table 5. While the agreement is not all that could be desired, it may served as a first approximation.

TABLE 5.—Values of U in Relation to S and L in Table 2, in Millionths.

River	From Table 2	Computed by Equation (5)	River	From Table 2	Computed by Equation (5)
Raccoon Creek	61.0	49.6	Walhonding River	42.0	33.7
Licking River	157.0	128.2	Tuscarawas River	32.0	33.2
Hocking River	54.0	50.8	Muskingum River	19.5	22.4

Examination of the extensive tabulations leading up to the desired hydrograph, as illustrated in Fig. 3, suggests the idea that a free-hand sketching of a curve under the pluviagraph (with ordinates varying from 1% to 30% of the corresponding pluviagraph values, and, with due regard to the time element for the given water-shed, the mounting percentage of run-off with higher degrees of saturation, after several days of storm, and whatever local data are available), may result in nearly as close approximations of the observed hydrograph as will normally follow from the more elaborate and detailed procedure. It is conceivable that the selection of the numerous constant values, the mastery of the extensive nomenclature, and the great number of computations involved in the author's method of determining stream flow, may be too much to expect of those who attempt to follow it. The value of dependable forecasts for different types of storms that habitually visit a region cannot be over-estimated; but it will require specialists in the science of hydrology and in the application of both meteorological and hydraulic data, to prepare such charts, with coefficients of variation to conform with seasonal and other changes of physical data affecting run-off.

---

[10] Senior Hydr. Engr., U. S. Geological Survey, Washington, D. C.

Before 1864 it was known that the annual run-off from the Mississippi water-shed was approximately "one-fourth of the downfall," or precipitation. Subsequent years of record, with gauging and meteorological stations multiplied in number, have demonstrated that the yield may range between approximately 14 and 31% of the rainfall; but these later records confirm the early investigations as to average percentage of yield. Therefore, a pluviagraph of this area would constitute a fairly reliable guide for a resulting hydrograph, with its peak covering the months of April and May, and its area between the curve and the horizontal axis representing about 25% of the area under the pluviagraph. For such a water-shed as that of the Mississippi, the human or personal equation would be kept within bounds more effectively by this means than if independent judgments were required to assign proper values to various constants in the several equations utilized, especially as some of these values constitute powers of certain factors. Furthermore, due regard to the grouping of rainfall days, and to the seasons in which they occurred, would justify a departure from the average value of 25% as representing run-off within the observed range of 14 to 31%; and, in this manner, the sketched hydrograph may prove to be as reliable as those resulting from voluminous computations, interspersed with occasional estimates that are just as difficult to apply and as far-reaching in their effects as those required in sketching the desired hydrograph from the pluviagraph.

After investigating or dealing with the entire category of reputable run-off formulas now available, the writer continues to incline toward simplification rather than toward multiplication of factors and processes. For first approximations to maximum, or for any other assumed rate of run-off corresponding to the probable frequency of recurrence, applicable to any given section of the United States, or of other countries, significant basic data have been presented by the writer.[11] The formula for maximum run-off which he has recommended is,

$$Q = 10\,000\, p \sqrt{M} \qquad \text{.......................} (6)$$

in which, Q is the peak discharge, in cubic feet per second; M, the drainage area, in square miles, and p, the percentage rating on the Myers scale, roughly equal, numerically, to the percentage of rainfall that appears as run-off during the most severe storms and floods of that area, except as modified by geometrical shape of basin and alignment of main drainage channels, or other water-shed characteristics. The streams of Northern Ohio are found to range from about 5 to 12% on the Myers scale, while those of Southern Ohio are usually 20% or more. This disparity is traceable partly to the difference in rainfall habits, but, in greater degree, to the difference in soil and surface characteristics, channel gradients, and valley storage. The maximum discharges recorded in Table 1 are found to rate, respectively, only 1.4%; 1.3%; 2.3%; 2.9%; 1.7%; and 6.8% on the Myers scale. The last-named item applies to the Muskingum River, which attained a rating of 28.4% at Marietta, Ohio, in 1913. The foregoing percentages, therefore, represent run-offs of relatively low volume and correspondingly high frequency of recurrence, perhaps attainable nearly every year.

[11] "Flood Flow Characteristics," *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 985; and "Rainfall Characteristics and Their Relation to Soils and Run-Off," *Loc cit.*, Vol. 95 (1931), p. 379.

LEROY K. SHERMAN,[12] M. AM. SOC. C. E. (by letter).—In this paper Mr. Bernard has confirmed the principle of the unit graph by analysis based on independent data. He has also developed certain new procedures.

The Distribution Graph.—The author expresses the typical graph of run-off, for a given drainage basin, in terms of percentages of distribution of the total volume of the run-off during a number of equal time intervals. The writer's unit graph[13] expresses this same drainage-basin characteristic in terms of distribution of rates of run-off due to a unit depth of effective rainfall (rainfall appearing as surface run-off), applied in a unit of time. The unit graph and the distribution graph are readily convertible one to another by applying the following formula:

$$q = p \times 26.88\, M \quad \text{.........................(7)}$$

in which, q is the average rate of run-off for a given day, read from the unit graph; p, the average percentage of run-off for the same time interval, read from the distribution graph; and M, the area of the drainage basin, in square miles.

The writer recognizes that the use of the distribution graph is preferable to the unit graph. It is a simpler mode of expression. Both graphs are predicated on the hypothesis that, for a given basin; (*a*) The distribution of percentages of run-off is constant for a run-off period due to rainfall occurring in a single day, or time unit; and (*b*) the duration of the run-off period, under aforesaid conditions, is a constant.[14] This hypothesis is confirmed by the seventeen cases given by Mr. Bernard in Table 1. It is also substantiated by the fair agreement between observed and computed hydrographs of stream flow made by Mr. Bernard and by the writer.

As a further check the writer recently computed, for comparison, two hydrographs based on the same duration of rainfalls on the same hypothetical drainage basin (see Fig. 6). One had a high rainfall intensity. The other had a low intensity of rainfall. Both were subject to infiltration loss and pondage effect. With a given stage-velocity curve for surface run-off, and with given channel elements of slope, cross-section, and coefficient of roughness, this becomes a problem in hydraulics. It was solved by the application of well-known and accepted laws. The stage-velocity curves for both overland flow and stream flow had large differences in velocity between high and low stages. Referring to Fig. 6, it will be noted that the duration of run-off was greater for the greater rainfall, but that at the time, 13 000 sec, the relative difference in rates of flow became insignificant; in other words, the run-off periods were practically the same. The total volumes of run-off

[14] Rept. of the Committee, Boston Soc. of Civ. Engrs., on Floods, *Journal*, Boston Soc. of Civ. Engrs., Vol. XVII, September, 1930, No. 7.

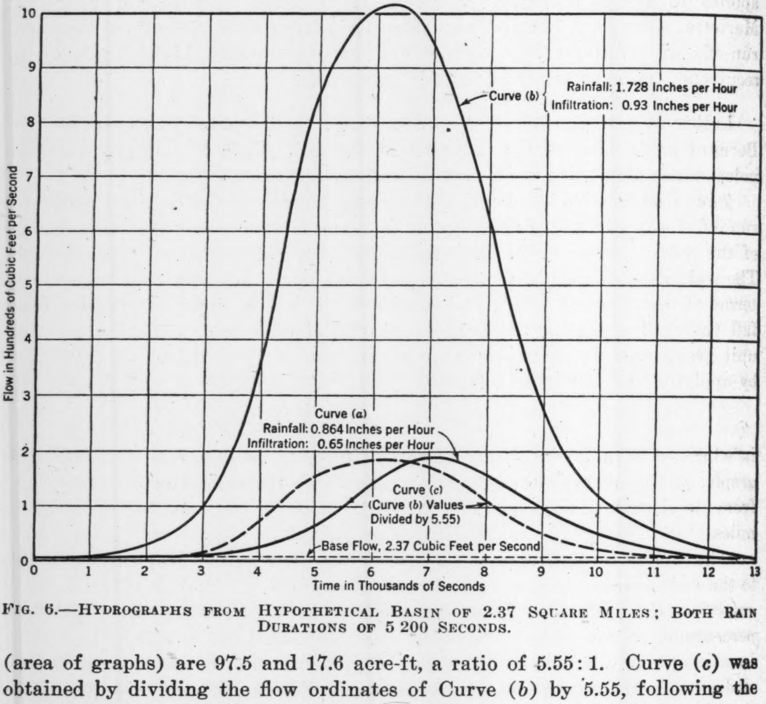

FIG. 6.—HYDROGRAPHS FROM HYPOTHETICAL BASIN OF 2.37 SQUARE MILES; BOTH RAIN DURATIONS OF 5 200 SECONDS.

(area of graphs) are 97.5 and 17.6 acre-ft, a ratio of 5.55 : 1. Curve (*c*) was obtained by dividing the flow ordinates of Curve (*b*) by 5.55, following the hypothesis used by Mr. Bernard. It will be noted that the peak of Curve (*c*) appears earlier than that of the smaller hydrograph, Curve (*a*). If Curve (*c*) is moved forward so that the peaks coincide, the two graphs will be found to be almost identical. This example illustrates an extreme range of conditions. The lack of synchronization is due to the fact that time of transit is shorter for the high stage. This effect is apparent in the examples of computed and observed flows made by both Mr. Bernard and the writer. At ordinary, and high, stages, especially on the many streams with almost vertical stage-velocity curves, the synchronization is almost perfect. Mr. Bernard's procedure of using the average of three observed distribution graphs is desirable. From an engineering standpoint small differences in time are immaterial, provided the peaks and troughs give correct rates of flow. If requirements warrant closer synchronization, a special low-flow distribution graph may be developed and applied.

The 24-hr rainfalls, furnished by the U. S. Weather Bureau, in Mr. Bernard's Table 1, may have occurred in 1 hr, 10 hr, or 20 hr. The close agreement of the three distribution graphs shows that this factor makes little difference on large areas.

The Water-Shed Factor.—The author has evaluated another procedure for determining the distribution graph of water-sheds approximately, where stream-flow data are not available. The writer views this accomplishment, in co-ordinating such complex factors, with sincere admiration. The frequent statement that certain phenomena of Nature are erratic is Man's comfortable and self-satisfying way of acknowledging his ignorance and bewilderment.

The Retention Coefficient.—In the procedure for reproducing a hydrograph of stream flow, Mr. Bernard uses, in Column (17), Table 3, a so-called "retention coefficient." This coefficient applied to rainfall depth gives the rate of stream flow. The latter is made up of surface run-off plus base flow, Although Mr. Bernard states, "the retention coefficient * * * expresses the value of the losses to run-off only," the numerator, *D,* in deriving the coefficient, includes base flow, as set forth in the U. S. Geological Survey records in Column (15), Table 3. In practice, this coefficient could not be derived from flow records. That record is the answer to be determined. The retention coefficient must be forecast.

The retention coefficient combines the two independent factors: Percentage or net amount of rainfall appearing as surface run-off, and base flow. The forecasting of this "retention coefficient" may be possible; it has not been done as yet. The writer deems the more usual procedure preferable, namely, application of the run-off percentage, or loss deduction, to rainfall, followed by the independent addition of the base flow. Refer, for example, to the computed run-off on October 7, 1926, as shown in Fig. 4. In Mr. Bernard's complete paper the summation sheet (a continuation of Table 3) gives the following values:

Distribution graph applied to weighted daily rainfall:		
Column (3), Table 3	0.001	
Column (4), Table 3	0.145	
Column (5), Table 3	0.048	
Column (10), Table 3	0.009	
Column (11), Table 3	0.002	
Column (12), Table 3	0.005	
Column (13), Table 3	0.024	
Effective rainfall depth, in inches (Column (14), Table 3)		0.234
Average 24-hr observed flow, in cubic feet per second (Column (15), Table 3)		7 680
Retention coefficient, *C* (Column (17), Table 3)		0.583
Computed stream flow, in cubic feet per second		8 900

The weighted daily rainfall in Column (2), Table 3, extended to include the period, September 28 to October 6, inclusive, is as follows: September 28, 0.29; September 29, 0.05; October 1, 0.09; October 2, 0.40; October 3, 0.01; October 5, 0.63; and October 6, 0.20. The computed flow for October 7 is seen to be 8 900 cu ft per sec as against an observed flow of 7 680 cu ft per sec. The writer finds as follows: The two hydrographs due to rainfalls of October 1 to 3 and October 5 and 6 can be segregated graphically. From this step, the percentages of run-off can be determined as 43 and 40. The base flow can be segregated, by the approximate method of Messrs. Meinzer and Houk,[15] which yields 1 400 cu ft per sec as of October 7. In the absence of the observed run-off these three figures could be approximated with fair accuracy by a competent hydrologist. Applying 43% to Mr. Bernard's data for October 7 in Columns (3), (10), (11), (12), and (13); and 40% to the values in Columns (4) and (5), results in a total surface run-off of 0.094 in., or 6 200 cu ft per sec, on October 7. Adding the base flow of 1 400 cu ft per sec gives the total stream flow as 7 600 cu ft per sec.

The problem of estimating infiltration, or the run-off coefficient, is a separate realm of hydrology. It is now in the process of evolution by a number of investigators. Ultimately, the best solution may come through an application of the principles noted[16] by Robert E. Horton, M. Am. Soc. C. E., in conjunction with a better forecasting of infiltration rates. The most accurate procedure probably will not be based on utilizing a coefficient of retention or run-off. It will be a deduction of infiltration rates from the data in each of Columns (3) to (13) Table 3, bearing in mind that infiltration is greatest at the beginning of a storm and practically ceases when surface run-off has reached the main stream.

The Pluviagraph.—The writer understands the pluviagraph to be the hydrograph of run-off if, or when, the surface of the drainage basin is impervious. This graph can be very useful in a study of the maximum rates of run-off due to a given storm under different and varying rates of infiltration. It is not necessary to assume the customary uniform rate of rainfall throughout the concentration period. Any possible sequence of rates of rainfall and infiltration may be compared. In Mr. Bernard's example (Fig. 5), the same maximum rainfall rate is used on different days. May not some other sequence in the 7-day storm produce a greater peak rate of flow? The way is provided for a better analysis of the rational method, the concentration period, and peak rate of flow.

The author is modest in his conclusions. Observed stream-flow records of long duration furnish the best guide for water supply or flood flow. Such stream data, however, are frequently lacking, whereas pertinent rainfall data for storms of maximum or other frequency are generally available. The method described by Mr. Bernard, in such cases, will furnish more reliable results than any of the existing empirical run-off formulas.

W. W. HORNER,[17] M. AM. SOC. C. E. (by letter).—Inspired (as he states) by Mr. Sherman's demonstration of the "unit graph," the author has taken another valuable step in systematizing the relation of rainfall and run-off. No doubt, the distribution graph will be accepted by hydrologists as a workable mechanism.

[17] Cons. Engr., St. Louis, Mo.

Many students of this subject have been of the opinion that the present difficulty in establishing a rational relation between run-off and rainfall might be largely overcome if the effect of the fixed drainage-area characteristics, such as shape, slope, and channel condition, could be isolated. In another connection,[18] Mr. Bernard made a nice academic approach to the problem; in his paper, he indicates a practical means of achieving this result.

He refers to his work as an "approach to determinate stream flow"; the qualification should be kept well in mind. Apparently, he has examined a great mass of data and has subjected it to analysis by his method. To substantiate the hypothesis fully will require a study on a larger scale than could be undertaken by any one person; it is to be hoped that Mr. Bernard's effort will bring about the necessary organization.

The idea that, for rain within the chosen time unit, run-off diagrams will fall into definite patterns corresponding to salient water-shed characteristics, and that this hydrograph may be considered as independent of variations in rainfall intensity within the time unit, will undoubtedly require some qualifications, as the author suggests under "Limitations of the Method." It is possible that variations in ground condition will be found to account for nonconformities with the distribution graph; that is, as certain areas are relatively more retentive than others at certain seasons, the effect may be similar to a shift in the water-shed boundaries. In recent studies of small areas, the writer has encountered vagaries that might be accounted for in this manner.

The writer's experience with small areas leads him to feel that Mr. Bernard's viewpoint as to "Coefficients" is too optimistic. For these small areas a synthetic treatment of the rainfall resulted in the development of "100% run-off curves," corresponding to Mr. Bernard's pluviagraphs. The method was adjusted so that these curves were quite similar to the measured hydrographs. A simple relation between the ordinates of the two diagrams was anticipated, but the results were disappointing, the ratios covering a wide range of values without appreciable seasonal significance.

It is doubtful whether, even within a particular storm period, a straight-line variation between rainfall and run-off will be found; probably the relation will be more complex, and the seasonal fluctuation will be difficult to index. In passing, the writer suggests that the coefficient of retention be a "coefficient of non-retention"; it is very like the old "percentage of run-off."

The suggested preparation of frequency pluviagraphs needs further study; it does not seem to follow that, because a value of C equal to unity occurs over a year, "the pluviagraph of a storm of known frequency may be taken as a hydrograph that will be reached or exceeded with that frequency"; for this to be true, it would seem to be necessary that the unit, C, persist throughout the year. The writer's studies indicate that high run-off values are generally the result of a combination of high values of C with not excessive precipitation intensities, but sometimes from the alternate combination. He is doubtful whether any satisfactorily simple plan can be devised for studying probabilities of the concurrence of particular values.

---

[18] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1150.

Mr. Bernard's method appears to be most valuable, with the present lack of knowledge of coefficients, as a suggestion for analyzing existing information on a large scale. If such analysis should produce regular patterns and consistent factors, it may become the plan of construction for synthetic hydrographs.

C. H. Eiffert,[19] M. Am. Soc. C. E. (by letter).—That the field of study along the line of correlating rainfall and run-off data is far from exhausted, is amply demonstrated in this valuable paper by Mr. Bernard. The author admits that his method has limitations and states in his "Conclusion" what he hopes it may do.

The writer would like to be able to believe that river discharges may be calculated by formula and that regional coefficients may be developed for such a formula, but to the present time his convictions point to quite the contrary.

Stream-flow or run-off formulas should be most valuable for use on drainage areas for which records are not available, or are few. If records are scarce, however, it will be difficult to arrive at the proper coefficient or formula for that region, and, therefore, the solution will be extremely uncertain. Furthermore, the time of year or season will cause a great variation in run-off due to the changes in the capacity of the ground to absorb rainfall. For instance, in the Miami Valley, the run-off from two very similar 1-day rains has varied from 1.25% to 114% of the rainfall.

The writer has not made any extensive use of Sherman's unit-graph method, but believes that the same statement would apply; that is, if records are scarce it will be difficult to arrive at the proper unit graph, especially if 1-day rainfalls from Weather Bureau records are used. Such rains sometimes are spread fairly uniformly over 24 hr, but often they occur in one-half as many hours, or less.

Of course, it must be acknowledged that no run-off figure can be arrived at without some kind of calculation; but in the last analysis the calculations that most nearly approach the correct result will contain a factor which depends largely on the engineering ability and judgment of the calculator. The best method of attack is through a more thorough and careful study of rainfall intensities and frequencies for the reason that rainfall records are much more voluminous than run-off records.

While engineers are using available records they should concentrate their efforts upon making these records better and more complete in the future. It is true, as stated by Mr. Bernard, that certain unavoidable sources of error must be recognized and accepted in using Weather Bureau data. Certainly, the engineer must recognize them and make the best possible use of the material, but he should not let it go at that. He should exert all possible influence to induce the Government and other departments collecting such information to make it more adaptable for the use of engineers. Considerable can be done along this line without necessarily increasing appropriations. Through better co-operation and co-ordination of data the various Federal

---

[19] Chf. Engr. and Gen. Mgr., The Miami Conservancy Dist., Dayton, Ohio.

Bureaus could make their records more useful to the Engineering Profession without limiting or reducing their usefulness for other purposes. Such matters as making time of readings uniform, obtaining better information on time limits of rainfall, and peak discharges of streams, instead of only the 24-hr maximum, should be easily adjusted. There are other condidtions that could be improved, such as the duplication of gauges by different departments, the breaking off of old records and the starting of others, and the more effective interrelated distribution of the Weather Bureau, Geological Survey, and Army stations.

Another fruitful line of study should be that of time of concentration on various sizes of drainage areas. Few data are available on this subject, except for metropolitan areas. This information will become available, of course, if rainfall periods and peak discharge are properly timed, measured, and recorded.

While studies such as those by Mr. Bernard ought to be encouraged, it must be remembered that nothing can take the place of adequate records. Engineers should be right "on their toes" to see that the errors or deficiencies of the past are not perpetuated.

CHARLES S. BENNETT,[20] M. AM. SOC. C. E. (by letter).—Great ingenuity and much patience are evidenced in the work of Mr. Bernard in developing the approach to determinate stream flow in this paper. The writer is impressed with the logical development of the plan for constructing the "pluviagraph" and the "distribution graph", and is of the opinion that if basic data were available the method would be of great use to hydraulic engineers.

Unfortunately, there are serious handicaps. The rainfall data of the U. S. Weather Bureau, while complete in a quantitative sense, does not permit of selection of rainfall intensities of less than 24-hr duration. In most instances, there is no way of determining whether a given 24-hr. percipitation occurred in a few minutes, or was distributed over a period of hours. As pointed out by Mr. Bernard, this is a serious drawback in selecting data for the construction of the basic graphs.

The determination of the "water-shed factors" presents practical difficulties. So many coefficients need to be determined, each of which depends largely upon the trained guess of the computer, that a mathematical solution of the equation for determining this factor, U, seems to the writer to be wasted effort.

The application of the method seems limited to streams upon which some previous flow records, including flood flows, are available. This will eliminate the use of the method for many streams.

In the present state of the science of applied hydraulics and meteorological observations, much time would be saved (and likewise laborious calculation) by using simple direct relationships, based on data at hand and judgment, to determine such estimates of stream flow as are necessary for the solution of a given problem.

---

[20] Engr., The Miami Conservancy Dist., Dayton, Ohio.

These criticisms are not intended to deprecate the value of such painstaking research as have been done by Mr. Bernard and numerous other engineers who have been working on the problem of devising means of determining run-off. Great credit is due those who have led the way in attacking the problem. However, many factors involved are indeterminate, and this should be fully recognized by those who attempt to apply the various methods to specific problems.

R. L. GREGORY[21] AND C. E. ARNOLD,[22] ASSOC. MEMBERS, AM. SOC. C. E. (by letter).—Based on the assumption that certain statements contained, and procedure outlined, in a paper[23] by L. K. Sherman, M. Am. Soc. C. E., are correct, the author has presented an ingenuous method for the determination of stream flow, which utilizes some of the factors occurring in the writers' formulas.[24] The method constitutes an approach to the construction of hydrographs at points on streams for which adequate flow records are not available. Engineers in general, and the writers in particular, fully appreciate the value of any thoughts, data, or methods that tend to advance the solution of this problem.

Previously, in his discussion of the writers' paper,[25] the author had separated and combined the run-off factors pertaining strictly to the drainage area from those influenced more directly by rainfall. This combination, Equation (1), omits the three remaining run-off factors, C, A, and R_H, contained in the general run-off equation.[26]

There can be no doubt that Equation (1) may serve as a convenient instrument for aiding in the analyzation and presentation of drainage data. The author, through its use, has already presented valuable data for consideration by the profession. There has arisen in the minds of the writers, however, a doubt as to the wisdom of using Equation (1) in a procedure based on hypotheses that inherently prohibit consideration of changes in the hydrograph due to differences in the magnitudes of storm intensities.

In his paper,[23] Mr. Sherman states, "for the same drainage area, however, there is a definite total flood period corresponding to a given rainfall, and all one-day rainfalls, regardless of intensity, will give the same length of base of the hydrograph"; that is, the same total period of run-off. As far as the writers have been able to determine, data have not been presented to substantiate the truth of this unqualified assertion. The statement could not be true, since a difference in the magnitude of intensity for a given time period would alter the quantity of water flowing and, consequently, the time of concentration, and the relative shape and length of the graph for the total period of run-off.

[21] Chf. Insp., County of Los Angeles. Storm Drain Div., Los Angeles, Calif.

[22] Storm Drain and Constr. Engr., Los Angeles County Surveyor's Office, Los Angeles, Calif.

[23] "Streamflow from Rainfall by Unit Graph Method", *Engineering News-Record*, April 7, 1932, p. 501.

[24] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1038.

[25] *Loc. cit.*, p. 1150.

[26] *Loc. cit.*, p. 1059, Equation (24).

For like reasons, and others, inspection leads to the conclusion that Mr. Sherman's Fig. 1 and the equations immediately following convey erroneous conceptions of the manner in which water combines in a drainage area to cause run-off.[26] Therein exists a disregard of the fundamental principle that the velocity of flow of water in streams and channels is a function of the quantity flowing.

The author's method embodies the unit-graph procedure as exemplified in his Table 3.

It is comparatively easy to make or to deny assertions, but sometimes difficult and tedious to prove their truth or falsity. The purpose of this discussion is to test the fundamentality of the procedure that the author follows in his method and to arrive at some measure of its departure from the truth in the construction of hydrographs.

To ascertain the effect on a stream hydrograph due solely to a difference in the quantity of water running requires the complete elimination of all variables with the exception of intensity of precipitation. Due to the many and varying factors and conditions contributing to flow of a drainage area, it is almost impossible to find a single experiment wherein all variables are definitely known.

For their purpose the writers have chosen a hypothetical drainage area; and have stripped it of all pondage, channel constrictions, and other features, which tend only to confuse the issue.

Consider a triangular water-shed[27] with streams concentrating along lateral lines to the main channel of flow, to be divided, as in Fig. 7, into time-contours, all points on which are equi-distant in time from the outlet.

Assume any definite proportions for the water-shed (say, ratio of length, L, to bottom width is 5 to 3). Then (all computations by slide-rule) since $L \propto A^{\frac{1}{2}}$, or $L = KA^{\frac{1}{2}}$, $K = 380.8$, in which, $A =$ area, in acres, and $L =$ length, in feet.

In a formula derived by the writers,[28]

$$v = 0.03162 F^{2} S^{\frac{3}{8}} Q^{\frac{1}{4}} \qquad \text{.....................(8)}$$

Let $v = K_1 \, Q^{\frac{1}{4}} = 0.3944 \, Q^{\frac{1}{4}}$ (which is the equivalent of assuming that $F = 4.02$, with $S = 0.5$, or other combinations of these factors).

It has been shown[29] that for a triangular water-shed of which Fig. 7 is a special case, subjected to a uniform intensity, the value of $P = 0.5$, $Q \propto A$, and $v \propto t$, the run-off coefficient being assumed as constant. Since $v \propto t$ and $v \propto Q^{\frac{1}{4}}$, then $t \propto Q^{\frac{1}{4}}$, or $Q \propto t^{4}$. To simplify computations and eliminate confusion, the run-off coefficient is herein assumed as equal to 1; that is, all rain that falls runs off.

For a given intensity of precipitation, the water from Area ACB, Fig. 7, will be first to contribute its maximum rate of run-off. If it rains long enough, Areas ***DFE, GIH, JLK,*** and ***MON,*** Fig. 7, will reach their maximum contributions in sequence as time increases.

---

[27] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1068, Fig. 5(*a*).

[28] *Loc. cit.*, p. 1094, Equation (50).

[29] *Loc. cit.*, p. 1068.

Case 1.—Assume a uniform intensity of $\frac{1}{4}$ in. per hr throughout the period of concentration of the entire area, and assign definite values to the area and its subdivisions. The hydrograph for the period of concentration is formed by Table 6(*a*), the rate, in cubic feet per second, and the time, in days, being shown in the part of the graph to the left of the peak discharge point in Fig. 8 ("Case 1: Calculated True Graph").

Case 1(a).—If the rain ceases when the full area concentrates, much water will be left on the shed in transit to the outlet. Its measure is easily found for this case. Since (as shown previously), $Q \propto t^4$,

$$Q = K_2\, t^4 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

K_2 being a constant. The volume of water that has passed the outlet at the time the full area concentrates, is,

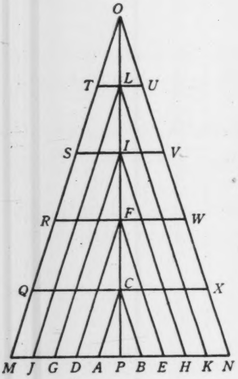

FIG. 7.—WATER-SHED.

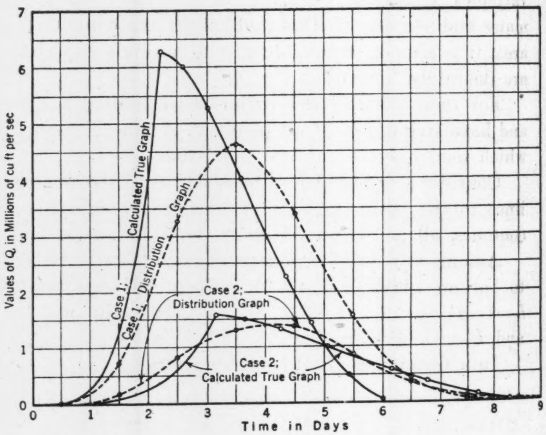

FIG. 8.—COMPARATIVE HYDROGRAPHS, CASE 1 AND CASE 2.

$$\int K_2\, t^4 = \frac{K_2\, t^5}{5} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

in which, t = time of concentration. Since $Q_{\max}\, t = (K_2\, t^4)\, t = K_2\, t^5$ = the volume of all rain that fell, one-fifth of the water has passed the outlet and four-fifths remains on the shed. Thus, using the data opposite the area, *MON,* of Table 6(*a*), the quantity remaining on the shed, in millions of cubic feet, is:

$$\frac{4}{5}\, Q_{\max}\, t = \frac{4}{5} \times 6\,250\,000 \times 193\,200 = 966\,000$$

The distribution of the water remaining on the shed at the time of concentration of the entire area may be ascertained by the following procedure: Find the quantities that have passed the various time-contour lines during the time of the rain. From the total rain, falling on the area above a given time-contour during the period, deduct the quantity passed, the remainder being the quantity left on the area.

TABLE 6.—VALUES FOR POINTS ON HYDROGRAPH FROM BEGINNING OF RAIN TO MAXIMUM RATE OF RUN-OFF

			(*b*) CASE 2			
....	250 000	190 400	15 625	2.205	86 400	1
ACB	1 000 000	380 800	62 500	3.12	122 000	1.414
DFE	4 000 000	761 600	250 000	4.41	172 700	2
GIH	9 000 000	1 142 400	565 000	5.40	211 400	2.45
JLK	16 000 000	1 523 200	1 000 000	6.24	244 000	2.83
MON	25 000 000	1 904 000	1 562 500	6.975	272 800	3.1623

For example, consider the time-contour, *DFE* (Fig. 7). At the end of the first day of the rain, Area *GIHEFD* ($A = 5\,000\,000$ acres; $Q = 1\,000\,000$ cu ft per sec) was contributing its maximum quantity to the contour. At the end of 1.414 days of rain, Area *JLKEFD* ($A = 12\,000\,000$ acres; $Q = 3\,000\,000$ cu ft per sec) was contributing its maximum. The entire area ($A = 21\,000\,000$ acres; $Q = 5\,250\,000$ cu ft per sec) above the time-contour was contributing its maximum after 1.73 days of rain. The times of concentration, to the time-contour, of the three areas are determined from, and are the same as, those for the respective parts of the areas contributing to the main channel between *FI*, *FL*, and *FO* (see Fig. 7). In Table 7(*a*), showing times and quantities to the time of concentration to this time-contour, *DFE*, the values of Q' correspond to the time-rendering areas, the time having been calculated from Equation (9) with substitution of data opposite Area *ACB*, of Table 6(*a*) or, the time of concentration, in days, equals:

$$t = 0.04472\ (Q')^{\frac{1}{4}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

TABLE 7.—EXPLANATORY DATA

(*a*) CASE 1			(*b*) CASE 3		
Flow, in Millions of Cubic Feet per Second		Time, in days	Flow, in Millions of Cubic Feet per Second		Time, in days
Q	Q'		Q	Q'	
0.44	0.04	0.633	0.21	0.01	0.4475
1.25	0.25	1.000	0.44	0.04	0.6325
3.00	1.00	1.414	0.69	0.09	0.775
5.25	2.25	1.73	0.96	0.16	0.8945
....	....	.....	1.25	0.25	1.000

In Fig. 9 the area (under the curve formed by plotting the data of Table 7(*a*)) designated *ABC,* represents the volume of water that had passed the time-contour, *DFE* (Fig. 7), to the time (1.73 days) the area above it had contributed its maximum run-off. This maximum rate of flow continues to pass the time-contour until the end of the rain, or to the time of concentration of the entire area. Hence, the total quantity of water passing the time-contour during the period of rain (2.236 days) is equal to the summation of the area (*ACB*) under the curve and the rectangle, *BCDE.* In like manner data were calculated for other time-contours and plotted in Fig. 9. The various contours are represented by their respective, tributary, maximum *Q*-values. In Table 8(*a*) these maximum *Q*-values are shown opposite the quantities, passed beyond and left on the water-shed above, the various time-contours represented.

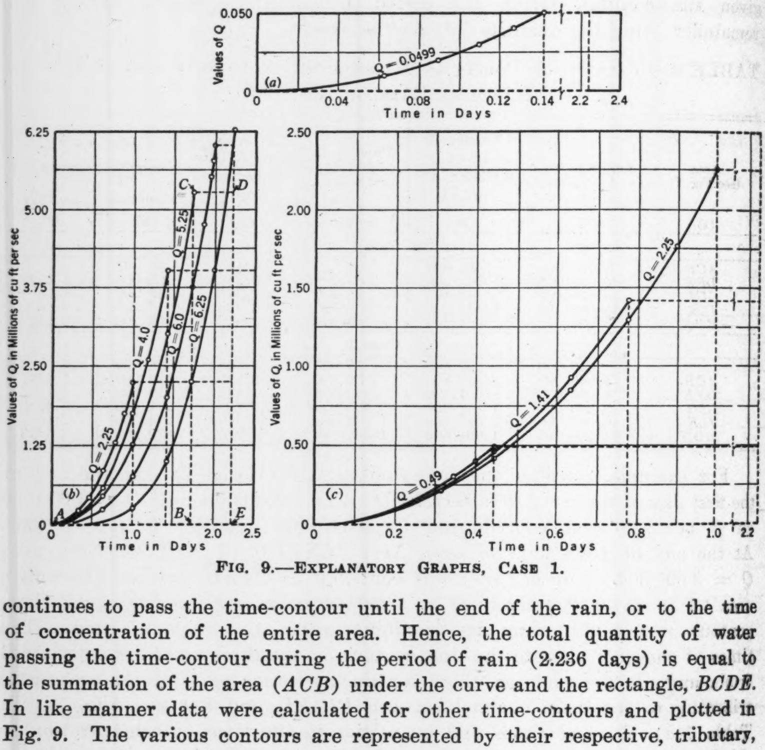

FIG. 9.—EXPLANATORY GRAPHS, CASE 1.

When a given value of *Q* (Column (1), Table 8(*a*)) has reached the outlet, its corresponding quantity (Column (4) Table 8(*a*)) will remain on the water-shed. If, therefore, a quantity (Column (4), Table 8(*a*)) is subtracted from the total quantity left on the entire water-shed at its time of concentration (shown hereinbefore to be 966 000 millions of cubic feet), the remainder will represent the quantity that has subsequently passed the outlet when the corresponding *Q*-value arrives.

These quantities, together with their corresponding *Q*-values, were used to construct the outflow curve as plotted to the right of the peak discharge in Fig. 8 ("Calculated True Graph"). This curve of Fig. 8 represents a true

hydrograph of the water-shed for the assumptions used, the area under the curve to the left of the peak discharge being one-fifth the total outflow of water and that to the right, four-fifths.

Case 2.—Assume a uniform intensity one-fourth that of Case 1, or $\frac{1}{16}$ in. per hr throughout the period of concentration of the entire area for this intensity. The hydrograph of this lighter intensity on the same area for its period of concentration is also shown in Fig. 8 ("Case 2: Calculated True Graph") as plotted from Table 6(*b*). Note that the time of concentration of the entire area (with the light intensity) is approximately 1.4 times as long as that for the higher one.

Case 2(a).—If the rain ceases when the full area concentrates, the same process is used in computing the data as for Case 1(*a*). The difference in results is due solely to the use of a lower intensity. Table 8(*b*) and Fig. 10 are to be compared with Table 8(*a*) and Fig. 9, respectively, of Case 1(*a*). The hydrograph is plotted in Fig. 8 and is labeled "Case 2: Calculated True Graph".

Equation (12) replaces Equation (11) of Case 1(*a*) since substitution of the data of Table 6(*b*) in Equation (9) renders:

$$t = 0.08944\ Q^{\frac{1}{4}} \qquad (12)$$

Case 3.—One-Day Duration of Rain; All Other Assumptions Identical with Case 1.—The procedure used in the solution for this case differs sufficiently from that for Case 1 to warrant a brief explanation. Note (see

Table 6(a) and Fig. 7) that the area, $ACB = 1\,000\,000$ acres, concentrates to a maximum rate of run-off of 250 000 cu ft per sec at the end of the first day of rain. During this period one-fifth the water that fell on this area had passed the outlet and four-fifths was left on the water-shed at the end of the day—from Equations (9) and (10). Thus, the total rainfall on Area $ACB = Q\ t = 250\,000 \times 86\,400 = 21\,600$ millions of cubic feet, of which 4 300 and 17 300 millions had passed the outlet and remained on the water-shed, respectively; but, the total rainfall on the entire water-shed during the 1-day period (see Table 6(a)) $= \left(\frac{A}{4}\right) t = 6\,250\,000 \times 86\,400$ $= 540\,000$ millions of cubic feet. Therefore, the quantity remaining on the entire water-shed at the end of the first day of rain $= 540\,000 - 4\,320$ $= 535\,680$ millions of cubic feet.

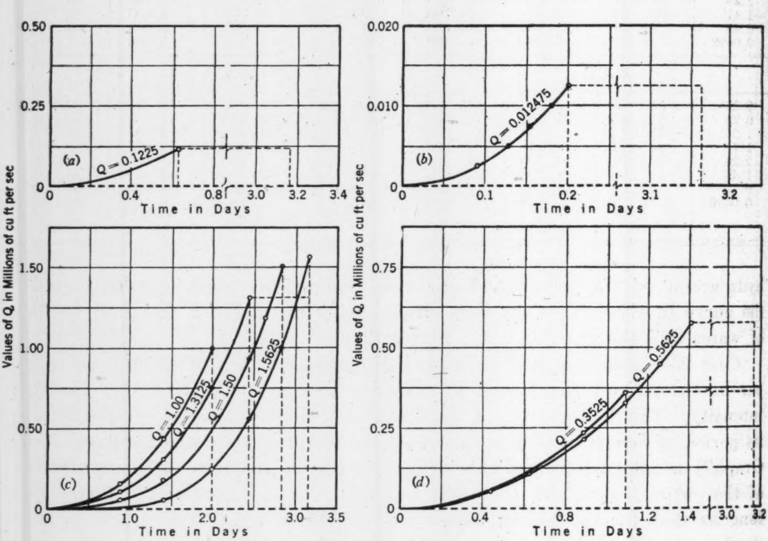

FIG. 10.—EXPLANATORY GRAPHS, CASE 2.

At the instant the rainfall ceases, the same rate of run-off, 250 000 cu ft per sec, will prevail at all points between L and P of Fig. 7. At this instant the maximum Q-values tributary to the time-contours, ACB, DFE, GIH, and JLK, are due to contributions from Areas $DACBEF$, $GDFEHI$, $JGIHKL$, and $MJLKNO$, respectively.

The quantity of water that has passed a given time-contour during the 1-day rain may be ascertained as illustrated by the example, which follows: Consider the time-contour, DFE (Fig. 7). Divide the tributary area (5 000 000 acres) into sub-contours, and determine the respective values of Q, Q', and t as illustrated under Case 1(a). As before, the time is found from Equation (11). These values are given in Table 7(*b*) and are plotted in Fig. 11(*a*) (see Curve *AB*).

In Fig. 11(*a*) the area, *ABC,* under Curve *AB,* represents the quantity of water having passed the time-contour, *DFE,* during the day's rain. If this is deducted from the total rainfall on the water-shed above the contour, the result will be the quantity left on the water-shed at the end of the period.

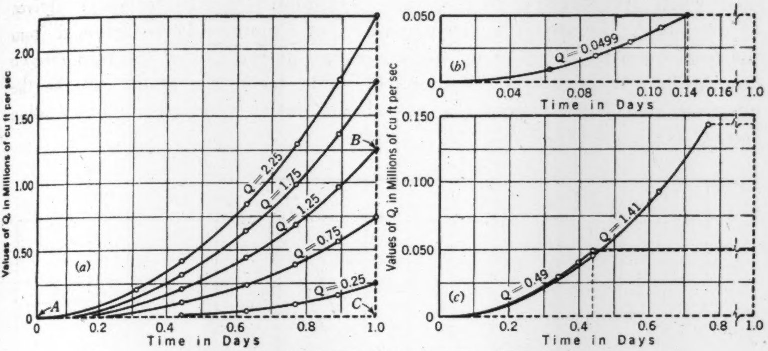

FIG. 11.—EXPLANATORY GRAPHS, CASE 3.

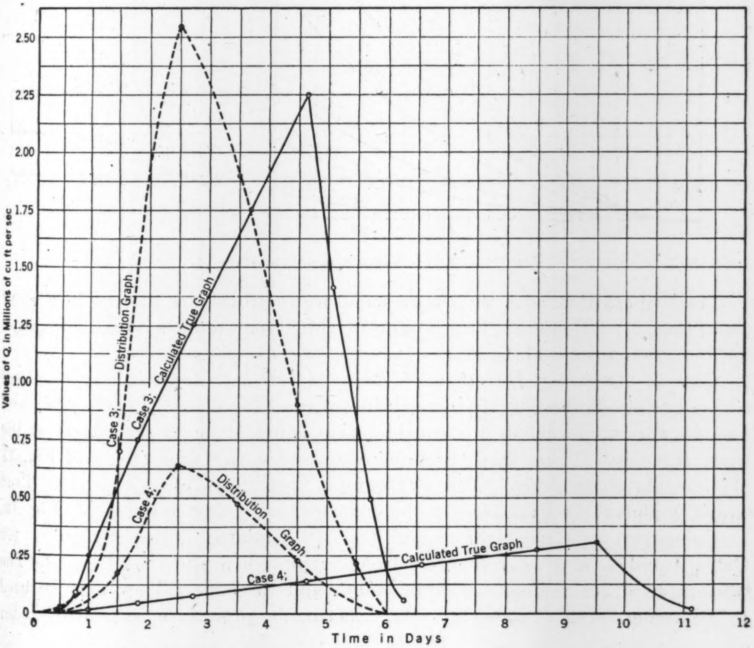

FIG. 12.—COMPARATIVE HYDROGRAPHS, CASE 3 AND CASE 4.

In Table 8(*c*) values are given for the total rainfalls on the area above, the quantities passed, and those left on the water-shed above, the various time-contours as represented by their respective maximum Q-values.

As before, a given quantity (Column (4), Table 8(*c*)) will still be on the shed when its corresponding Q-value (Column (1), Table 8(*c*)) arrives at the outlet. Hence, if a given quantity of Column (4) is deducted from the total quantity of water on the water-shed at the end of the rain (shown hereinbefore to be 535 700 millions of cubic feet), the result will be the quantity that has subsequently passed the outlet when the corresponding flow, Q (Column (1), Table 8(*c*)), arrives.

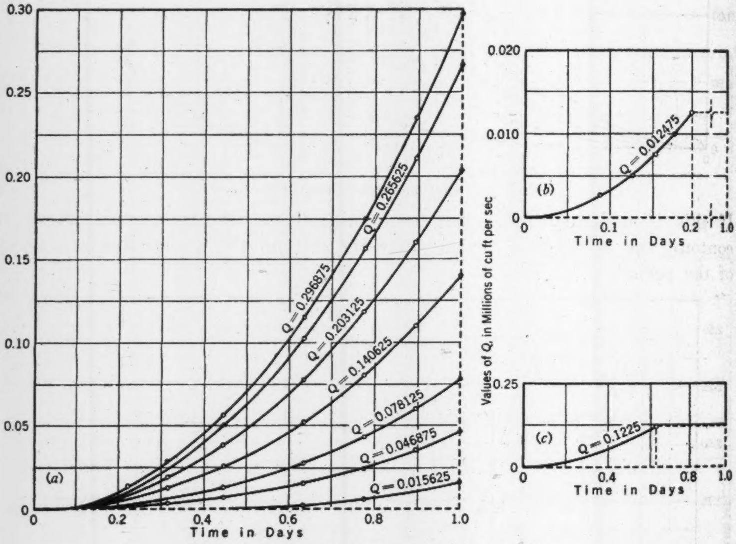

FIG. 13.—EXPLANATORY GRAPHS, CASE 4.

These quantities, with their corresponding Q-values, are plotted in Fig. 12 (see "Case 3: Calculated True Graph") which represents a true hydrograph for the assumptions of Case 3.

Case 4.—One-Day Duration of Rain; All Other Assumptions Identical with Case 2.—Following the procedure outlined for Case 3, Table 8(*d*) and Fig. 13 were constructed, due consideration being given to the effects of the lower intensity. These data are to be compared with Table 8(*c*) and Fig. 11 of Case 3, respectively. The hydrograph (see "Case 4: Calculated True Graph") platted in Fig. 12, is to be compared with that for Case 3, Fig. 12.

Comparisons.—The hydrograph (see "Calculated True Graph"), for Cases 3 and 4, may be compared directly through a study of Fig. 12. The two graphs differ radically both in length and in shape. They may be used to construct graphs following Mr. Sherman's procedure as outlined for

Fig. 1 of the "Unit-Graph Method"[28]. Marked differences in results will be noted, for the two cases, as to total length of graphs, times to maximum rate of run-off, and shapes of graphs. If these graphs, so constructed, are compared with the two hydrographs of Fig. 8 (see "Calculated True Graphs"), a more complete idea as to the magnitude of errors resulting from disregard of fundamentals may be gained. Conversions to the unit-graph method are omitted herein in order to conserve space.

The distribution graph method, as proposed by the author, is more pertinent to this discussion; and for the purpose of making comparisons, data for constructing a distribution graph were selected from the hydrograph of Fig 8 (see "Case 1: Calculated True Graph"). These data are shown in Table 9.

TABLE 9.—DISTRIBUTION GRAPH FOR CASE 1, FIG. 8

(Total Discharge = 1 207 500 Millions of Cubic Feet)

Day	Discharge, in millions of cubic feet	Approximate percentage of total discharge (distribution graph)	Day	Discharge, in millions of cubic feet	Approximate percentage of total discharge (distribution graph)
1	4 300	0.4	4	364 500	30.2
2	133 500	11.1	5	173 000	14.3
3	492 000	40.7	6	39 800	3.3

The distribution graph of Table 9 was then applied to Cases 1, 2, 3, and 4, using the data for rainfall assumed herein and following the author's method, as exemplified in his Table 3. The results are shown in Table 10 and the reproduced hydrographs are plotted in Figs. 8 and 12, as represented by the dashed curves. Little comment is necessary. Comparisons may be made directly with the calculated true hydrographs as platted on the same diagrams. In each case the variation is due solely to the complete disregard (which is inherent in the method) of the effects of a difference in intensity.

The variation incidental to the choice of the time-unit may be obviated by plotting the ordinates of the calculated true graphs in terms of the average flow, Q, per day. The resulting curves (plotted by the writers, but not published herein) still show marked variations from the distribution hydrographs.

Conclusion (a).—The water-shed selected, its size, shape, and manner of concentration, together with assumptions for intensity and characteristics, which rendered the foregoing variations, was chosen merely for the purpose of arriving at definite results for use in making comparisons. Another water-shed of any size and with other uniform intensities of the same ratio, but with the same shape, manner of concentration, and remaining assumptions, will render similar variations for comparison. Any given water-shed, similarly subjected to two different uniform intensities, will show results varying in the same general direction. Pondage, channel constrictions, and

* Derived from Fig. 8 (see, " Case 1: Calculated True Graph.")

the existence of water in the channels immediately before the rains would tend to "iron out" the peaks and generally to make the variations less marked. On the other hand, perviousness of the area, causing a greater difference in the ratio of resulting run-offs than that of applied intensities, would increase the variations above those obtained for the completely impervious area assumed for the foregoing cases.

Any method or system, proposed for devising hydrographs, should at least embody within its scope the opportunity for designers to use their judgment in allowing for the effects on run-off of all fundamental factors and relations.

Conclusion (b).—The procedure, outlined and followed in the foregoing computations for the calculated true graphs of Figs. 8 and 12, although utilized for special cases, for the purpose of obtaining results to be used in making comparisons with those of the author's method, may serve as a guide in the determination of hydrographs for points on streams where adequate flow records are not available. A few more comments may serve further to clarify the applicability of this procedure to any water-shed.

Usually, it will be desired in such cases to consider a rain that lasts as long as the time of concentration of the area. The time of concentration to the maximum rate of run-off and the resulting average intensity for the assumptions may be ascertained through use of the writers' formulas and methods.[24]

Any alterations of these times and intensities, due to pondage or other delays, will depend, of course, on the judgment of the designer, as guided by any information that he may possess. These formulas and methods will also be of service in dividing the water-shed into time-contours. The distribution of the water left on the shed at the end of the rain (being the total estimated run-off less the area under the hydrograph from the beginning to the end of the rain) may be determined through the procedure outlined under Case 1.

The ordinary water-shed, of course, is irregular in shape and manner of concentration, as are also the time-contours by which it may be divided. Instead of a simple equation (as Equation (11), for Case 1) for use in conjunction with time-rendering areas in determining the quantities that have passed a given time-contour, resort should be made to the special tables[30] of the factor P, previously introduced by the writers. Since $P = \frac{v}{V}$, and since the value of V can be computed for the known quantity of water and average slope, the average velocity, v, is readily obtained. The known length divided by v will render the required time.

The detail required for a given problem and any abridgment of the method may well be left to the judgment of the engineer.

Gordon R. Williams,[31] Jun. Am. Soc. C. E. (by letter).—The unit-graph method has interesting possibilities in the determination of flood flows. The author considers the feasibility of establishing magnitude-frequency relations through the use of an equation for rainfall intensities and the pluviagraph, thereby assuming a storm coefficient of unity. In regions where melting snow is a component of stream flow the assumption of a storm coefficient of unity or greater than unity is reasonable, but there are many places where such an assumption would not be in accord with hydrologic experience. In such places it might be possible, by the author's methods, to determine the frequency with which storm coefficients approach maximum values. The next question is to determine the frequency of flood-producing storms. This necessitates a consideration of the intensities of rainfall, the areas covered by rains of various intensities, the positions of the storm centers, and the directions of storm movement. If the task of combining these factors so that they can be properly expressed in relation to frequency could be accomplished, there still would remain the problem of combining this result with the frequency of maximum storm coefficients in order to attain the ultimate goal, which is the frequency of flood discharges of various magnitudes.

The unit-graph method appears to be applicable to the determination of rare floods that can be expected from moderate-sized drainage areas. The author states that the method has been applied for other purposes to drainage areas approximating 6 000 sq miles. The determination of the probable maximum flood is a preliminary step in deciding upon suitable designs for most hydraulic structures. It would be of value in almost any method for analyzing floods, even in purely theoretical procedures, such as that presented by Professor J. J. Slade, Jr.[32]

[32] *Proceedings*, Am. Soc. C. E., October, 1934, p. 1118.

Flood studies bring out the fact that the smaller the drainage area the greater the potentialities for producing high yields per unit area. Small drainage areas usually have the important requisites for producing floods; that is, they can be entirely surrounded by areas having higher rates of rainfall, they have steep slopes, and they lack the essentials for natural flood detention. Many of the most severe floods are those produced by so-called "cloudburst" storms. The periodicity of such floods may be very great when expressed in years, so great, in fact, that a study by statistical methods[33] of what might be considered a long record in the United States would not indicate that such a flood is likely to occur. Examples of these rare floods occurred on the Miami River, in Ohio, in 1913,[34] on the Arkansas River, at Pueblo, in 1921,[35] and on many rivers in Vermont in 1927.[36] The discharges in these floods were two or three times greater than would be expected from a study of a magnitude-frequency relation. For such floods, statistical methods appear to be inadequate. The unit-graph method, on the other hand, may make it possible to arrive at an approximation to the limiting flood through the application of high rainfall rates, together with high, but altogether possible, storm coefficients, and the placing of a hypothetical storm in a critical position.

On large drainage areas, such as that of the Ohio River or the Tennessee River, where the application of the unit-graph method might encounter difficulties, the statistical method seems to offer a partial solution, provided a long record is available. On such drainage areas the differences in percentage between the leading floods in the record are usually small in comparison to those from a small drainage area, thus making the periodicity a relatively less important factor in relation to magnitude. A frequency curve derived from perhaps a 40-yr to 50-yr record of a large drainage area might be extended to a periodicity of materially greater length, with the assurance that an approximation to the maximum flood had been reached.

W. G. HOYT,[37] M. AM. SOC. C. E., AND L. L. HARROLD,[38] AND F. F. SNYDER,[39] JUNIORS, AM. SOC. C. E. (by letter).—In connection with general studies of relations between rainfall and run-off being made by the U. S. Geological Survey, in collaboration with the Water Planning Committee of the National Resources Board, the writers have had an opportunity to investigate the distribution graph devised by Mr. Bernard based on the unit graph set forth by Leroy K. Sherman,[40] M. Am. Soc. C. E., to study relations between precipitation and surface run-off. Although the studies have not progressed far enough to warrant definite conclusions, it is believed that a brief summary of some of the problems encountered will be of value to hydrologists and engineers who may be interested in water utilization. It should be recognized that the distribution graph described by Mr. Bernard effects the same purpose as Mr. Sherman's unit graph, and that, in theory at least, both relate wholly to direct surface run-off, because in the development of a unit graph all flow occasioned by precipitation previous to the storm under consideration is segregated from the flow resulting from the 1-day storm. The accuracy with which a unit graph and a distribution graph can be developed, therefore, depends upon the accuracy with which the stream flow resulting from antecedent rainfall can be determined—a problem with which many hydrologists and hydraulic engineers have been concerned.

[40] "Stream Flow from Rainfall by Unit-Graph Method," *Engineering News-Record*, April 7, 1932, p. 50.

By definition and example, Mr. Bernard develops a so-called "recession curve" by combining the recessions of the hydrograph of several storm periods followed by intervals of no rainfall, which he states "gives a dependable idea of how the base flow would have fallen and the flood flow would have receded had no subsequent rainfall occurred," and he uses this curve to determine the so-called "base flow". It would seem that this method properly excludes surface run-off resulting from antecedent rainfall, but does not take into account the facts that base flow—or, as otherwise defined, ground-water flow, or seepage flow—is a variable quantity and that recession curves based on hydrographs of stream flow, unless made up of segments of the hydrograph representing periods when no surface run-off is in the stream, may not be comparable with depletion curves of ground-water flow. For example, in drawing the base-flow curve for the Muskingum River at Dresden, Ohio, Mr. Bernard assumes that the base flow would have fallen from 1 500 to 700 cu ft per sec in 11 days during March, 1929, and similarly during the two storms in July, 1925, and in July and August, 1927, that were used to determine the average-distribution graph. This use of a fixed "recession curve" does not take account of the fact that during March the water-table in the Muskingum Basin may be high enough to maintain a base flow between 2 000 and 5 000 cu ft per sec, whereas, in July, it may be only high enough to maintain a flow of 1 000 cu ft per sec, or less. Use of a fixed "recession curve" in the determination of the unit graph seems to rely on the accuracy of an average curve and to ignore departures therefrom due to variations in gound-water levels and ground-water flow and to recharge from the storm under consideration. If the storm producing the surface run-off occurs at a time when the ground-water flow corresponds to the lower end of the fixed recession curve, the error introduced may be negligible, but if the storm producing the surface run-off occurs when the ground-water is high, the error may be very appreciable. In each case, of course, the error depends on the magnitude of the storm run-off in relation to the ground-water flow. Different methods[41] have been used to segregate surface run-off from ground-water run-off, but apparently none of them is subject to exact analysis, and care must be taken that the method used eliminates, and does not include, any ground-water flow in the determination of the unit graph.

---

[41] R. E. Horton, M. Am. Soc. C. E., in his discussions of "The Rôle of Infiltration in the Hydrologic Cycle", pub. in the *Transactions* of the Am. Geophysical Union, National Research Council, of the National Academy of Science, June, 1933, p. 446, outlines methods that have been used to separate surface flow from ground-water flow and gives valuable references.

If the fundamental requirements are observed the writers have found, as Mr. Bernard did, that the theory of the unit graph or distribution graph seems to apply to a remarkable degree in actual practice. In their derivation, however, the following factors must receive due consideration:

1.—In deriving unit graphs it is necessary to select storms that conform as closely as possible to the ideal, which is rainfall of uniform intensity and 24-hr duration. Since such storms do not occur in Nature over any extended area, the peaks of unit graphs of 1-day storms vary somewhat, depending on whether the storm center is near or remote from the gauging station. Conversely, in the application of an average unit graph to actual precipitation, the results will differ from the recorded data to the extent that the storm pattern differs from the average condition used in determining the unit graph.

2.—The published records of the U. S. Weather Bureau do not indicate whether the recorded precipitation on any one day occurred during 1 hr, or was well distributed over the 24 hr. In a similar manner an ideal 24-hr storm may be recorded in equal amounts on two consecutive days. Unit graphs for storms lasting 1 hr may not be comparable with those for storms lasting 24 hr, and in the application of the determined unit graph the resultant pluviagraph will differ from the recorded flow to the extent that the unit graph of storms of less than 24-hr duration differs from that of storms of 24-hr duration. Published records of precipitation give the total for the day, and published discharge records give the average flow for the day. These limitations in the details of recording basic data make it impossible to determine comparable unit graphs from small basins, but in the opinion of the writers they do not disprove the essential theory of the unit graph. These limitations also make it difficult to combine or average the separate unit graphs for the same basin. For example, a unit graph of one storm may show no rise on the day the precipitation was recorded, while that of another storm may show an appreciable rise, a difference which may result from inadequacies in the refinement of recording, or from causes not now definitely determined, such as varying initial rates of infiltration and interception, or water required and held in initial surface wetting.

3.—Theoretically, it would seem that, as a result of differences in channel velocities, the unit graph of a 1-day storm occurring when the river is at a high stage would differ from that of a storm occurring when the river is at a low stage.

4.—Unit graphs of 1-day storms apparently cannot be obtained in basins where the infiltration capacity exceeds the rainfall rate, or where the direct surface run-off is substantially delayed either by artificial or by natural storage. To a moderate extent both these conditions occur in many basins, and the Rock River above Afton, Wis., is herewith discussed as an example of the difficulties which may be encountered in the preparation of distribution graphs of surface run-off resulting from 1-day storms. The drainage area is 3 190 sq miles. Lakes and marshes occupy between 10 and 15% of the area; channel slopes are small, and the soil is largely sandy loam. These conditions give rise to a large ground-water and sustained flow and a relatively small quantity of direct surface run-off. An examination of the daily hydrograph of the Rock River, at Afton, for the period, October, 1914, to September, 1933, failed to disclose an instance in which the rise in the hydrograph could be associated with a 1-day storm. All pronounced rises in the hydrograph were the result of rainy periods of from 4 to 10 days' duration. Although in this particular instance it might be possible to develop distribution graphs based on 5-day storms, they would not seem applicable to any 1-day storm.

Notwithstanding these apparent limitations, distribution graphs having the same general pattern, have been obtained by the writers from basins ranging in area from 1 000 to 40 000 sq miles. Although the distribution graphs follow the same general pattern, the variations between peak magnitudes are very appreciable. These variations may be a source of inconsistencies in the application of an average distribution graph to hydraulic problems.

After developing an average unit graph or distribution graph, Mr. Bernard transposes the total weighted daily precipitation on the basin into so-called "pluviagraph values" and, in his examples, compares these values with total run-off by means of "retention coefficients" obtained by dividing the total observed run-off for the several days making up the storm period by the total pluviagraph value or by distributed rainfall for the same period.

Two questions have puzzled the writers in regard to the pluviagraph: First, is it fundamentally logical to distribute total rainfall by means of a distribution graph based on direct surface run-off (rainfall minus infiltration and storage); and, second, is it logical to compare rainfall thus distributed with total recorded flow? In connection with the general studies previously mentioned, the writers found that the average annual direct surface run-off in all major sub-basins of the Mississippi River, above Keokuk, Iowa, ranged from about 2% of the precipitation for the Minnesota River Basin to about 26% of that for the Black River Basin. In other words, by the application of Mr. Bernard's method to the Minnesota River Basin, 98% of the pluviagraph would be built up of precipitation that did not appear as direct surface run-off. In the application to the Black River Basin, which apparently has the maximum surface run-off of all the larger basins in the Upper Mississippi River drainage area, use of Mr. Bernard's procedure would distribute about 74% of the precipitation that did not appear as surface run-off.

Of the precipitation that did not appear as direct surface run-off, about 1% in the Minnesota River Basin and about 6% in the Black River Basin eventually appeared as sustained or ground-water flow. It seems illogical to the writers to include in a pluviagraph precipitation which, even if it does eventually appear as stream flow, arrives there through the ground and manifestly follows laws different from those controlling direct surface run-off as reflected in the unit graph.

For isolated storms, Mr. Bernard's "retention coefficient" is the simple relation between the total storm precipitation and the total run-off. For the Tuscarawas River, at Newcomerstown, Ohio, which he has used as an example, it is the relation between the total pluviagraph value and the total recorded run-off for the period between consecutive troughs on the hydrograph.

More and more hydrologists are looking upon stream flow as made up of two distinct parts, one of which results from direct surface run-off and the other from that part of the precipitation which is either retarded on the surface, or which passes through the ground and eventually reaches the stream channel. For the direct surface run-off the time between the occurrence of the precipitation and its appearance at the gauging station is relatively short, as shown by the unit graph. For the sustained or ground-water flow the time is much longer and can probably be measured in terms of months rather than of days. For example, the late J. F. Hayford,[42] M. Am. Soc. C. E., found, by strict mathematical analysis, that in the Wagonwheel Gap area, in Colorado, the flow on any one day depended, in part at least, upon the meteorologic conditions existing during the preceding 257 days. To the extent that the total flow is made up of ground-water flow dependent on conditions antecedent to the time covered by the distribution graph, relations between total pluviagraph records and total run-off seem valueless. If ground-water is deducted, however, comparisons between total pluviagraph records and observed stream flow less ground-water flow may have value. If they can be carried back through the distribution graph, these relations might show, to the extent that the surface run-off followed the average distribution graph, the amount of infiltration day by day. Furthermore, it may be possible to correlate the relations with past and present conditions to an extent sufficient at least to make use of total pluviagraph records in determining surface run-off from storms of great magnitude.

The writers are studying both methods of approach, and the results, to date (1935), seem to indicate, as Mr. Sherman and others have found, that antecedent conditions, as well as amount and intensity of the particular rainfall considered, play an important part. For example, under similar storm conditions, low rates of infiltration with resulting high run-off relations, will apply on Ohio streams during normal spring periods, when soil moisture and ground-water levels are at a maximum, and high rates of infiltration with resulting low run-off relations will apply during normal Septembers, when conditions are reversed. However, if conditions are abnormal and moisture conditions in the spring are comparable to normal fall conditions, the infiltration and run-off relations for the two periods tend to be comparable. In so far as total surface run-off throughout the year is concerned, the applicability of the unit-graph method will depend upon the accuracy with which relations between several factors can be determined.

---

[42] "A New Method of Estimating Stream Flow" by the late J. F. Hayford, M. Am. Soc. C. E., and J. A. Folse, *Publication 400*, Carnegie Inst., Washington, D. C.

With respect to the value of the "retention coefficient" in connection with flood flows, a somewhat different condition exists. Floods result when infiltration is at a minimum, with corresponding high run-off relations. If there is no snow on the ground the pluviagraph record should represent, within reasonable limits, the maximum surface run-off possible with zero infiltration. It is believed that studies and experiments will eventually disclose infiltration limits that may be reached and thus make possible the determination of limiting run-off rates which, when used with Mr. Bernard's pluviagraph, will make it possible to determine flood run-off in a rational manner.

The author is to be commended for clarifying the basic principles of the unit graph, for his development of the distribution graph, and for his conception of the pluviagraph. Although it is far from an exact process for computing stream flow, the writers have found that it yields reasonably comparable distribution graphs, and that when net rainfall, as used by Mr. Sherman, or total precipitation, as used by Mr. Bernard, was distributed by means of an average unit graph or distribution graph, the peaks of computed and observed surface run-off occurred on the same day or, if not, rarely more than one day apart. The concepts developed are of material assistance in the analysis of run-off in relation to its causes, thus promoting a better understanding of the occurrence of trends and the possible affects of storage, land drainage, agriculture, and other factors that may be of importance in considering the wise utilization of water resources. They furnish a tool for analysis of rainfall and run-off that may be of practical value where detailed knowledge of hydrology is important, as in (*a*) manipulation of storage on large systems of river development for power and water supply; (*b*) obtaining definite knowledge of run-off characteristics of urban areas, where special conditions make such knowledge of exceptional value; and (*c*), analysis of potentialities of drainage basins for producing floods.

MERRILL M. BERNARD,[43] M. AM. SOC. C. E. (by letter).—In 1934 and 1935, the writer was associated with a group in the U. S. Geological Survey which has been engaged on a study of floods and flood frequencies, and rainfall, run-off, and inter-related factors. A large part of his time was devoted to the application of the unit-hydrograph method to run-off resulting from storms of high magnitude. Underlying principles and methods have been studied by other members of the group, as outlined in the discussion of Messrs. Hoyt, Harrold, and Snyder. In the preparation of his closing discussion, the writer has drawn on his own additional experience as well as on the ideas and studies of his associates.

---

[43] Cons. Civ. Engr., Crowley, La.

The simplified form of Equation (1), suggested by Mr. Jarvis in Equation (5), should be accceptable, in general, particularly in cases where channel characteristics are not known. The factor, U, is purely an abstract one, having its principal use in the construction of regional charts, as shown in Fig. 2.

The suggestion that the pluviagraph be used as a guide to the shape of the hydrograph has possibilities. Recent studies indicate that, where only definite flood hydrographs are considered, the ratio, $\frac{\Sigma \text{ hydrograph}}{\Sigma \text{ pluviagraph}}$, for any basin follows a rather well-defined trend throughout the seasons. Such a trend curve can be developed from a comparatively short record of flow, and would be a more dependable guide to run-off coefficients for a particular locality within the Mississippi Basin than the range of from 14 to 31%, suggested by Mr. Jarvis.

The writer is in accord with Mr. Sherman on the points covered by his discussion. Particularly does he join him in concurring with Mr. Horton and others in the belief that infiltration loss should be considered as a deduction from daily rainfall. It has been the writer's experience, however, that average or gradually decreasing infiltration deductions throughout periods of continuous or intermittent rainfall do not produce net rainfalls that can be converted directly into the stream hydrograph with the use of the distribution graph. For storm periods consisting of two or three days of appreciable rainfall, preceded by several days of light rainfall, all such light rainfall, together with the greater part of the first day of heavy rainfall, may have been consumed by infiltration, whereas the following days of heavy rainfall largely account for the resulting stream flow. It is also believed that the rainfall-recording interval of 24 hr obscures comparatively long periods between actual rainfalls which have been recorded as continuous, making the practical correlation of a daily infiltration deduction with antecedent conditions difficult.

The phenomenon of infiltration, which is the principal loss to rainfall, is so unlike that of surface run-off, that the two should not be directly combined to give the total loss. Infiltration activity is more logically associated with that of rainfall. Like rainfall, it can be applied to a unit of area and is practically accomplished within the duration of rainfall, whereas run-off, very shortly after it is created, is to be associated with surface and channel storage, and stream flow. In the case of a unit-time rainfall, producing a unit hydrograph, surface run-off has reached the stream system within that period, to a great extent, thus becoming identified with storage. With the exception of such minor losses as channel seepage and surface evaporation, withdrawals of water from the basin, as measured stream flow, constitute the changes in storage. The equation of these factors, including storage, could be stated as follows:

$$\underset{\text{(Daily rainfall)}}{\text{Inflow}} - \underset{\text{(Infiltration)}}{\text{Outflow}} = \text{Change in Storage} + \underset{\text{(Stream flow)}}{\text{Outflow}}$$

It would seem, then, that to preserve the rationality of the unit-hydrograph theory, the distribution of run-off or stream flow throughout the run-off period should be made by applying a distribution graph to rainfall excess, or average daily rainfall minus a depth lost through infiltration.

The pluviagraph is the hydrograph of 100% run-off; but it is not the graph of run-off plus infiltration in that such a definition would imply the distribution of infiltration loss throughout the period of run-off in proportion to run-off. The writer has found the pluviagraph useful as a limiting or enveloping hydrograph from which the hydrograph of a particular flood resulting from a continuous storm period can be reproduced by the application of two related coefficients. First, it must be recognized that the pluviagraph of a unit-time rainfall is nothing more than the mechanical distribution of such rainfall throughout the period of surface run-off in proportions fixed by the distribution graph, establishing the proportionality between the ordinates of the pluviagraph and those of the resulting unit hydrograph. The relation between the unit pluviagraph and the unit hydrograph is linear, therefore, making the cumulative plot of distributed rainfall (pluviagraph) and stream flow from surface run-off (unit hydrograph) a straight line, the slope of which

can be called a storm or flood coefficient. The application of such a coefficient to the pluviagraph of a day's rainfall is the same, in effect, as the distribution of the rainfall excess which remains after the deduction of infiltration from the day's rainfall, and which will produce the unit hydrograph direct.

The relation of the factors involved in the development of the unit graph and the distribution graph is given in Table 11, which presents as an example the effect of a completely isolated storm of September 29 and 30, 1924, on the Susquehanna River Basin above Towanda, Pa. This storm, although recorded in 2 days, is believed to have been confined to a continuous period approximating 24 hr. The factors of this unit hydrograph are shown in relationship in Fig. 14, together with the cumulative curves of rainfall, infiltration, run-off, and storage.

With less accuracy, but within practical limits, the pluviagraph of a multiple-day storm may be reduced to the approximate flood hydrograph by the application of a compound linear coefficient, as demonstrated with the typical storm of May 21 to 25, 1919, on the same basin, as reported in Table 12. The cumulative plot of the pluviagraph against that of surface run-off takes a

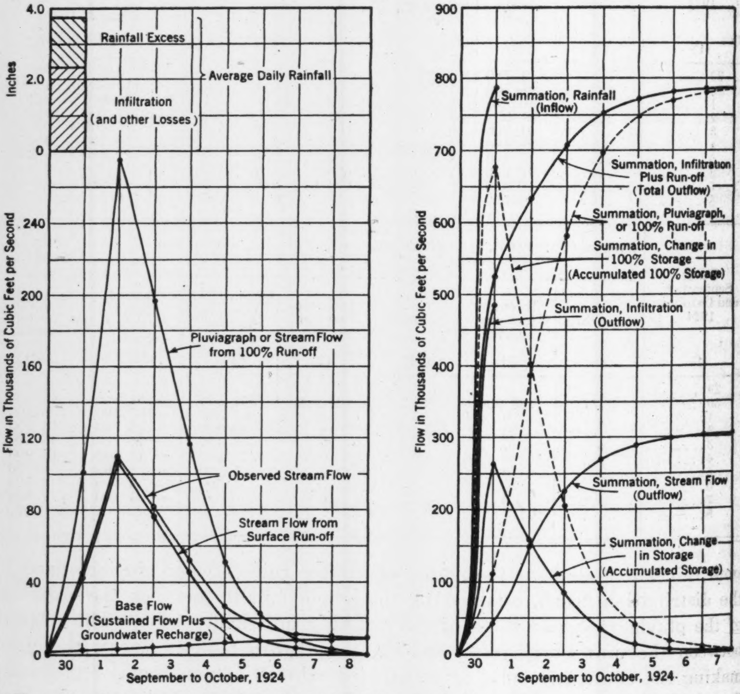

FIG. 14.—RELATIONS OF RAINFALL, INFILTRATION, STORAGE, AND STREAM FLOW, SUSQUEHANNA RIVER, AT TOWANDA, PA.

flatter slope for the first two days than that for the remainder of the run-off period, indicating the greater rate of loss through infiltration, which is to be expected. The accuracy with which these results can be obtained will depend largely on how near the prevailing rainfall, surface, and ground-water conditions are to those represented by the average distribution graph used.

* Includes the distribution of effective antecedent rainfall.

The writer made no attempt to correlate a run-off coefficient or deductive infiltration factor with antecedent conditions, except to comment on the apparent seasonal trend in the value of his "retention coefficient," which he now more properly refers to as a "flood coefficient." Subsequent experience discourages the hope that such correlations are simple. The method of estimating daily rainfall excess on a percentage basis, proposed by Mr. Sherman[2] in his original paper, has not, as far as the writer knows, been improved upon.

Mr. Horner is correct in his criticism of the frequency graphs in Fig. 5. These might be regarded as "possibility" or "limiting" graphs, accepting the assumption that it is physically possible for a flood coefficient equal to unity and the 100-yr storm to occur in the same season. More recent studies in which the unit-hydrograph method has been applied to limiting storms indicates its usefulness in this field.

As stated by Messrs. Eiffert and Bennett, time should not be lost in improving, in several ways, methods of gathering and recording climatological and hydrological data by the various governmental agencies. This is no criticism of the bureaus themselves, for they have "spread" their appropriations remarkably well, but rather is it a challenge to all interested engineers to co-operate more fully in the improvement of this service.

The discussion of Messrs. Gregory and Arnold, the writer believes, fails to make its point and does not disprove the theory of the unit hydrograph by proving that rainfall, run-off, and stream flow relate themselves in another manner. In the first place they have deviated from the principle of the unit-hydrograph method in developing their distribution graph from the 3-day storm of Case 1, thereby assuming a time unit of 3 days, after which they apply the resulting distribution graph to 1-day storms. Although the use of a distribution graph developed from their 1-day storm would not have brought the two methods into accord, the absence of any mention of this deviation from the principle of the unit hydrograph would confuse a reader hopelessly who, not being particularly conversant with the unit-hydrograph theory, would attempt to associate the discussion by Messrs. Gregory and Arnold with the writer's paper.

There is only one answer to the discussion by Messrs. Gregory and Arnold. The conclusions, as determined from their hypothetical example, have not been found in Nature. It is possible that their assumptions, among which are uniform rainfall intensity over a 3-day period, no losses to run-off, and no sustained or base flow, may contribute to the abnormal results obtained.

A recent study in which the writer has been engaged, has developed distribution graphs on about fifteen or twenty basins, ranging in area from 500 to 60 000 sq miles. The one nearest in size to the hypothetical problem given by Messrs. Gregory and Arnold (the Red River, at Denison, Tex., of 38 000 sq miles) is selected for the purpose of making the comparison between the natural phenomenon and that visualized by these discussers.

They have presented four conditions of rainfall: Case 1, a heavy rainfall for a duration of 3 days; Case 2, a light rainfall for a duration of 3 days; Case 3, a heavy rainfall for a duration of 1 day; and Case 4, a light rainfall for a duration of 1 day. From their analysis the conclusion is reached that the base of the unit hydrograph and the position of its peak will vary between wide limits, caused principally by the great variation through which average velocity passes in going from low to flood stage. The following list gives their results in terms of "lag" (this term being defined as the time interval between the center of mass of rainfall and the peak of the flood):

Case	Lag-days	Case	Lag-days
1..........	0.53	3..........	4.20
2..........	1.10	4..........	9.00

Under natural conditions it is found that the lag and hydrograph base for 1-day storm periods are approximately the same regardless of rainfall intensity. Furthermore, for continuous rainfall the lag does not change, regardless of intensity or deviations from the average. Fig. 15 shows, for the same basin, the lag of 3 days for rainfalls of various intensities for durations of 3, 4, and 5 days.

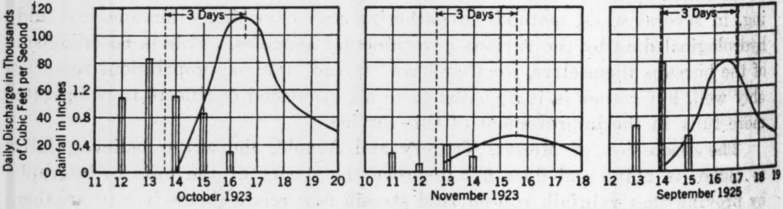

FIG. 15.—LAG OF PEAK RUN-OFF BEHIND CENTER OF MASS OF RAINFALL FOR THREE, FOUR, AND FIVE-DAY STORM PERIODS, RED RIVER, AT DENISON, TEX.

Table 13 shows the relations between rainfall intensity and lag, to the nearest day, for a group of unit hydrographs for the Red River at Denison, Tex.

December 4 and 5, 1930	1.54	December 7	3	......	......	......	......

Comparable results obtained by W. W. Horner, M. Am. Soc. C. E., and F. L. Flynt, Assoc. M. Am. Soc. C. E.,[44] also substantiate the unit-hydrograph theory and disprove the contentions of Messrs Gregory and Arnold.

Mr. Williams directs attention to the use of the unit-hydrograph method as the means of determining the limiting flood on any basin. Such procedure is possible in any case where a record of flow exists sufficiently long to yield the unit hydrographs (preferably not less than three) necessary to the development of the distribution graph for the basin and a sufficient number of well-defined flood periods to indicate the probable limiting value of the flood coefficient. With the distribution graph and the limiting coefficient at hand, outstanding storms that have visited the region may be superimposed upon the basin in a critical position and the resulting flood hydrograph obtained.

The studies of the unit-hydrograph method, referred to in the discussion of Messrs. Hoyt, Harrold, and Snyder, have contributed to the further development and refinement of the method. They have greatly improved the technique of constructing the distribution graph and have shown that seasonal changes in ground-water flow may seriously affect results, in many cases, if not taken into account.

In conclusion the writer expresses the hope that his paper, together with the discussions, is a step in the approach to a fuller and more rational conception of the relation of rainfall to run-off and stream flow. The unit hydrograph, as now understood, relates exclusively to surface run-off, a point to be kept in mind in any application of the method to hydraulic problems. The writer admits readily that such devices as the distribution graph, the pluviagraph, and the flood coefficient are not scientifically precise in all respects. They are tools of practical value, however, the complete explanation of their various functions being bound up in the further development of the unit-hydrograph method.

DISCHARGE FORMULA AND TABLES FOR SHARP-CRESTED SUPPRESSED WEIRS

By C. G. Cline,[1] Esq.

With Discussion by Messrs. Jasper O. Draffin, W. Bruce McMillan, and C. G. Cline.

Synopsis

The new discharge formula presented in this paper applies to sharp-crested weirs that occupy the full width of the channel; that is, weirs with the end contractions suppressed. This formula is entirely empirical and was developed by a mathematical study of the results of a series of weir experiments[2] made at Cornell University by E. W. Schoder, M. Am. Soc. C. E., and the late Kenneth B. Turner, Assistant Professor of Hydraulics. It differs from those in use at present in that a variable exponent, increasing with the head, replaces the customary fixed exponent (1.5), thus making it possible to obtain accurate discharges, even at low heads, by a comparatively simple form of coefficient. Furthermore, correction for the velocity of approach, which has been developed, depends entirely on the physical dimensions of the weir and can be applied directly.

Curves in this paper offer a comparison between the results of the Schoder and Turner experiments in comparison with the new formula and with the three standard formulas of Francis, Bazin, and Rehbock. These three standard formulas differ from one another, but each is supported by the experimental data over certain ranges of head and height of weir; however, over the entire range of head and height of weir covered by the experiments, the new formula agrees with the data more closely than any of these standard formulas. A set of complete tables for use in applying the new formula has been placed on record in Engineering Societies Library, New York, N. Y.[2a]

Note.—Published in January, 1934, *Proceedings*.

[2a] These tables were reproduced and placed on sale at Society Headquarters in January, 1934.

STATUS OF WEIR FORMULAS

The sharp-crested suppressed weir has been in use as a measuring device for many years, and a number of eminent hydraulic engineers have proposed formulas for computing its discharge. The paper by Professor Schoder and the late Professor Turner previously referred to, and the discussions thereon, together constitute an excellent review of the present status of this subject; the limitations of the various weir formulas in use are pointed out, with the net result that the question of a standard weir formula is left still unsettled. The weir experiments described in that paper comprise the most comprehensive set yet published, but the tentative formula proposed as an interpretation of these data does not seem convenient for practical use, since it requires such extensive measurements of the velocities in the approach channel as to constitute in themselves practically a measurement of the discharge. The formula presented in the present paper, based on part of the same data, can be used without any such auxiliary velocity measurements.

The paper by Professors Schoder and Turner contains a tabulation of the results of a large number of weir experiments. The set selected for this present analysis consists of Series D and O[3], in all of which the crest was a 12-in. brass plate. In making this selection, the intention was to have a set of accurate measurements all made under the same conditions except for the changes in the two variables, head and height of weir. Accordingly, all runs were omitted in which the natural flow of the water was disturbed by special fences; it was found necessary, also, to omit all those in which the head was less than 0.04 ft. In cases where two or more runs were made at practically the same head, mean values of head and discharge were used. Particulars as to height of weir, range of head, number of measurements, etc., taken mainly from the Schoder and Turner paper,[4] are listed in Table 1. All the weirs were 4.22 ft long, the full width of the channel, with no end contractions.

[4] *Loc. cit.*, Table 1, pp. 1000-1001.

Notation

In the metric formulas and tables of this paper, all lengths are in meters, and the discharges are in cubic meters per second. For purposes of conversion, note that 1 ft equals 0.3048 m. Unknown corrections (see Equation (10)) are expressed as *du, db,* etc. The following notation is introduced for the guidance of discussers:

a = a formula constant.
b = a formula constant (Equation (7)).
c = a constant coefficient (Equation (7)).
d = a substitution factor (Equation (7)).
f = a substitution factor (Equation (19)).
g = acceleration due to gravity.
h = head (see, also, H); $h_v =$ head corresponding to mean velocity of approach for use in Equation (2).
i = a substitution factor (Equation (18)).
k = a function of $P = \log a + K$ (Equation (8)).
n = a formula constant (Equation (7)).
r = a residual.
u = a formula constant.
v = a formula constant (Equation (16)).
x = a variable exponent of H.
C = a constant $= c \sqrt{2\,g}$ (Equation (9)).
H = head on weir; $\phi H =$ dimensionless function, with single argument, H; $\phi(P\ H) =$ dimensionless function with two arguments, P and H (this constitutes the velocity of approach correction (see, also, h)).
K = a function of $P = k - \log a$ (Equation (14)).
L = length of crest of weir.
P = height of weir; $\phi(P\ H) =$ dimensionless function, with two arguments, P and H (this constitutes the velocity of approach correction).
Q = discharge.
θ = a dimensionless multiplier.
ϕ = a symbol denoting function; $\phi H =$ dimensionless function, with single argument, H; and $\phi(P\ H) =$ dimensionless function with two arguments, P and H (this constitutes the velocity of approach correction).

General Algebraic Form of Equation

With sufficient accurate experimental data available, the main difficulty in developing an accurate weir formula lies in selecting the proper algebraic form. Once this is done, it is comparatively simple, although sometimes somewhat laborious, to compute the best numerical values of the constants contained in the formula.

For a sharp-crested, suppressed weir, it is known from dimensional analysis that the equation for the discharge per foot of crest is of the form:

$$\frac{Q}{L} = \sqrt{2\,g}\; H^{\frac{3}{2}}\,\theta \qquad (1)$$

in which, Q = total discharge of weir; L = length of crest; H = head; g = acceleration due to gravity; and θ = dimensionless multiplier.

Nearly all weir formulas are of this general type, the only difference being in the treatment of the term, θ, and in the "velocity of approach" correction. For purposes of comparison throughout this paper, three standard equations have been selected:

The Francis Formula:

$$\frac{Q}{L} = 3.33 \left\{ (H + h_v)^{\frac{3}{2}} - h_v^{\frac{3}{2}} \right\} \qquad (2)$$

The Bazin Formula:

$$\frac{Q}{L} = \left(0.405 + \frac{0.00984}{H}\right) \left\{ 1 + 0.55 \left(\frac{H}{H + P} \right)^2 \right\} \sqrt{2\,g}\, H^{\frac{3}{2}} \qquad (3)$$

The Rehbock Formula:

$$\frac{Q}{L} = \frac{2}{3} \left(0.605 + \frac{1}{320\,H - 3} + 0.08\,\frac{H}{P} \right) \sqrt{2\,g}\, H^{\frac{3}{2}} \qquad (4)$$

in which, h_v is the head corresponding to the mean velocity of approach.

In the experiments summarized in Table 1, changes in the discharge, Q, are due either to changes in the head, H, or to changes in the height, P, of the weir crest above the bottom of the approach channel. All other conditions remain unchanged. In Series E and M, $P = 0.5$ and 7.5 ft, respectively. Simultaneous values of $\log \frac{Q}{L}$ and $\log H$ for these two series are shown graphically in Fig. 1. The points for each series fall on a separate curve, which is practically a straight line for small values of H, but which shows definite curvature for large values. Series E, with the smaller value of P, has the greater discharge, the difference increasing as the head increases, so that its graph has a greater curvature.

A consideration of these two graphs, and of the principles of dimensional analysis, led to the conclusion that for the experiments summarized in Table 1, θ may be written as the product of two dimensionless functions, as follows:

$$\theta = \phi H \times \phi(P\ H) \qquad (5)$$

in which, ϕH is a dimensionless function, with a single variable argument, H; and $\phi(P\ H)$, a dimensionless function, with two variable arguments, H and P. Using this expression for θ, Equation (1) may be written in the form:

$$\frac{Q}{L} = \phi H \times \sqrt{2\,g}\, H^{\frac{3}{2}} \times \phi\,(P\ H) \qquad (6)$$

In the ordinary terminology of hydraulics, ϕH is the discharge coefficient, and $\phi(P\ H)$ is the "velocity of approach" correction, expressed as a separate multiplier. In the Francis formula, $\phi H = \dfrac{3.33}{\sqrt{2g}}$, which is constant for all values of H, and the velocity of approach correction is applied by an indirect method involving a series of approximations. In the Bazin formula, $\phi H = \left(0.405 + \dfrac{0.00984}{H}\right)$ and $\phi\ (P\ H) = \left\{1 + 0.55\left(\dfrac{H}{H + P}\right)^2\right\}$. In the Rehbock formula, $\phi H \times \phi(P\ H) = \dfrac{2}{3}\left(0.605 + \dfrac{1}{320\ H - 3} + 0.08\ \dfrac{H}{P}\right)$. Evidently, the Bazin formula is the only one that is of the same form as Equation (6).

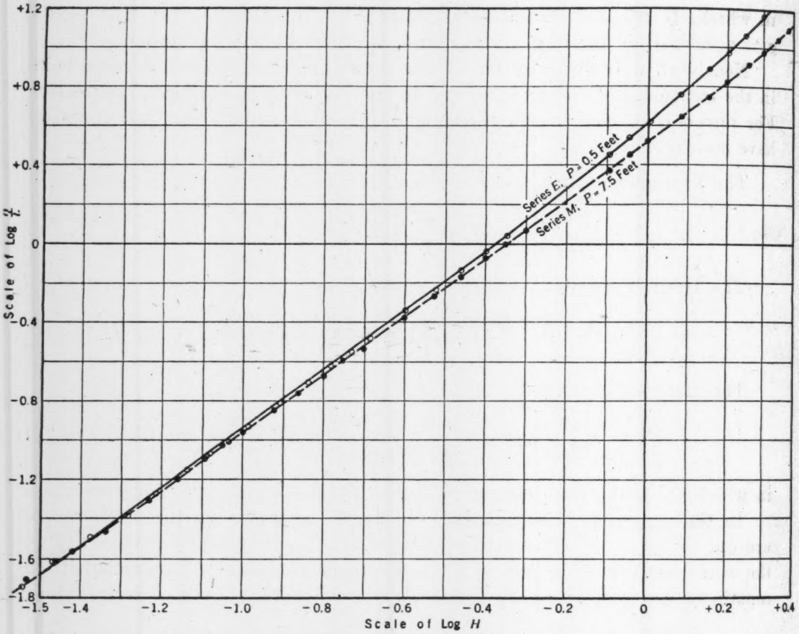

FIG. 1.—PLOTTING OF LOGARITHMIC VALUES OF $\frac{Q}{L}$ FROM SCHODER AND TURNER EXPERIMENTS, SERIES M AND E.

ALGEBRAIC FORMS OF ϕH AND $\phi(P\ H)$

The algebraic forms proposed in this paper for ϕH and $\phi(P\ H)$ are different from those used in the Bazin formula. They are entirely empirical, having been derived mainly by studying the results of the Schoder and Turner experiments, and without much dependence on purely theoretical considerations.

If a set of experiments were available with an infinite height of weir, P, so that the velocity of approach could be neglected ($\phi(P\ H) = 1$), the only unknown in Equation (6) would be the coefficient, ϕH, and for each observed value of H the corresponding value of ϕH could be computed. It should then be possible to determine an algebraic form with suitable numerical constants, such that the values of ϕH given by this formula would agree with those given by the experiments, within the limits of the experimental errors.

Similarly, by combining the results of such a set of experiments with others in which the value of P was not infinite, it would be possible to compute values of $\phi(P\ H)$ for various values of P and H; and thus determine an algebraic form for $\phi(P\ H)$ also.

A modification of this general method can be applied to the experiments of Table 1, by using a process of approximations that leads finally to reasonably accurate results. First, let it be assumed that part of the curvature of the graph of Series M in Fig. 1 is caused by $\phi H \times H^{\frac{3}{2}}$. The algebraic form selected for $\phi H \times H^{\frac{3}{2}}$ must then be such that log ϕH will give a curve when plotted against log H. If $\phi H \times H^{\frac{3}{2}}$ is to be of the form, $c\ H^x$, then, in order to produce the curvature, either c or x must change when H changes. As a first approximation, to be modified later if necessary, assume c constant for all values of H and write the exponent, x, in the form $n\ H^b$ ($= d$) so that it will change as H changes. Then, $\phi H \times H^{\frac{3}{2}}$ will be expressed as:

$$\phi H \times H^{\frac{3}{2}} = c\ H^d \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

in which, d ($= n\ H^b$) is a substitution factor introduced to simplify typography and c, n, and b are arbitrary constants (n being very nearly equal to $\frac{3}{2}$ and b very small).

Similarly, one set of approximate values of $\phi(P\ H)$ can be found by subtracting log $\frac{Q}{L}$ for Series M from log $\frac{Q}{L}$ for Series E. This can be done directly, since there are a number of experiments in which the value of H is approximately the same in both series. When these values of log $\phi(P\ H)$ are plotted against H, all the points fall close to a straight line through the origin. Evidently, log $\phi(P\ H)$ can be written in the form:

$$\log \phi(P\ H) = kH \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which, k is a constant when P is constant. The slope of the line gives an approximate value of k for Series E; and approximate values of k for the other series can be found in a similar manner.

Application of Method of Least Squares

The logarithmic equivalent of Equation (6) may now be written in the form:

$$\log \frac{Q}{L} = \log C + n H^b \log H + k H \ \ldots\ldots\ldots\ldots\ldots (9)$$

in which, $\log C = \log c \sqrt{2g}$ and $\log C$, n, b, and k are unknown constants, k having a different value for each different value of P. By adopting Equation (9) as a general equation for all the experiments listed in Table 1, and applying the method of least squares to the entire list, it was possible to secure additional information, as follows: (1) To determine more precise values of k for each value of P covered by the experiments, so that the relation between k and P may be expressed algebraically; (2) to determine more precise values of $\log C$, n, and b for use in a second solution; and (3) to show that this form of equation is adequate to represent the data of Table 1, by completing the solution, computing the residuals, and examining them.

In each solution by the method of least squares, the same general procedure was followed. The logarithmic form of equation was used so that each experiment would be of equal weight. Continuing the process of approximations, a differential formula was established (by partial differentiations of the original logarithmic formula), which showed the proportionate change in $\log Q$ (or in the logarithmic residuals), that would result from small changes in each of the constants. The residuals were found by substituting in the original logarithmic equation, assumed approximate values of the unknown constants. Each experiment in Table 1 furnished one residual, and each residual an observation equation, so that there were 335 observation equations in all. From these, the normal equations were formed and solved, and the most probable set of corrections was found. The application of these corrections to the approximate values assumed for the constants in the beginning, furnished the most probable values of the constants. In the final solution, the probable error of each constant in the formula was computed; the probable error of a single observation was also computed, or, more correctly, the probable difference between an observed and a computed discharge. As logarithmic equations were used, some of the probable errors are expressed as percentages.

The practical application of this process involved considerable work, especially in computing the residuals and in forming and solving the normal equations. The computations were arranged in tabular form and numerical checks were carried along with them. Adding and calculating machines, and tables of products, were used whenever possible.

This general method of utilizing the data of the experiments involves the assumption that all observations of head are exactly correct, and that any discrepancies that occur are due to errors in the discharge. This assumption, of course, is not strictly correct. A solution based on the assumption that errors of head and errors of discharge are equally probable, might be expected to give slightly different values for the constants, but it is doubtful whether such a refinement is warranted in this case.

In the first solution, the differential observation equation derived from Equation (9), was as follows:

$$d\,(\log C) + H^{(b_1)} \log H\, dn + 2.3026\, n_1\, H^{(b_1)}\, (\log H)^2\, db + H\, dk = r_1 \quad \ldots (10)$$

in which, $d\ (\log C)$, dn, db, and dk are the unknown corrections which, when applied to the approximate values used in Equation (11), will give the most probable values of the unknown constants. Common logarithms are used in Equation (10), as in all other formulas in this paper. The residuals, r_1, are found from the equation:

$$r_1 = \log \frac{Q}{L} - (\log C_1 + n_1 H^{(b1)} \log H + kH) \ldots\ldots\ldots (11)$$

in which, $\log \frac{Q}{L}$, and H are given by the experiment and $\log C_1$, n_1, $(b1)$, and k are the assumed approximate values of the unknown constants. For the first solution, $n_1 = 1.5$, $(b1) = 0.008$, and the values used for k were those found by the graphical method described in the preceding section. The corrected values obtained for $\log C$, n, and b were used in computing residuals for the second solution, the small size of these residuals showing the suitability of the algebraic form used. The corrected values of k, for the various values of P, are listed in Table 2, from which it may be noted that there is a definite relation between k and P, although a curve plotted from these data indicates certain minor inconsistencies.

TABLE 2.—VALUES OF k FOR DIFFERENT VALUES OF P

H.....	2.0	0.0245	....	....	....

FINAL ALGEBRAIC FORMS

In order to complete the weir formula, it is necessary to express, algebraically, the relation between the values of P and k in Table 2. For the smaller values of P, k decreases quickly as P increases, but, for the larger values, there is little change in k for relatively large changes in P. Furthermore, when the corresponding values of $\log k$ and $\log P$ are plotted, the resulting graph is not straight, but curved. From these considerations, and continuing the process of approximations by substituting trial values for certain of the constants and solving for the others, the following algebraic formula was finally adopted:

$$k = \log a + \frac{u}{1 + v\,P^{\frac{3}{2}}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

By choosing suitable numerical values for the constants, Equation (12) can be made to agree well, although not perfectly, with the values of k in Table 2. That is the only reason for selecting this particular algebraic form, and it is quite possible that some other form might be found that would be more suitable.

Being a constant, log a is independent of P and, therefore, belongs in ϕH rather than in $\phi(P\ H)$, so that the final algebraic forms of ϕH and $\phi(P\ H)$ (see Equations (7) and (8)) are as follows:

$$\phi H = \frac{c\, a^H\, H^a}{H^{\frac{3}{2}}} \qquad (13)$$

and $\phi(P\ H) = 10^{KH}$, or $\log \phi(P\ H) = KH$, in which,

$$K = k - \log a = \frac{u}{1 + v\, P^{\frac{3}{2}}} \qquad (14)$$

These algebraic forms give reasonably accurate results, but there is no absolute certainty that they make an exactly accurate division between ϕH and $\phi(P\ H)$.

Final Least Squares Adjustment

A final adjustment of the entire equation was made by a second least squares solution. For this, Equation (9) was re-written in the form:

$$\log \frac{Q}{L} = \log C + n H^b \log H + H \log a + \left(\frac{u}{1 + v\, P^{\frac{3}{2}}}\right) H \qquad (15)$$

and the corresponding differential and residual equations are, as follows:

$$d\ (\log C) + H^{(b2)} \log H\ dn + 2.3026\ n_2\ H^{(b2)}\ (\log H)^2\ db + H\ d\ (\log a) + \left(\frac{1}{1 + v\, P^{\frac{3}{2}}}\right) H\ du - \left\{\frac{u\, P^{\frac{3}{2}}}{(1 + v\, P^{\frac{3}{2}})^2}\right\} H\ dv = r_2 \qquad (16)$$

and,

$$r_2 = \log \frac{Q}{L} - (\log C_2 + n_2 H^{(b2)} \log H + H \log a + \frac{u\, H}{1 + v\, P^{\frac{3}{2}}}) \qquad (17)$$

in which, the values of log C_2, n_2, and $(b2)$ were given by the first solution and the values of log a, u, and v were those found by the trial method previously mentioned.

Numerical Values

The numerical values of the constants obtained in this final adjustment, together with their probable errors, are given in Table 3.

TABLE 3.—NUMERICAL CONSTANTS IN WEIR FORMULA

Symbol	Numerical value	Logarithmic value	Probable error	Symbol	Numerical value	Logarithmic value	Probable error
$C = c\ \sqrt{2\,g}$.	3.2765	0.5154	±0.03%	b....	0.0081	....	±0.00015
a......	1.0195	0.0084	±0.03%	u....	0.2713	....	±0.00014
n......	1.5064	....	±0.00027	v....	6.1452	....	±0.00012

The complete formula, with the numerical values of the constants, may now be written in the logarithmic and numerical forms, as follows:

$$\log \frac{Q}{L} = 0.5154 + 0.0084\ H + 1.5064\ H^{0.0081} \log H + K\, H \qquad (18)$$

or,

$$\frac{Q}{L} = 3.276 \times (1.0195)^{H} \times H^{f} \times 10^{KH} \ldots\ldots\ldots\ldots\ldots (19)$$

in which, to simplify typography, $f = 1.5064H^{0.0081}$, and,

$$K = \frac{0.2713}{1 + 6.1452\ P^{\frac{3}{2}}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (20$$

Furthermore,

$$\sqrt{2\,g}\ \phi\, H = \frac{3.276 \times (1.0195)^{H} \times H^{f}}{H^{\frac{3}{2}}} \ldots\ldots\ldots\ldots\ldots (21)$$

and,

$$\phi(P\ H) = 10^{KH} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Table 4 has been prepared to show, for various values of the argument, H, the corresponding numerical values of the variable exponent, $f = 1.5064\ H^{0.0081}$,

TABLE 4.—NUMERICAL VALUES OF VARIABLE EXPONENT AND COEFFICIENTS

Head, H, in feet (1)	Equation (19)		Equations (21) and (6)
	Exponent, $1.5064H^{0.0081}$ (2)	Coefficient, $3.276\ (1.0195)^{H}$ (3)	Coefficient, $\sqrt{2\,g}\ \phi H$ (4)

2.0	1.515	3.406	3.441
2.5	1.517	3.439	3.495
3.0	1.520	3.472	3.549

and the variable coefficient, $3.276\ (1.0195)^{H}$, in Equation (19). This table also gives the coefficient $\sqrt{2\,g}\ \phi H$ from Equation (21), for use with the fixed exponent, 1.5, in Equation (6). The value of the variable exponent (Table 4) is 1.5 at 0.6 ft, 0.022 less than 1.5 at 0.1 ft, and 0.020 greater than 1.5 at 3.0 ft; so that the greatest differences from 1.5 are less than ±1.5 per cent. However, this comparatively small change in the exponent makes a considerable difference in the corresponding coefficient, as can be seen by plotting Column (1), Table 4, against Column (4). The coefficient for use with the variable exponent (Column (3), Table 4) plots as a straight line, whereas the coefficient for use with the constant exponent, 1.5 (Column (4), Table 4), is a somewhat complicated curve, intersecting the straight line at the two points, $H = 1.0$ ft and $H = 0.6$ ft, practically a straight line above $H = 1.0$ ft, but with rapidly increasing curvature below $H = 0.6$ ft.

This peculiarity of the coefficient for use with the fixed exponent, 1.5, is one of the most serious difficulties in devising an accurate weir formula. It is neglected entirely in the Francis formula, probably because Francis did not make any experiments with heads less than 0.6 ft; but it is reproduced more or less accurately in the Bazin and Rehbock formulas by the introduction of a term containing H in the denominator.

The coefficient, $3.276\ (1.0195)^H$, varies as a straight line. When expanded by the binomial theorem, neglecting the third term and all subsequent terms, it becomes $3.276\ (1 + 0.0195H)$ which is the equation of a straight line. The value of the neglected third term is only 0.1% for $H = 3$ ft, and less for smaller values of H; so that for all practical purposes the two expressions are equal and may be used interchangeably in Equation (19). However, the original form is more convenient for use with logarithms.

ACCURACY OF NEW FORMULA

The probable difference between an observed and a computed weir discharge, as given by the final least squares solution, is ±0.65 per cent. If the weir experiments could be regarded as exact, this would be the probable error of a single value of discharge computed by the formula, and its smallness shows that Equation (19) agrees very closely with the measurements. If the formula is regarded as exact, ±0.65% is the probable error of a single weir experiment, which is an indication of a high order of consistency in the experiments.

The agreement of the new formula (Equation (19)), with the weir experiments is shown graphically in Fig. 2, for three values of P. Similar agreement was found for intermediate values. In order to condense the figures as much as possible, the discharge per foot of crest, $\frac{Q}{L}$, has been divided by $H^{\frac{3}{2}}$, and the quotient for each experiment, plotted against the corresponding value of H, is shown by the circles.

The full line curves in Fig 2 represent the corresponding values given by Equation (19). All these individual curves have been assembled in Fig. 3. They constitute a "family" of curves that change shape and inclination to the H-axis when the value of P is changed. Each individual curve, in addition to fitting its own points as closely as possible, must also maintain a symmetrical position in Fig. 3. There are certain minor inconsistencies among the experiments themselves that make it impossible for any such symmetrical family of curves to fit all the points perfectly; this may be due partly to certain features of the weir equipment, which are discussed in another section of this paper. On that account, although the present set of curves differs from the experiments by more than 1% in some cases, it is felt that the search for an accurate weir formula has been carried as far as these experiments warrant. The method of least squares, of course, has resulted in the selection of the best numerical values of the coefficients in the particular type of formula proposed and any improvement could be made

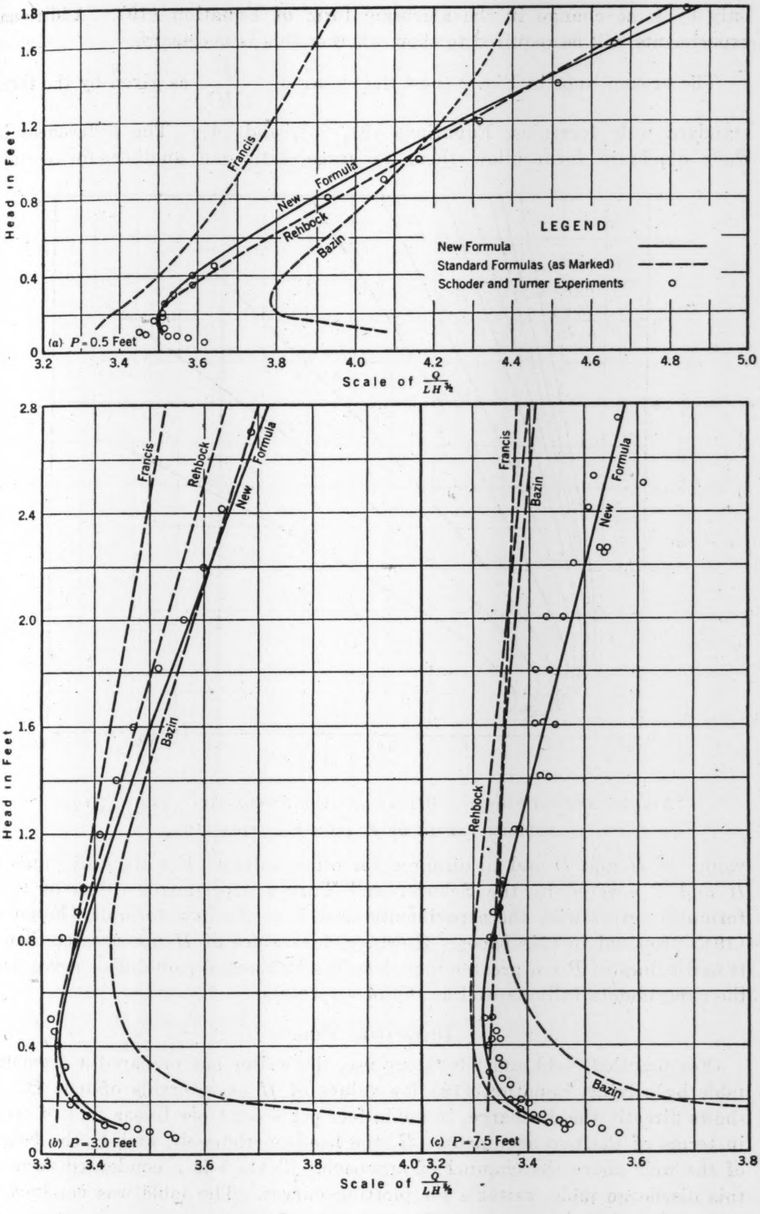

Fig. 2.—Plotted Values of $\frac{Q}{LH^{\frac{3}{2}}}$ from Schoder and Turner Experiments from Equation (19), and from Three Other Formulas.

only by some change in the algebraic form of Equation (19). Additional experiments will be required to show whether this is necessary.

The broken lines in Fig. 2 show the values of $\frac{Q}{L H^{\frac{3}{2}}}$ as given by the three standard weir formulas, Equations (2), (3), and (4). The differences in their algebraic form allow them to agree with one another for certain values of H and P and to disagree for other values. For the full range of H and P covered by the Schoder and Turner experiments, none of these formulas agrees with the experiments as well as the new formula (Equation (19)) proposed in this paper. However, for values of H not greater than 2 ft and values of P not greater than 4 ft, the Rehbock formula does agree with the experiments fully as well as the new formula.

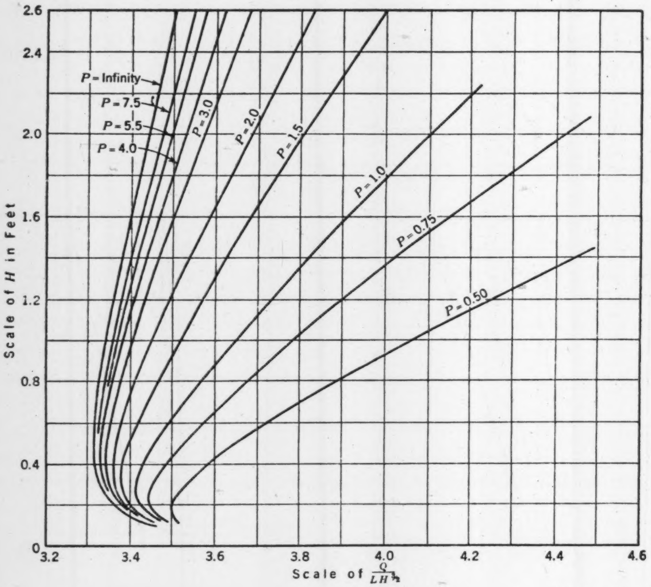

Fig. 3.—Curves Showing Relationship Between Head and $\frac{Q}{L H^{\frac{3}{2}}}$ for Various Values of P, from Equation (19).

Discharge Tables

For practical field and laboratory use, the writer has prepared a discharge table by solving Equation (18) for values of H at intervals of 0.01 ft. It shows directly the discharge, in cubic feet per second per linear foot of crest, in terms of the two arguments: H, the head on the weir, and P, the height of the weir above the channel of approach. Table 5 is a condensed form of this discharge table, suitable for plotting curves. The table was confined to the range of heads covered by the experiments, except that, for the higher weirs, it was extended to an even 3 ft, although the experiments go only to 2.7 ft. Column (11), Table 5, shows the discharge computed for a weir of infinite height; that is, with no velocity of approach.

TABLE 5.—DISCHARGE FOR SUPPRESSED WEIRS, IN CUBIC FEET PER SECOND PER FOOT OF CREST LENGTH

Table 6 is a selected list of K-values computed by Equation (20), for values of P from 0.5 to 8.0 ft. A complete table, for intervals of $P = 0.1$ ft, is necessary, but for purposes of demonstration the trends indicated by Table 6 must suffice. Tables such as Table 4 (Column (4)) and Table 6, may be used for computing discharges independently of Table 5 by means of the following formula:

$$\frac{Q}{L} = \sqrt{2\,g}\,\phi H \times H^{\frac{3}{2}} \times 10^{KH} \quad \ldots\ldots\ldots\ldots\ldots\ldots(23)$$

This method is useful for computing the discharge for low weirs with heights intermediate between those listed in the discharge table, in which simple interpolation between the columns will not give the correct discharge for high heads. Tables in metric units similar to Table 4 (Column (4)) and Table 6, in English units, are necessary in some computations and have been prepared by the writer.

WEIR DESIGN

Strictly speaking, the discharge tables offered for discussion in this paper should be used only with weirs constructed and arranged similarly to that on which the experiments were performed, a detailed description of which is given in the paper by Professors Schoder and Turner.[2] The weir plate was of rolled brass, 12 in. wide, with the top edge machine-beveled and with the up-stream face smooth. The head was measured, at a section 11.74 ft up stream from the crest, by direct measurement in the channel, with a steel tape and also by a gauge in a stilling-well. This distance of 11.74 ft is greater than the 6 ft used by Francis and less than the 16.4 ft used by Bazin.

Back-water must be avoided, of course; the jet must be fully aerated, and should not cling to the weir plate. At very low heads, a violation of this latter condition may introduce erratic results; on that account, the discharge table was not carried below 0.05 ft.

In the Schoder and Turner experiments, the water was supplied by a 30-in. pipe which emptied into the weir structure about 25 ft from the crest and only 5 ft below it. It is not the intention in this paper to suggest the duplication of this supply arrangement, which presumably was necessitated by local conditions, but rather to draw attention to the suggestions[5] of Professor Th. Rehbock that: (*a*) The approach channel should be of sufficient length and of the same width throughout; (*b*) the water should enter the approach channel axially; and (*c*) its free approach to the weir should not be disturbed by built-in structures. This provides a natural arrangement that can be duplicated readily.

The Schoder and Turner experiments, in which the approach conditions differed most from conditions suggested herein, namely, those in which special fences were used, were specifically excluded from consideration in this paper, but apparently some of the experiments that were used have been affected somewhat by other features of the special approach arrangements. Those with high heads and consequent high velocities of approach would be affected more than those with low heads and low velocities. If the experiments for high heads were omitted, the curves could be made to fit the remaining points better (see Fig. 2). Professor Rehbock's contention that the position of the supply pipe must have interfered with the free flow of water for weirs 5.5 and 7.5 ft high, may account for the fact that, for certain heads, the discharge is greater for the 7.5-ft weir than for the 4-ft weir.

---

[5] *Transactions*, Am. Soc. C. E., Vol. 93 (1929) p. 1143.

However, these inconsistencies are really of small magnitude (possibly of the order of ±1%), and their mention here should not detract seriously from the merit of the experiments; nor should they obscure the fact that the new formula agrees with the entire set of experiments with a probable error of only ±0.65 per cent.

Standard Discharge Tables

A standard set of discharge tables for suppressed weirs would be of great practical value. Having such tables, the practical man need not concern himself with the value of the discharge coefficient, the method of applying the velocity of approach correction, nor indeed with any particulars of the formula. The only question he need ask is whether the discharges given by the tables are accurate; the remainder he can leave to the computer who prepares the tables.

The discharge table, of which Table 5 is a sample, is submitted as a tentative discharge table for standard weirs with the approach conditions suggested by Professor Rehbock as stated previously, even if it is based on the Schoder and Turner experiments, which were made with somewhat different approach arrangements. It is probable that the table is not seriously in error from this cause, but it would be an advantage to have it extended to include higher heads; also, additional experiments would possibly allow a more precise determination of the formula. Accordingly, a program is suggested by means of which this tentative table might be extended and if necessary corrected, as follows: (1) Adopt a standard design of suppressed weir; (2) using weirs of this standard design, make a set of precise weir experiments, similar to those made by Professors Schoder and Turner; (3) select an algebraic form of equation that will be sufficiently flexible to agree with the results of the experiments over the entire range of all the variables introduced into the experiments; (4) use the method of least squares to determine the best values of the numerical constants in the formula; and (5) use the formula to compute a set of discharge tables covering the entire range of all the variables.

Changing to Metric Units

Discharges in metric units may be found from Table 5 by converting the head from meters to feet and the discharge from cubic feet per second to cubic meters per second, or liters per second. However, it would be more convenient to use a discharge table in metric units, and such a table can be computed by solving Equation (23), or its logarithmic equivalent, together with the values of $\sqrt{2\,g}\;\phi H$ and of K, which have been computed for the metric system and are on record in Engineering Societies Library as stated previously.

The discharge formula and the auxiliary terms, with the numerical values of the coefficients for the metric system, are given in the "Summary."

SUMMARY

The general type of discharge formula proposed in this paper for sharp-crested suppressed weirs (see Equation (6)) is as follows:

$$\frac{Q}{L} = \sqrt{2\,g}\,\phi H \times H^{\frac{3}{2}} \times \phi\,(P\,H) \quad\ldots\ldots\ldots\ldots\ldots\ldots(24)$$

in which (see Equation (13)), $\phi H = \dfrac{c \times a^H \times H^d}{H^{\frac{3}{2}}}$; $\phi\ (P\ H) = 10^{KH}$; and (see Equation (14)), $K = \dfrac{u}{1 + v\,P^{\frac{3}{2}}}$. Whence,

$$\frac{Q}{L} = C \times a^H \times H^d \times 10^{KH} \quad\ldots\ldots\ldots\ldots\ldots\ldots(25)$$

in which, $C = c\sqrt{2\,g}$.

Inserting the numerical values of the coefficients for the two systems of units, Equation (25) becomes in English units (feet and cubic feet per second):

$$\frac{Q}{L} = 3.276 \times (1.0195)^H \times H^f \times 10^{KH} \quad\ldots\ldots\ldots\ldots\ldots(26)$$

and (see Equations (18) and (19)),

$$\log\frac{Q}{L} = 0.5154 + 0.0084\,H + 1.5064\,H^{0.0081}\log H + K\,H \quad\ldots\ldots(27)$$

in which, $K = \dfrac{0.2713}{1 + 6.1452\,P^{\frac{3}{2}}}$; and $f = 1.5064\ H^{0.0081}$. Furthermore (see Equation (21)):

$$\sqrt{2\,g}\,\phi H = \frac{3.276 \times (1.0195)^H \times H^f}{H^{\frac{3}{2}}} \quad\ldots\ldots\ldots\ldots\ldots(28)$$

In metric units, Equation (25) becomes,

$$\frac{Q}{L} = 0.3044 \times (1.0654)^H \times (3.2808\,H)^i \times 10^{KH} \quad\ldots\ldots\ldots\ldots(29)$$

and,

$$\log\frac{Q}{L} = 1.4834 + 0.0275\,H + 1.5210\,H^{0.0081}(\log H + 0.5160) + K\,H\ldots(30)$$

in which, $K = \dfrac{0.890}{1 + 36.52\,P^{\frac{3}{2}}}$; and $i = 1.5210\ H^{0.0081}$. Furthermore,

$$\sqrt{2\,g}\,\phi H = \frac{0.3044 \times (1.0654)^H \times (3.2808\,H)^i}{H^{\frac{3}{2}}} \quad\ldots\ldots\ldots\ldots(31)$$

The complete discharge table at intervals of $H = 0.01$ ft is not published, a condensed form (Table 5) being considered adequate for purposes of discussion. It shows directly the discharge, in cubic feet per second per linear foot of crest, in terms of the two arguments, both expressed in feet, namely.

H, the head on the weir; and P, the height of the weir above the bottom of the channel of approach. A table compiled for intervals of $H = 0.01$ ft is probably sufficiently accurate for most practical purposes, but it has been shown how the results of future experiments may be used to make small corrections in the table, if necessary, and to extend it for higher heads.

Tabular values of $\sqrt{2g}\,\phi H$ and of K, are contained in Tables 4 and 6. Tables such as these, compiled for intervals of $H = 0.01$ ft and $P = 0.1$ ft, respectively, may be used in Equation (23) for computing discharges independently of the discharge table, or to supplement that table.

The adoption of a standard design for sharp-crested suppressed weirs and the preparation of an elaborate and accurate set of standard discharge tables, as advocated in this paper, should help to restore the lost prestige of the weir as an accurate device for measuring water.

DISCUSSION

JASPER O. DRAFFIN,[6] M. AM. SOC. C. E. (by letter).—The view is held by some hydraulic engineers that a weir is not an acceptable device for measuring the flow of water, partly because no formula has been found which will give with sufficient accuracy the discharge for all heads and weir heights. In this paper the author derives a formula which he claims is more exact and easier to use than other existing formulas and which agrees with experiments. This still leaves untouched the question of whether or not a given sharp-crested weir will continue to discharge at the same rate after it has been in use for several years.

The formula proposed by Mr. Cline is more complex than the Rehbock formula, or that proposed by Schoder, but it may be used with ease when tables or curves have been constructed, as they have been by the author.

The Bazin and Francis formulas do not give results which agree with the Schoder and Turner experiments, except for limited ranges of head and weir height, but the results given by the Rehbock formula agree very closely with the measured quantities for heads not in excess of 2 ft and for weir heights of not more than 4 ft. Beyond these values the Rehbock formula is but little better than either the Francis or the Bazin formula and none of them agrees with the Schoder and Turner experiments. Rehbock accounts for this lack of agreement by claiming that "the data for the 5.5 and 7.5-ft weir [Series D, K, L, M, and O, Table 1] are obviously unreliable."[7] He attributes the lack of reliability to the approach channel conditions, measurement of head, and the possibility of insufficient aeration of the jet, and shows that the data are not consistent among themselves. Schoder, however, points out that the jet was fully aerated. Rehbock also states that "sharp-crested weirs more than 4 ft in height are almost never used in practice."[7]

The Cline formula gives results which are decidedly better than any of the other formulas when the whole range of heads and weir heights is considered. Even if the Schoder and Turner data for high heads and weir heights are somewhat erratic, the Cline formula gives a good average of the measured quantities. The fact that Equation (23) agrees so closely with the experimental quantities at the lower heads and weir heights, as well as at the higher ones, indicates that the form of the equation is correct. Of course, the weak point in it is the fact that the constants were derived to fit data which seem somewhat erratic and which might be different under different experimental conditions. However, the author does not propose the formula as a final one, but as one which may be modified as further experiments are made, and he has made clear the method which should be followed in making a revision. A series of experiments should be carefully planned and performed in which the approach channel, aeration of jet, and measurement of head will all be of an accepted standard condition. Then, if the Cline formula does not exactly fit the new data, the constants in it may be modified in the manner which he suggests.

[7] "Precise Weir Measurements," *Transactions*, Am. Soc. C. E. Vol. 93 (1929), p. 1155.

Certainly, the author deserves much credit for his splendid approach to the problem and for the large amount of work which he has done in deriving the formula which he proposes, and in computing the tables.

W. BRUCE MCMILLAN,[8] M. AM. SOC. C. E. (by letter).—This paper again brings forth the important subject of measurement of water by weirs. The sharp-crested suppressed weir is the type that may be most readily standardized for more precise measurements. If the conditions under which the experiments are made, are duplicated, or made standard, the formulas that represent these experiments accurately may be said to be precise, as limited by the accuracy of observation.

The writer has derived a tentative formula by curve-fitting to substantially the same experiments (Series D to P) as those upon which the paper is based[9] and has arrived at a form similar in general to the Rehbock formula. This same general form may be reduced from the author's formula. Equation (19) may be expressed as follows,

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.276\ \frac{H'}{H^{\frac{3}{2}}}\ [1.0195\ (10)^{K}]^{H}\ \ldots\ldots\ldots\ldots\ldots (32)$$

The first bracket may be represented by:

$$\frac{H'}{H^{\frac{3}{2}}} = 0.9812 + \frac{0.0067}{H} + 0.01209 \cdot H$$

and the second bracket by:

$$[1.0195\ (10)^{K}]^{H} = \left[\,1.017 + \frac{0.095}{P^{1.25}}\,\right]^{H}$$

Substituting in Equation (32) and expanding $(1.017)^{H}$ by the binomial theorem:

$$\frac{Q}{L\,H^{\frac{3}{2}}} = \left(3.212 + \frac{0.02405}{H} + 0.0949\ H\right)\left(1 + \frac{0.0934}{P^{1.25}}\right)^{H} \ldots\ldots (33)$$

Expanding by the binomial theorem again and casting out the smaller terms:

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.212 + \frac{0.02405}{H} + \left(0.0949 + \frac{0.30}{P^{1.25}}\right) H \ldots\ldots\ldots (34)$$

Equation (34) is shown to complete the conversion, but it is not accurate. The studies leading to the writer's tentative formula,

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.22 + \frac{0.021}{H} + \left(0.105 + \frac{0.31}{P^{1.33}}\right) H$$

were refined and were adjusted somewhat in deference to the author's determination by least squares, but with deliberate deviation in the case of the highest and lowest weirs for better accord with the experimental data (see Fig. 4). The writer's revised formula is:

---

[8] Cons. Engr., Palo Alto, Calif.

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.222 + \frac{0.0222}{H} + \left(0.081 + \frac{0.340}{P^{1.25}}\right) H \qquad (35)$$

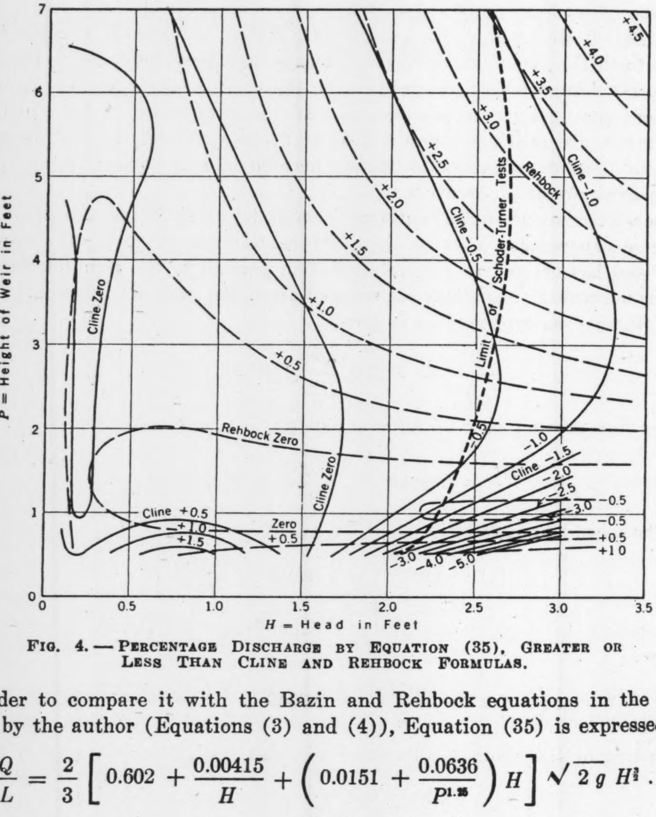

FIG. 4.—PERCENTAGE DISCHARGE BY EQUATION (35), GREATER OR LESS THAN CLINE AND REHBOCK FORMULAS.

In order to compare it with the Bazin and Rehbock equations in the form given by the author (Equations (3) and (4)), Equation (35) is expressed as:

$$\frac{Q}{L} = \frac{2}{3}\left[0.602 + \frac{0.00415}{H} + \left(0.0151 + \frac{0.0636}{P^{1.25}}\right) H\right]\sqrt{2\,g}\;H^{\frac{3}{2}} \qquad (36)$$

Equation (33) gives values of $\frac{Q}{L\,H^{\frac{3}{2}}}$ almost identical with those by the author's formula. Equation (35) is preferred for greater simplicity in computation as well as being in a more nearly rational form. Fig. 4 shows the percentage deviation of Equation (35) greater or less than by the author's and the Rehbock formulas. Fig. 5 shows a comparison of the same formulas for weirs 0.50 and 7.50 ft high, for extremely low heads. A curve is also shown for Equation (35) with an additional factor, $\left[1 - \frac{(1.122)^{\frac{1}{H}}}{200}\right]$, as a multiplier to the second term, $\frac{0.0222}{H}$. This factor forms an end point to the curves, where the nappe adheres, and follows the experimental data better for heads less than 0.06 ft; but aside from this it is a matter of interest rather than utility. The conformity of the curves of Fig. 5 is shown by comparison with the curves published by Schoder and Turner, showing measured discharge.[9]

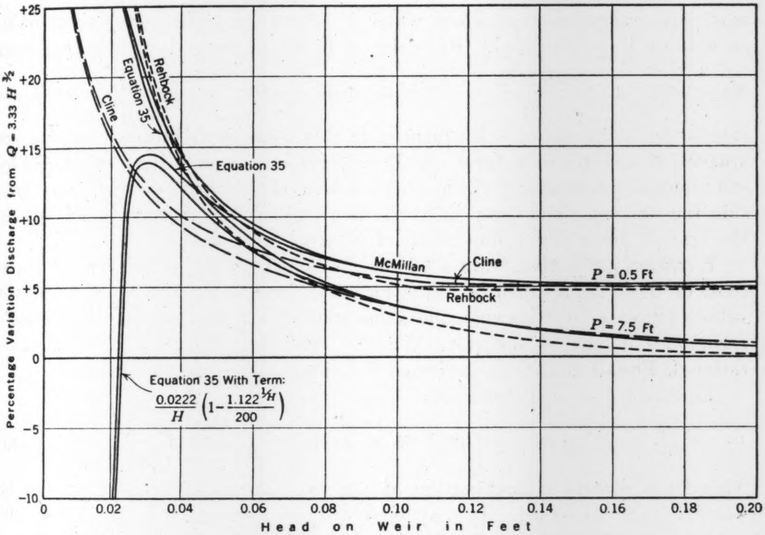

FIG. 5.—COMPARISON OF EQUATION (35) WITH CLINE AND REHBOCK FORMULAS FOR EXTREMELY LOW HEADS.

The generalized Francis formula,

$$\frac{Q}{L} = \frac{2}{3}\ C \left[\left(1 + \frac{\alpha\, h}{H} \right)^{\frac{3}{2}} - \frac{(\alpha\, h)^{\frac{3}{2}}}{H} \right] \sqrt{.\, 2\, g}\ H^{\frac{3}{2}} \ \ldots\ldots\ldots (37)$$

is the fundamental form from which most, if not all, weir formulas are derived and may be shown to be the genesis of Equation (35). Eliminating the second term within the bracket, Equation (37) may be expressed in very general terms,

$$\frac{Q}{L} = \frac{2}{3}\ C \left[1 + f\,(H,\, P) \right]^{\frac{3}{2}} \sqrt{2\, g}\ H^{\frac{3}{2}} + A + B \ \ldots\ldots\ldots (38)$$

By a process of curve-fitting and solving for the constants, together with consideration of the studies leading to the original formula and Equation (35), the following is obtained:

$$\frac{Q}{L} = \frac{2}{3}\ (0.602) \left(1 + \frac{0.0683\ H}{P^{1.20}} \right)^{\frac{3}{2}} \sqrt{2\, g}\ H^{\frac{3}{2}} + 0.081\ H^{\frac{5}{2}} + 0.0222\ H^{\frac{1}{2}}$$

---

[9] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), Fig. 11, p. 1029.

or,

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.222\left(1 + \frac{0.0683\ H}{P^{1.20}}\right)^{\frac{3}{2}} + 0.081\ H + \frac{0.0222}{H} \quad \ldots\ldots(39)$$

Through expansion of Equation (39) by the binomial theorem the form of Equation (35) is obtained. The second or third terms, or both, might be included in the bracket to the $\frac{3}{2}$ power, and the inclusion of these terms was tried with resulting expressions which followed the experimental data quite as well as Equation (39). Professor Rehbock suggests including the term corresponding to $\frac{0.0222}{H}$, ascribing this factor to be attributable to capillarity.[10] As shown subsequently, if this term is maintained outside the bracket, it appears in a form which suggests a crest condition controlled by sub-atmospheric pressure. It is probable that this term is more rational outside the bracket. The term, 0.081 H, is also probably more rational outside the bracket since it is independent of velocity of approach.

Equation (39) gives values of the coefficient within a fraction of a per cent. of those determined by Equation (35), except for low weirs where the values increase in somewhat the same manner as do those of the author's formula, but not to the same degree. Although Equation (39) is more rational, Equation (35) is preferred for simplicity of computation.

Equation (35) may be expressed as:

$$\frac{Q}{L} = 3.222\ H^{\frac{3}{2}} + 0.0222\ H^{\frac{1}{2}} + 0.081\ H^{\frac{5}{2}} + 0.340\left(\frac{H}{\sqrt{P}}\right)^{\frac{5}{2}} \quad \ldots.(40)$$

This form reveals a combination of simple elements of flow which may be dissected and analyzed. It may be noted, in passing, that Equation (40) lends itself to facility in computation through the use of commonly published tables of squares and the $\frac{3}{2}$ and $\frac{5}{2}$ powers of numbers. The first term, $q_1 = 3.222\ H^{\frac{3}{2}}$, is the theoretical or ideal discharge over a weir of unit width in the familiar form of the Francis formula without velocity of approach, and is the principal term.

The second term, $q_2 = 0.0222\ H^{\frac{1}{2}}$, is the theoretical discharge through an orifice under a head, H, and may be expressed as $q_2 = 0.00277\sqrt{2\,g\,H}$, which represents the discharge of an orifice, or a 0.00277-ft, or $\frac{1}{32}$-in., slit of unit width, without contraction or friction. This term accounts for an increasing value of the coefficient for heads decreasing from 0.20 ft (see Fig. 5). The term is apparently most affected by the top thickness and by the sharpness of the crest and, no doubt, to some extent by the condition of roughness of the up-stream face of the weir close to the crest. This is indicated by tests of Walker and Weidner[11] and may be explained by the condition of sub-atmospheric pressure between the top of the crest and the nappe, induced by the velocity of the water at this point, and a function of $H^{\frac{1}{2}}$. This reduced pressure and consequent orifice action becomes increasingly effective with an increase in thickness of the top of the crest.

---

[10] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), Equations (15) to (18), pp. 1148–1149.

[11] *Loc. cit.*, p. 1046, Fig. 26.

The third term, $q_3 = 0.081\ H$, represents the theoretical discharge without contraction or friction over a triangular weir of constant $\frac{b}{H}$ per unit width, in which, $\frac{b}{H} = 0.0379$ in the familiar formula, $q_3 = \frac{4}{15}\sqrt{2\,g}\left(\frac{b}{H}\right)H^{\frac{5}{2}}$.

The fourth term is the theoretical discharge without contraction or friction over a triangular weir, in which, $\frac{b}{H} = \frac{0.159}{P^{1.25}}$, in the formula, $q_4 = \frac{4}{15}\sqrt{2\,g}\left(\frac{b}{H}\right)H^{\frac{5}{2}}$, and accounts for what is ordinarily referred to as velocity of approach.

These elements of the formula may be represented graphically (Fig. 6), to show a hypothetical distribution of velocity in the nappe. These are not necessarily the actual velocities, but the assumption that they do occur provides an insight to the mechanics of flow over sharp-crested weirs. The third and fourth terms representing discharge over triangular weirs are shown on Fig. 6 to be equivalent increased velocities as measured by the virtual triangular area, to give the same discharge. The parabola, OAX.

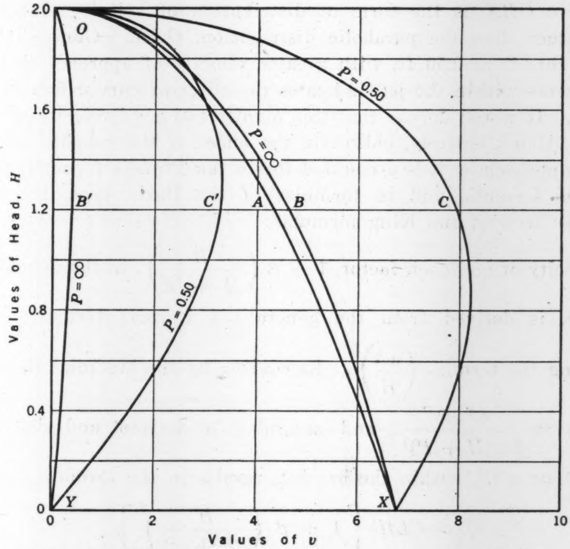

FIG. 6.—HYPOTHETICAL DISTRIBUTION OF VELOCITY IN NAPPE, EQUATION (40).

represents the velocity at any point at which, $v = 0.602\sqrt{2gy}$, and the area, *OAXY*, represents the discharge, $q = 3.222\ H^{\frac{3}{2}}$. The curve, *OB′Y*, is the hypothetical increased velocity due to the third term, $0.081\ H_2$, and *OBX* is the distribution of velocity due to this term and likewise the distribution of velocity when the height of the weir is great, at what is usually referred to as "zero velocity of approach". The curve, *OC′Y*, is the increased velocity due to the fourth term, $0.340\left(\frac{H}{\sqrt{P}}\right)^{\frac{5}{2}}$, and *OCX* is the distribution of velocity due to the third and fourth terms, in which, $P = 0.50$ ft, the curves being based on $H = 2.0$ ft. The area, *OCXY*, represents the discharge according to Equation (40) or Equation (35), neglecting the term, $\frac{0.0222}{H}$, which is nominal for a head of 2 ft. The velocity distribution is hypothetical, but the form is suggestive of the forces that act within the jet. Curve *OBX* for a weir of great or infinite height suggests the effect of the factor of curved flow, or the inertia of the stream filaments in curved flow, with special reference to the upward direction of the contraction filaments at the crest. Curve *OBX* is the form of distribution of velocity that would be expected rather than the parabolic distribution, *OAX*. Curve *OCX* for a weir of height, $P = 0.50$ ft, with greater velocity of approach and velocity of the filaments within the jet, indicates the effect of curved flow to be more pronounced. It would appear that this manifestation of velocity of approach does partly, if not entirely, obliterate the effect of the velocity head in the velocity of approach as it is accounted for in the Francis formula, the Fteley and Stearns formula, and in formulas of the Bazin type, including the Frese, Swiss Society, and King formulas.

The velocity of approach factor, $1 + \beta\left(\frac{H}{H + P}\right)^2$, in the formulas of the Bazin type, is derived from the generalized Francis formula (Equation 37), omitting the term, $-\left(\frac{\alpha h}{H}\right)^{\frac{3}{2}}$. Expanding by the binomial theorem, substituting $h = \frac{C^2 H^2}{2g(H + P)^2}$, and assigning a derived and definite value to α and C, or $\alpha\ C^2$, within the bracket, results in the formula,

$$Q = CLH^{\frac{3}{2}}\left[1 + \beta\left(\frac{H}{H + P}\right)^2\right]$$

in which, $C = \left(3.248 + \frac{0.079}{H}\right)$ in the Bazin formula and in various forms for others of the same type. As a matter of fact both α and C vary as a function of H and P and the writer's attempt to formulate these values, based on the Schoder and Turner measurements, has led to Equation (39).

Casting out a small term involving an error of less than 1%, the Bazin formula may be expressed as:

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.248 + \frac{0.079}{H} + H\left[\frac{1.786\,H}{(H + P)^2}\right] \ldots\ldots\ldots\ldots (41)$$

If the envelope of the factor, $y = \dfrac{1.786\,H}{(H + P)^2}$, is substituted in its place, the modified formula will read:

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.248 + \frac{0.079}{H} + \frac{0.447\,H}{P} \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

The similarity to the Rehbock formula and Equation (35) is apparent. By introducing the factor, $\dfrac{4\,H\,P}{(H + P)^2}$, the Bazin formula is expressed in a different form:

$$\frac{Q}{L\,H^{\frac{3}{2}}} = 3.248 + 0.079 + 0.447\,\frac{H}{P}\left[\frac{4\,H\,P}{(H + P)^2}\right] \ldots\ldots\ldots (43)$$

When $\dfrac{H}{P}$ is unity in Equation (43), the factor within the bracket becomes unity and Equation (43) is identical with Equation (42). Furthermore, when $H = P$ the factor, $\dfrac{4\,H\,P}{(H + P)^2}$, is a maximum, which accounts for the point of inflection of the Bazin curve and others of the same type (see Fig. 2, for $P = 0.50$ ft). This is also the point of common tangency of the curves for Equations (41) and (42). Due to the fact that formulas of the Bazin type show this inflection while the experimental data show, if anything, a continued curvature or increase of coefficient with head (accounted for in the author's formula and to a lesser degree in Equation (39)), it would appear that formulas of the Bazin type, involving the velocity of approach factor, $\left[1 + \beta\left(\dfrac{H}{H + P}\right)^2\right]$, are incorrect.

It has been advocated many times, and again by the author, that a standard design of suppressed weir be adopted. This is important with reference to the control of the distribution of velocity in a short channel and particular study should be given to the design of a simple means of inducing water in a natural way to a short approach channel if it is not possible to obtain an approach of a length sufficient to insure axial undisturbed flow. A standard distance of point of observation of head becomes increasingly important in the case of high ratio of head over height of weir, due to the water surface draw-down of what approaches the hydraulic drop at the end of a horizontal flume. A standard crest of specific top thickness can readily be duplicated, but there should be no question as to the sufficiency of ventilation beneath the nappe.

The writer has presented several formulas and suggested variations, resulting from three separate studies in derivation. They all reduce most naturally to the general form of Equation (35). This formula, as well as the author's formula and tables, may be applied with confidence for general use. If a high degree of accuracy is required the crest must be truly sharp and $\frac{3}{32}$ in. thick at the top[12] and the approach channel and means of induction of water should conform to that used by Schoder and Turner. However, the importance of the duplication of approach conditions may be overstressed, due to the fact that the water in a normal unobstructed channel tends to adjust itself to a natural regimen on approaching the jet. Inspection of Fig. 4 shows the close conformation of Equation (35) to the Rehbock formula for low weirs. The Rehbock formula is based on careful and comprehensive experiments on weirs from 0.41 ft to 1.64 ft high under comparatively low heads, up to 1.362 ft. Reference to Fig. 2 for $P = 0.5$ ft, shows the Rehbock formula meeting the experimental data as well as, if not better than, the author's formula.

The Schoder and Turner experiments and the formulas based thereon show greater discharge for high weirs (low velocity of approach) than any of the recognized formulas. These older equations have been extrapolated for use not supported by tests. It would appear that it has been the prevailing supposition that high weirs under little or no velocity of approach, under substantial heads, discharge according to parabolic distribution of velocity in the jet—that is, simply at the $\frac{3}{2}$ power of the head. It is indicated herein that the distribution of velocity is reasonably not parabolic and that, due to the action of centrifugal forces in curved flow, the weir discharges an extra quantity above that accounted for by parabolic distribution, determined here to be measured by the term, $q = 0.081\ H^{\frac{5}{2}}$. The possible eccentric approach conditions which may have existed in the run of the Schoder and Turner experiments would be less effective for high weirs with concomitant lower velocity of approach than for low weirs under the same head, and it is reasonable to suppose that the experiments for high weirs are inherently the more accurate. These experiments, complete and comprehensive in range, must be presumed to be correct, at least until they are proved otherwise. The explanation of failure to conform to the recognized formulas is reasonable, and the formulas presented herein are properly substantiated for high as well as for low weirs.

C. G. CLINE,[13] ESQ. (by letter).—As pointed out by Mr. McMillan, the results of the Schoder and Turner experiments must be presumed to be correct until they are proved otherwise. The fact that they do not agree with many of the standard formulas must be taken as an indication that the formulas are at fault.

Professor Draffin discusses a number of formulas and shows how they compare with the Schoder and Turner experiments. Messrs. McMillan and Draffin both agree with the writer that a standard design of suppressed weir should be adopted, a set of carefully planned experiments should be made, and a standard discharge formula and tables computed to agree with the results of the experiments. The computations can be made by using the method of least squares to determine the best numerical values of the coefficients in the algebraic formula selected. This general procedure can be followed without necessarily retaining the particular type of formula used by the writer as an illustration. Mr. McMillan has shown that there need be no scarcity of algebraic formulas; his Equation (35) is relatively simple and yet seems to be sufficiently flexible to cover the entire range of head and height of weir.

In the meantime, as Mr. McMillan states, either his Equation (35), or the writer's Equation (18) and the tables that have been computed from it, may be applied with confidence for general use.

LABORATORY TESTS OF MULTIPLE-SPAN REINFORCED CONCRETE ARCH BRIDGES

BY WILBUR M. WILSON,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. C. B. McCULLOUGH, CARROLL L. MANN, JR., M. HIRSCHTHAL, AND WILBUR M. WILSON.

SYNOPSIS

The multiple-span arch bridge differs from a single-span arch in that, for the latter, the ends are fixed, whereas, for the former, the fixed points of the structure are the outer ends of the two end spans and the bases of the intermediate piers. As a live load crosses a multiple-span arch bridge the uneven loading of the two spans adjacent to a pier produces a horizontal thrust and moment at the top of the pier which move the top even if the pier bases and abutments are fixed. This movement of the pier top produces reactions at the end of the span differing materially from those that would be produced by a fixed abutment supporting a similar single-span arch carrying the same load.

The structures tested in this investigation include: (1) A three-span structure consisting of a rib without deck; (2) two three-span structures each consisting of a rib, spandrel columns, and deck, the deck being a considerable distance above the rib of the crown; and (3) two three-span structures consisting of a rib, spandrel columns, and deck, the deck being so low as to be integral with the rib at the crown. Of the two structures constituting each of the latter two groups, one had expansion joints in the deck over the piers only, and the other had expansion joints over the piers and at intermediate joints near the one-third point of each span. These structures were tested at pier heights of 20 ft, 15 ft, and 10 ft, except the structures having a low deck, which were tested at a pier height of 20 ft only.

NOTE.—Presented at the Joint Meeting of the Structural Division, Am. Soc. C. E., and the Applied Mechanics Division, Am. Soc. M. E., Chicago, Ill., June 29, 1933. Published in April, 1934, *Proceedings*.

INTRODUCTION

Object and Scope of Investigation.—The objects of the tests of the three-span structure consisting of a rib without deck were to determine its load-carrying capacity and to compare the values of reactions and strains measured in the laboratory with values of the corresponding quantities obtained by the elastic theory. There are a number of reasons why this comparison is desirable.

The elastic theory is complicated when applied to a multiple-span arch series on high elastic piers, taking into account the deformation of the piers. Comparatively few engineers have acquired the mastery of this analysis that justifies them in using it with the complete confidence they should have in designing large important structures. It is believed that an experimental verification of this theory will be welcomed by engineers who are called upon to use it.

Tests of a multiple-span arch series having a rib without deck are also desirable to determine whether or not errors in the assumptions upon which the analysis is based, cause errors in the results. Engineers who have mastered the analysis have the same confidence in it that they have in that of simpler structures. In other words, they are confident that the results will be correct if the assumptions upon which the analysis is based are correct; but the assumptions upon which the analysis of an arch is based, are known to be in error. Tests of single-span arches with fixed ends[2] indicate that the errors in the assumptions upon which the analysis of single-span arches is based, do not seriously affect the results. It was hoped that, as a result of these tests, a similar statement could be made relative to multiple-span structures.

The structures consisting of a rib, spandrel columns, and a deck are not readily susceptible of algebraic analysis. An experimental study is especially desirable for these structures since many of this type have been built. In the investigation of these structures, the following information was determined: (1) The elastic constants for a single span; (2) the influence ordinates for fixed-end reactions for a single span; (3) the influence ordinates for reactions at the springing of all spans of the three-span structures; (4) the magnitude and position of the thrust due to the design load; (5) the effect of intermediate expansion joints in the deck upon the load-carrying capacity of the three-span structure; and (6) the maximum carrying capacity of the three-span structure.

Stresses were computed from influence ordinates, determined experimentally, and the maximum stress produced by a given live load was compared for the different structures, all having identical ribs but varying in pier height and type of deck. As a result of the investigation a combined experimental and algebraic method of analyzing multiple-span arch bridges with decks is proposed, which, it is believed, will be useful in designing structures of this type.

DESCRIPTION OF SPECIMENS AND APPARATUS

Specimens.—The three-span structure consisting of a rib, spandrel columns, and a high deck, is shown in Fig. 1. The details of the ribs and piers (which were alike for all specimens) and the spandrel columns, and deck, are shown in Figs. 2 to 5, inclusive. Fig. 2(*a*) shows the specimens having a high deck and Fig. 2(*g*) those having a low deck. The concrete was designed to have a strength of 2 200 lb per sq in. at 28 days. A 1 : 3 : 3 mix having a 1.2 water-cement ratio (by volume) was used, the quantities for a batch being determined by weight. The sand passed a $\frac{1}{4}$-in. sieve and the gravel a 1-in. sieve. The proportions and the materials were the same for the concrete for all structures, except for the piers of the low-deck bridge. The concrete in these piers contained more water than was used in the other structures. The cylinders and arches were stripped when 10 days old, and the cylinders were stored in the laboratory near the arch so as to be subject to the same atmospheric conditions. The strength of the control cylinders at the time of the final test was 3 310 lb per sq in., for the structure without deck, and 3 412 lb per sq in., for the one with a high deck. The moduli of elasticity for the two structures were 3 293 500 lb per sq in. and 3 145 000 lb per sq in., respectively. For the structure with a low deck the concrete in the arches had an ultimate strength of 4 281 lb per sq in., and a modulus of elasticity of 4 243 000 lb per sq in. The corresponding values for the concrete that went into the piers were 2 871 lb per sq in. and 3 501 000 lb per sq in.

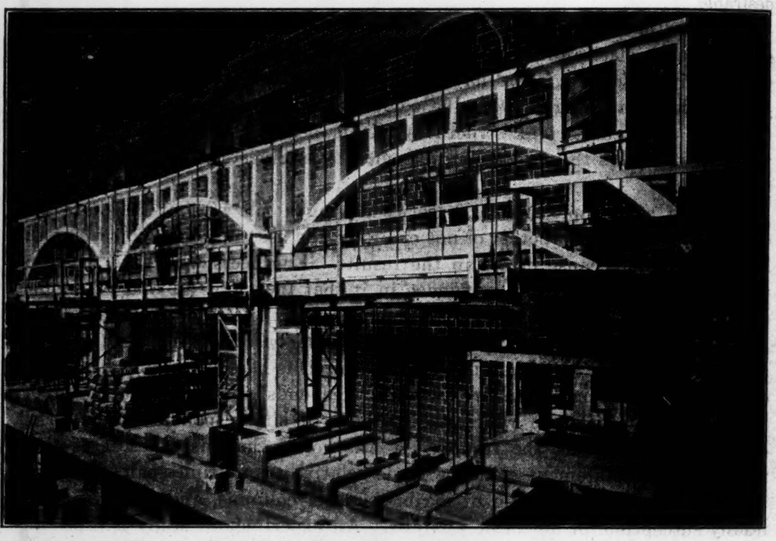

FIG. 1.—THE THREE-SPAN STRUCTURE, WITH A HIGH DECK.

The specimen is not a model, to a definite scale, of a larger structure; but the proportions were based on the design of an arch with a span 135 ft long.

five times the length of the spans tested. Likewise, the selection of the live load to be used in testing the arch was based on the live load that would be used in designing a 135-ft highway bridge with two ribs and two lanes of traffic. The weight of the specimen was not great enough to produce a dead-load stress commensurate with the dead-load stresses encountered in the design of a full-sized bridge. A load, designated as the design dead load, was selected, arbitrarily, therefore, distributed so as to have a thrust line within the kern of the rib, and of a magnitude such that the maximum dead-load stress would be of the order of the dead-load stresses existing in actual bridges. The design live load consisted of a distributed load of 960 lb per panel, with a single concentration of 1 800 lb superimposed upon the distributed load. The live load, as usual, was distributed for maximum stress at the section being studied in each instance. The design dead load and live load for maximum stress at Section C_4 for the rib without deck, are shown in Fig. 3. The live load shown is designated as "one L. L."; "two L. L.'s" and "three L. L.'s" are groups of loads two and three times, respectively, the group designated as "one L. L.", in Fig. 3.

FIG. 3.—POSITION OF MEASURED REACTIONS, THREE-SPAN RIB WITHOUT DECK.

Apparatus.—The apparatus was built especially for this investigation and it was designed to perform certain specific functions. For example, the support for each terminal, abutment, or pier base, had to be capable of holding the terminal or of returning it to its normal position, and of giving the terminal each of the three component movements, x, y, and θ, in any predetermined amount. Instruments were provided for measuring each of these component movements.

The supports for the abutments and pier bases are shown in Fig. 4 and Fig. 5, respectively. Each abutment was supported on two vertical scales, as shown. The load was transmitted from the abutment to the scales by jacks, two for each scale—one on the north, and the other on the south, side of the abutment. The contact with the jacks is through knife-edges embedded in the abutment so that the line of action of the vertical forces weighed by each scale is accurately known. An abutment can be raised or lowered without rotation by extending or depressing all jacks the same amount; or it can be

rotated about a horizontal north-and-south axis by extending both the east jacks and depressing both the west jacks, or the reverse. The vertical scales were mounted on carefully machined steel rollers, 10 in. in diameter, that ran upon a carefully machined track so that the vertical scales offered practically no resistance to horizontal motion.

The horizontal reaction of each abutment was measured by means of a scale, as shown in Fig. 4. This scale consists of two right-angle levers (bell cranks), one on the north, and the other on the south, side of the abutment, that received the horizontal thrust through links and converted it into a vertical force which was delivered to a platform scale. The link connecting an abutment and horizontal scale had knife-edge contacts at both ends, and was maintained in a horizontal position, and the line of action of the horizontal thrust was determined from the position of the knife-edge embedded in the abutment. An abutment could be moved horizontally by turning the link, since the latter had a right-hand thread at one end and a left-hand thread at the other.

The vertical reactions of the pier bases were measured with apparatus similar to that used for the abutments. The horizontal reaction of each pier base was measured with two horizontal scales, one on the north, and the other on the south, side of the structure, shown in Fig. 5.

The relative vertical movement of the piers and abutments was measured with a hydrostatic gauge. This consists of four hook-gauges, one attached to the structure at the top of each pier and one attached to each abutment, connected by a pipe line so that the water level was the same for all gauges at any instant. The vertical movement of the load points on the arch rib was measured relative to two *J*-and-*L* pony **I**-beams, one on each side of the rib, continuous from end to end of the structure. A ½-in. vertical rod embedded in the concrete and projecting below the rib on its center line, was provided directly below each load point. The distance from the lower end of the rod to the **I**-beams was measured with an Ames dial mounted on a steel rod. The **I**-beams, from which the deflections were measured, were also used in measuring the horizontal movement of the west abutment and of the tops of both piers, relative to the east abutment. These beams were attached to a 1-in. pin that extended through the rib at the east springing of the east span in such a way as to cause the beams to move horizontally with the east abutment. The beams were supported at the pier tops and at the west abutment on rollers that enable the pier tops and west abutment to move horizontally relative to the beams. Ames dials attached to the beams, with their plungers bearing on pins through the ribs at the springings, indicated horizontal movement of the west abutment and of the tops of the piers, relative to the east abutment.

The horizontal movement of the pier bases relative to the east abutment, was measured by means of the frame shown in Fig. 6. The member, *A B C D*, consists of the **I**-beams from which vertical deflections were measured. The frame, *B C F E*, was suspended from these beams. The main members of the frame were 12-in. junior **I**-beams. Ames dials attached to the lower corners of this frame had plungers bearing upon the pins, *E* and *F*, which projected from the sides of the piers. The pins, E and F, were 20 ft below the springing of the arches; Pins E' and F' and Pins E'' and F'' were 15 ft and 10 ft, respectively, below the springing. The horizontal movement was measured at Pins E and F, E' and F', and from Pins E'' and F'', when testing the structure at pier heights of 20 ft, 15 ft, and 10 ft, respectively. In tests requiring one pier to be raised, shims were inserted at that pier between the beam, $A\ B\ C\ D$, and its support. When the pier was raised, the shims were removed so that Points B and C on the beam remained at the same level; the sides of the suspended frame remained in a vertical position; and the corners, E and F, did not move horizontally because of the vertical movement of the piers.

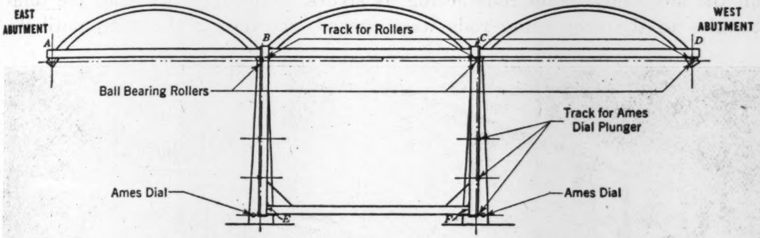

FIG. 6.—FRAME FOR MEASURING HORIZONTAL MOVEMENT OF PIER BASES RELATIVE TO ABUTMENTS, THREE-SPAN SERIES.

The angular position of the abutments and pier bases was determined with level bubbles attached to the structure at the points where the rotation was to be measured. The bubbles at the abutments were carried on steel bars embedded in the concrete and projecting from the rib at its center line and normal to the axis of the rib at the springing. The bubbles for the piers were carried on horizontal bars embedded in the concrete, one at the top and one each at distances below the top of 20 ft, 15 ft, and 10 ft. The former was used to determine the rotation of the top of the pier and the latter, to determine the rotation of the base when testing the structure at various pier heights.

In tests for which the abutments and the bases of the piers were fixed, the bubbles were adjusted so as to be in their mid-position before the test began and, after the load was changed, the abutments and pier bases were rotated until the bubbles returned to their central position. In tests for which a predetermined angular movement was to be produced, the bubble was adjusted to its mid-position before the test began and then the piers and abutments were rotated by manipulating the jacks supporting them until the bubble was off center by an amount which, as shown by a previous calibration, corresponds to the desired rotation.

The strain in the concrete was measured with an 8-in. Berry strain-gauge. Readings were taken on two gauge lines on the intrados and two on the extrados at the section midway between each pair of adjacent load points. Strains were measured for the design load tests and for the tests to determine the load-carrying capacity of the structure.

The load on the structure was produced by suspending concrete blocks of known weight at the load points. For each load point there was one large concrete block suspended by four steel rods, as shown in Fig. 7, which served as a loading platform on which to place smaller blocks which, in combination with the loading platform, constitute the total load to be applied at a particular point. When the arch was unloaded, the loading platform rested on the concrete girders of a trestle provided for the purpose and the loading beam, which extended across the top of the arch above the loading shelf, was carried on the steel suspension rods acting as struts. To apply the load, the turnbuckles in the suspension rods were turned, shortening the rods, until the loading beam came into contact with the loading shelf. The turnbuckles were then turned, successively, by small amounts, in order, back and forth from one end of the structure to the other, thereby transferring the weight of the loading platforms gradually from the girders to the arch. Each loading shelf on the arch was capped with a steel plate containing a $\frac{3}{4}$-in. steel ball located in its top surface and at the point of application of the load. The loading beam had a small steel block attached at the center of the bottom flange. A small depression in the bottom of this block fitted over the top of the ball in the steel plate on the loading shelf, thus locating, accurately, the point of application of the load.

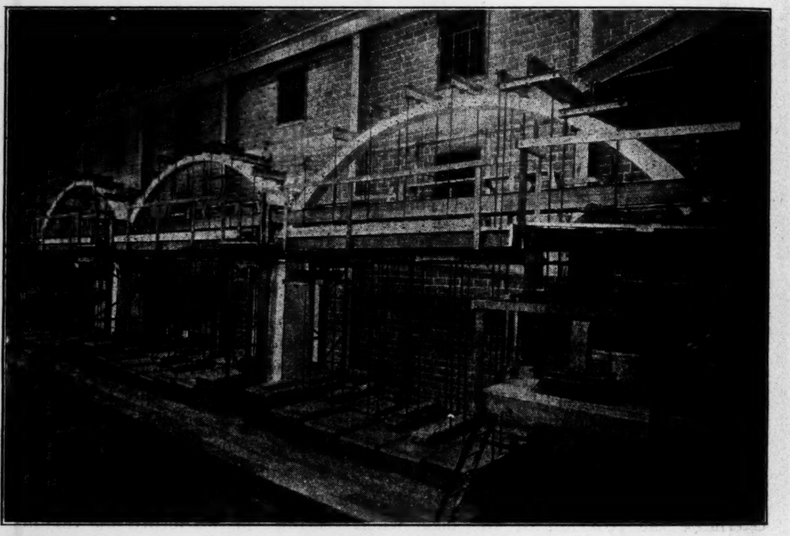

FIG. 7.—THREE-SPAN STRUCTURE CONSISTING OF A RIB WITHOUT DECK WITH APPARATUS ATTACHED READY FOR TESTING.

The load at a given load point, for a particular test, was obtained by placing concrete blocks of known weight on the loading platform until the desired load had been obtained.

DESCRIPTION OF TESTS

Influence Ordinates by Unit Loads.—The direct objective of many of the tests was to determine the influence ordinates for the reactions at the springings of the various spans since, with these influence ordinates known, each span is statically determinate under any system of loads.

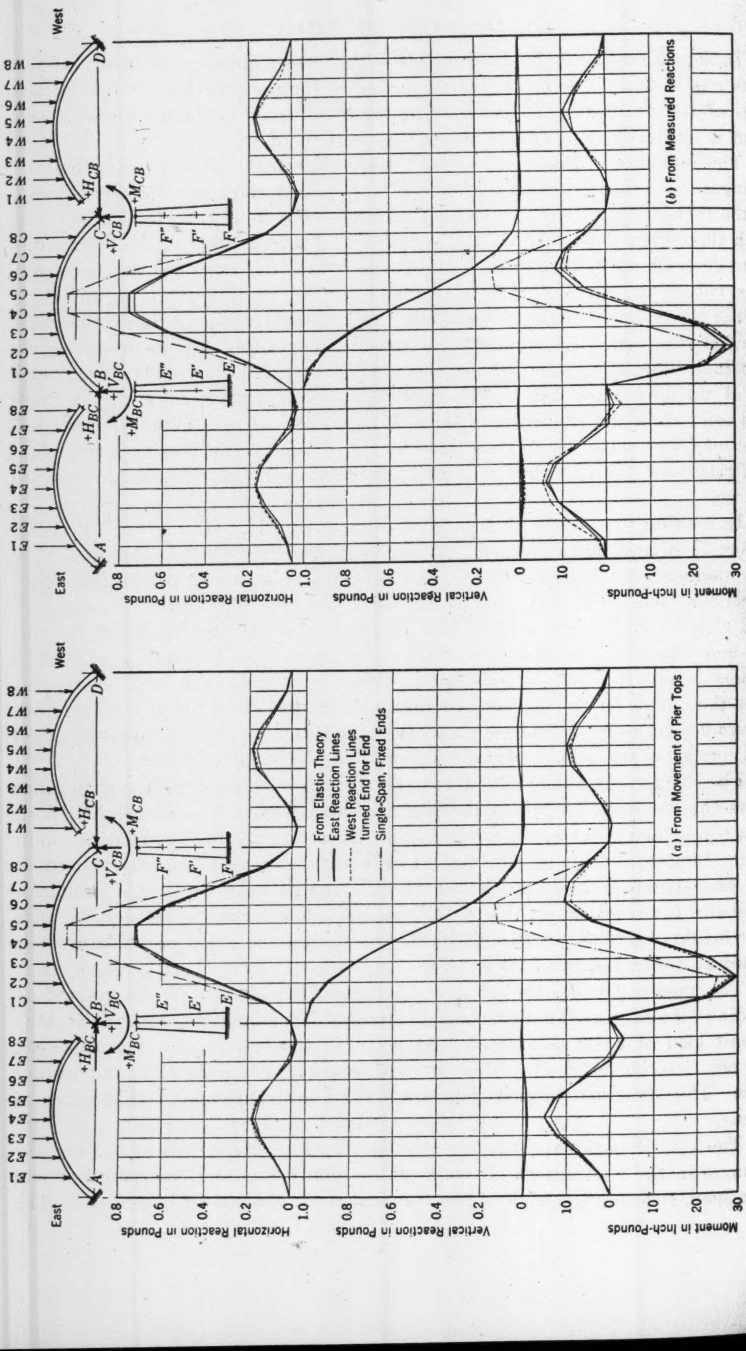
The influence ordinates were determined experimentally by measuring the changes that occurred when a unit load was applied and removed, successively, at the various load points. The unit load was 2 000 lb and the tests were made with the design dead load on the structure. The reactions at the springings were determined in two ways: (1) By weighing the reactions at the terminals, before and after the application and removal of the unit load, and computing the moment and the horizontal and vertical components of the reactions at the springings from the changes in the readings of the scales at the terminals; and (2) by measuring the components of the movement (x, y, and θ) of the pier tops, due to the application and removal of the unit load, and computing the moment and the horizontal and vertical components of the reactions corresponding to these movements. This presupposes that the fixed-end reactions due to a unit load and the elastic constants for the arches are known.

In making these tests all terminals were returned to their normal position before readings were taken so that the only changes would be those due to the application and removal of the load. Three sets of observations were made for each load point: Before the load was applied, after it was applied, and after it had been removed; that is, the changes in reactions, due to adding and removing the load, were determined separately. The average of the two results is reported in each instance. Tests were made for each load point over the entire length of the structure. Since the structure is symmetrical, values determined for load points on the east half were checked against values for corresponding points on the west half of the same structure.

The effective height of the pier is the vertical distance from the springings of the arches to the point on the pier that was returned to its original position before and after each load change. By attaching the instruments indicating the position of the pier base at different distances below the springings, the one structure could be tested at different pier heights. The influence ordinates for reactions at the springings were determined for structures with pier heights of 20 ft, 15 ft, and 10 ft, except that the low-deck structure was tested at a pier height of 20 ft only.

The fixed-end reactions for each of the two end spans were determined by reading all scales at the abutments before and after applying (and removing) a unit load of 2 000 lb at each load point in the end spans. For this test, the points to be returned to their normal position are the abutments and pier tops. The structure carried the design dead load throughout this series of tests.

The elastic constants for the end spans were determined by noting the changes in the readings of all scales at the abutments due to giving one end of a span, successively, each of the component movements (x, y, and θ). The



(a) From Movement of Pier Tops

(b) From Measured Reactions

FIG. 8.—INFLUENCE LINES BY UNIT LOADS; REACTIONS, TOPS OF 20-FOOT CENTER-SPAN PIERS.

design dead load was on the structure during this test, and one end of the span being tested was fixed and the other end restrained so as to have only the one component of movement being studied.

The elastic constants and the fixed-end reactions, determined in the manner just described, were used to compute the reactions at the springings from the movement of the pier tops accompanying the application and removal of a unit load.

The influence lines for the reactions at the springings of the center span for a three-span structure, consisting of a rib without deck and having 20-ft piers, determined from the movement of the pier tops, are shown in Fig. 8(*a*). The difference between the influence lines for the middle span of a three-span series and for a single span with fixed ends, is worthy of note. The influence lines of Fig 8(*b*) are for the same functions and for the same structure as those in Fig 8(*a*) but the lines derived by experiment were determined from the measured reactions at the terminals instead of from the movement of the pier tops. The light full lines representing the computed values are the same for the two diagrams.

Diagrams similar to those shown in Fig. 8(*a*) and Fig. 8(*b*) were also constructed for the abutment, and for the pier reactions of the end spans. They were constructed for the structure having a rib without deck when tested, and analyzed with pier heights of 20 ft, 15 ft, and 10 ft. The same diagrams, except those based on the algebraic analysis, were constructed for the high-deck bridges both with and without intermediate expansion joints, and they were also constructed for the low-deck type but, for the latter, the diagrams were drawn for the structures having 20-ft piers only. Lack of space has excluded most of these diagrams from this paper, but the results of the tests they represent have influenced the conclusions in the "Summary of Results."

Algebraic Analysis Based on Elastic Constants Determined Experimentally.—The analysis of the three-span arch series involves the use of elastic constants for the pier and arch span. These constants can be determined algebraically for structures consisting of a rib without deck; but the corresponding constants for the arch span cannot readily be determined algebraically for a structure with spandrel columns and a deck. However, Donald E. Larsen, Jun. Am. Soc. C. E., under the supervision of the writer, has developed[8] a method for analyzing these structures by using experimentally determined elastic constants for the arch spans in the otherwise algebraic method. The small circles of Figs. 9 and 10, represent the influence ordinates obtained by this combination experimental and algebraic method.

It is believed that the algebraic analysis of a multiple-span structure in which experimentally determined elastic constants are used, gives accurate results. The fact should be borne in mind, however, that the results obtained by the algebraic method are based on the fixed-end reactions for a single span, and an error in these will introduce an error in the results of the analysis of the three-span structure.

(*a*) Without Intermediate Expansion Joints

(*b*) With Intermediate Expansion Joints

FIG. 9.—INFLUENCE LINES, HIGH-DECK SPANS, BY UNIT LOADS; REACTIONS, TOPS OF 20-FOOT CENTER-SPAN PIERS.

Capacity Tests.—Tests were made (at only one pier height, 20 ft) to determine the load-carrying capacity of all structures. For the structure consisting of a rib without deck, the capacity test was begun with no load on the structure, except its own weight. Readings were then taken from which to determine the reactions at the terminals, the vertical movement of points on the arch rib directly beneath the load points, and the strain in the concrete of the rib at sections midway between the load points. The first load increment was the design dead load. This was followed by increments of one live load until four live loads had been applied.

The structure consisting of ribs, spandrel columns, and a high deck, was first tested with no intermediate expansion joints in the deck, the method of testing being similar to that used in the test of the structure having a rib without deck. The structure was first loaded for maximum stress at Section *B* of Span *BC*. Five live loads were applied, and then the test was discontinued. The same structure was then tested in a similar manner, but the load was distributed to produce a maximum moment about the arch axis on a section through the load point, C_4. This test was also discontinued after five live loads had been applied. Intermediate expansion joints were then cut through the deck at the sections indicated in Fig. 2(*a*), and the resulting structure was subjected to a capacity test, the live load being distributed to produce a maximum stress in the rib at the section through the load point, C_3. The structure with a low deck was tested in the same manner as the one with a high deck.

Movement at Expansion Joints Due to a Change in Span.—The need of expansion joints in the deck of an arch bridge depends upon the movement that would take place if such joints were provided. Tests were made on the structures having a deck with intermediate expansion joints to determine the relation between a change in span and the corresponding opening and closing of the expansion joints.

For this test the structure carried the design dead load, and the initial readings were taken after the east and west abutments had each been moved inward 0.075 in., thereby making the total length of the structure 0.15 in. less than normal. Ames dials attached to the deck indicated the change in width of the expansion joints. After the initial readings had been recorded, the abutments were moved out 0.30 in., thereby increasing each span 0.10 in. The tops of the piers were brought to the same vertical and angular position as for the initial readings; and the Ames dials indicating the changes in span at the tops of the piers and the movement at the expansion joints, were read, thereby giving the change in span of each arch and the movement at each expansion joint due to the increase in span. The abutments were then returned to their initial position, and the readings were again recorded after the pier tops had been adjusted for vertical and angular position.

The ratio of the movement at an intermediate expansion joint to the change in span was 0.25 for the structure with a high deck and 0.11 for the structure with a low deck. For both structures the joint closed as the span increased.

(b) With Intermediate Expansion Joints

FIG. 10.—INFLUENCE LINES, LOW-DECK SPANS, BY UNIT LOADS; REACTIONS, TOPS OF 20-FOOT CENTER-SPAN PIERS.

DISCUSSION OF RESULTS

Effect of Deck on Fixed-End Reactions.—The experimentally determined influence lines for fixed-end reactions of a rib without deck and an arch having a high deck, both with and without intermediate expansion joints, are compared in Fig. 11(*a*). A similar comparison for a rib without deck and an arch with a low deck is made in Fig. 11(*b*). The curves show that the values of the horizontal thrust for the four structures having a deck are nearly alike and that they are much less than the value for the rib without a deck. The vertical reactions for the structures having a deck, with expansion joints, are about the same as for a rib without deck, and both differ materially from the reactions for a structure having a deck, without expansion joints. The fixed-end moment is much less for the structure having a deck, without expansion joints, than it is for a rib without deck; and the fixed-end moment for the structure having a deck with expansion joints lies between the values of the same function for the other two structures. The fixed-end moment

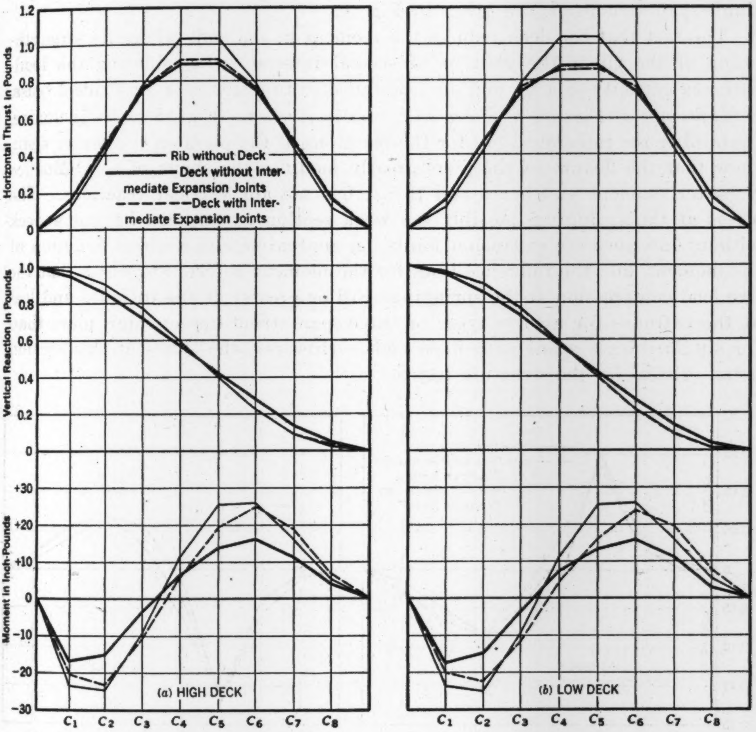

FIG. 11.—INFLUENCE LINES FOR FIXED-END REACTIONS; VARIOUS TYPES OF STRUCTURES.

is about the same for a structure having a high deck, without expansion joints, as it is for one having a low deck, without expansion joints.

The stress at the springing of a single span is governed almost entirely by the fixed-end moment. It is, therefore, much less for the structure having a deck without expansion joints than it is for the other two structures. For the single span having expansion joints in the deck, the weak section is at Section C_3. The influence lines for stress at this section for various types of single-span structures, are given in Fig. 12.

The fact that the deck reduces the moment at the ends where its strengthening of the rib is the least, is of special interest in considering the load-carrying capacity of a rib and deck designed to function as a Vierendeel truss.

Influence of Flexure of Piers on Stress in Arches.—Figs. 8 to 10, inclusive, containing the influence lines for the reactions of the piers on the center span, show that the flexure of the piers greatly modifies the shape of the influence lines for moment and horizontal thrust but not for vertical reactions. The stress at the springing, possibly the weak section of an arch having a deck without intermediate expansion joints, is, approximately, a direct function of the moment, and the influence lines for the moment referred to, show that the live load compression at the springings will be greater at the intrados and less at the extrados for all five types of three-span structures on high piers than for similar single spans with fixed ends. However, the stress at this section is not critical for the structure tested.

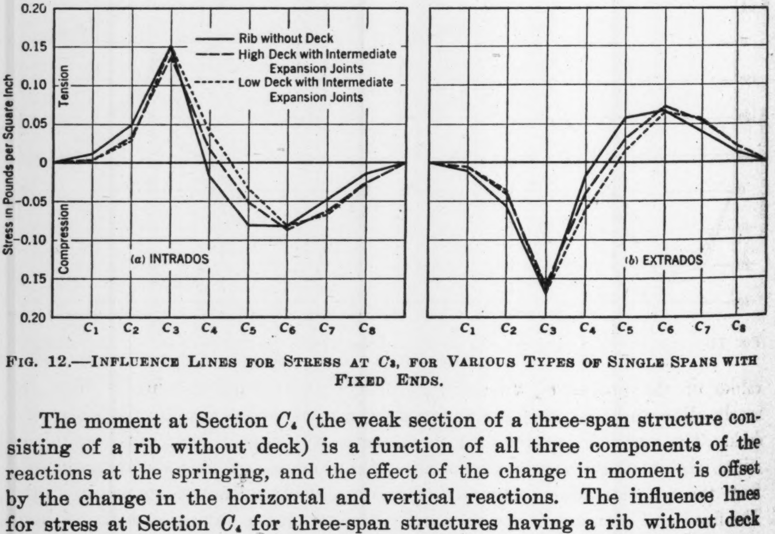

Fig. 12.—Influence Lines for Stress at C_3, for Various Types of Single Spans with Fixed Ends.

The moment at Section C_4 (the weak section of a three-span structure consisting of a rib without deck) is a function of all three components of the reactions at the springing, and the effect of the change in moment is offset by the change in the horizontal and vertical reactions. The influence lines for stress at Section C_4 for three-span structures having a rib without deck and having pier heights of 20 ft, 15 ft, 10 ft, and 0 ft (single span with fixed ends) are given in Fig. 13. These diagrams show that, even if the flexure of the pier greatly affects the reactions at the springings, the effect of the pier height on the stress at Section C_4 is much less. The stress at Point C_4 due to the design live load is 36% greater for a three-span structure having 20-ft piers than it is at Section C_3 for a single span with fixed ends. The stress at the same point due to the total design load, dead load plus live load, is 13% greater for a three-span structure having 20-ft piers than the maximum stress in a single span with fixed ends. All the values used in this comparison were determined by the elastic theory and are based on a value of E for the concrete of 3 333 000 lb per sq in. It was assumed, furthermore, that concrete takes tension and that the abutments and the bases of piers are fixed.

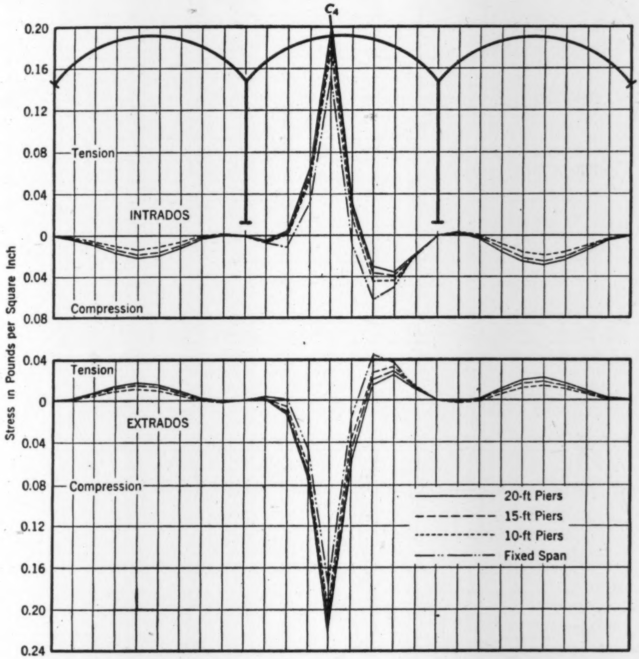

FIG. 13.—INFLUENCE DIAGRAM FOR STRESS AT LOAD POINT C_4.

The moment at Section C_3, the weak section of a structure having a deck with intermediate expansion joints, is a function of all three components of the reaction at the springing. The influence lines for stress at Section C_3 for a three-span structure having a high deck with intermediate expansion joints and pier heights of 20 ft, 15 ft, 10 ft, and 0 ft (single span with fixed ends), are given in Fig. 14(a). These influence lines were determined from an algebraic analysis based on experimentally determined elastic constants. The stress due to the design live load is somewhat greater (145 lb per

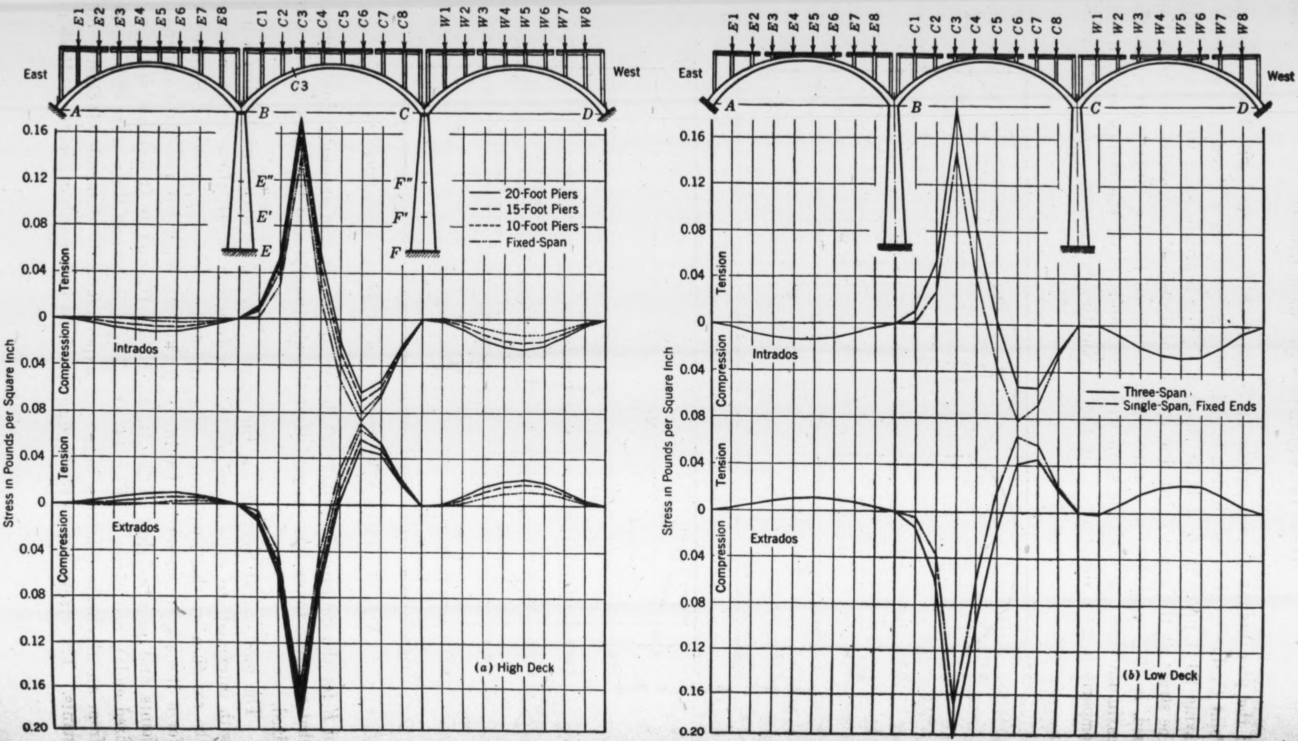

FIG. 14.—INFLUENCE LINES FOR STRESS AT C_6, WITH INTERMEDIATE EXPANSION JOINTS (FROM ALGEBRAIC ANALYSIS).

sq in.) for the structure with a high deck having 20-ft piers than for a similar single-span structure with fixed ends. This increase is 28% of the stress due to live load and 14% of the stress due to dead load plus live load in a single span with fixed ends.

The influence lines for stress at Section C_8 for a three-span structure having a low deck with intermediate expansion joints and pier heights of 20 ft and 0 ft (single span with fixed ends), are given in Fig. 14(*b*). The stress due to the design live load is 173 lb per sq in. greater for the three-span structure having 20-ft piers than for a similar single span with fixed ends. This is 31% of the stress due to the live load and 16% of the stress due to the live load plus dead load.

For a composite structure consisting of a rib and deck without intermediate expansion joints, the moment over the central portion of the span is greater than for a single span with fixed ends; but the composite structure consisting of the rib and deck has a much greater moment-resisting capacity than a rib without deck and the presence of a large moment over the central portion of the span is more than offset by the strengthening effect of the deck.

Effect of Variations in the Modulus of Elasticity of the Concrete on Stress in the Rib.—In the study made to determine the effect of a variation in the modulus of elasticity of the concrete on the stress in a three-span arch series having decks, the influence lines for stress were determined for two structures which had the same dimensions, but which were assumed to have been made of material having different physical properties. For the first structure, the elastic constants were the same for all spans, but for the second structure, while the elastic constants for the center span were the same as for the first structure, those for the end spans were only two-thirds as great. This comparison was made for structures having a high deck with and without intermediate expansion joints, the pier height being 20 ft in both instances. The assumed variations in the physical properties did not greatly change the influence ordinates and it is believed that any probable variation in the modulus of elasticity of the concrete will not seriously affect the live load stresses. However, because of the peculiar action of a multiple-span arch on high piers, the effect of variations in the properties of the material on the dead load stresses is not easily determined.

For the three-span structure consisting of a rib without deck, the weak section is at Section C_4. For a homogeneous symmetrical structure, the dead load stress should have the same value at Sections E_4, E_5, C_4, C_5, W_4, and W_5. The most dependable experimental method of obtaining the dead load stress is to determine the magnitude of the thrust from the measured reactions and the position of the thrust from the measured strain at the intrados and extrados. The consistent relation between the pressure centers located from the measured strain and the thrust line located by the elastic theory, shown in Fig. 15, appears to justify the conclusion that the dead load stresses in this structure did not differ greatly from those in a similar single-span arch subjected to the same dead load.

FIG. 15.—THRUST LINES; TEST TO FAILURE (20-FOOT PIERS).

For the structures having a deck without intermediate expansion joints the critical stress is at the intrados of Section *B* of Span *BC*. The dead load stress should be the same at the springings of all spans. The stresses at these sections, determined from the measured thrust the line of action of which was located from the measured strain, are given in Table 1. The maximum and average values for the structure having a high deck are – 338 lb per sq in. and – 232 lb per sq in., respectively, and the maximum and average values for the structure having a low deck are – 198 lb per sq in. and – 155 lb per sq in.

TABLE 1.—DEAD-LOAD STRESSES DETERMINED FROM THE THRUST. THREE-SPAN STRUCTURE HAVING A DECK WITHOUT INTERMEDIATE EXPANSION JOINTS

	STRESS AT INTRADOS AT SECTION:						
	A of Span *AB*	*B* of Span *AB*	*B* of Span *BC*	*C* of Span *BC*	*C* of Span *CD*	*D* of Span *CD*	Average
High deck.....	—287	—267	—176	—110	—215	—338	—232
Low deck......	—181	—198	—137	—122	—137	—154	—155

For the structures having a deck with intermediate expansion joints the critical stress is at the extrados of Section C_3. The thrust line and centers of pressure for these structures are shown in Fig. 16. The dead load stresses at the sections corresponding to Section C_3, determined from the measured thrust the line of action of which was located by the measured strain, are given in Table 2. The maximum and average values for the structure having a high deck are – 782 lb per sq in. and – 647 lb per sq in., respectively, and the corresponding values for a structure having a low deck are – 755 lb per sq in. and – 646 lb per sq in., respectively.

TABLE 2.—DEAD-LOAD STRESSES DETERMINED FROM THE THRUST. THREE-SPAN STRUCTURE HAVING A DECK WITH INTERMEDIATE EXPANSION JOINTS

	STRESS AT EXTRADOS AT SECTION:						
	E_3	E_6	C_3	C_6	W_3	W_6	Average
High deck.....	—711	—437	—782	—606	—638	—707	—647
Low deck......	—560	—755	—610	—685	—626	—637	—646

The data given in the preceding paragraphs have value only as interesting information pertaining to a limited number of individual structures and cannot be made the basis of any general conclusions relative to the effect of variations in the material on the dead load stresses in a multiple-span arch bridge. They do indicate, however, the possibility of the random occurrence of a dead load stress at some section 100 to 150 lb per sq in. greater than the dead load stress at the corresponding section in a similar single-span arch subjected to the same load; but it is not clear that this excess in the dead load stress is due to variations in the properties of the concrete. An extended study of this subject is suggested. The structures used in this study should consist of a rib without deck so as to be readily susceptible of algebraic analysis.

and the modulus of elasticity of the concrete should be assigned different values in various parts of the structure. Algebraic analyses of these structures should establish the probable effect of the variations in modulus of

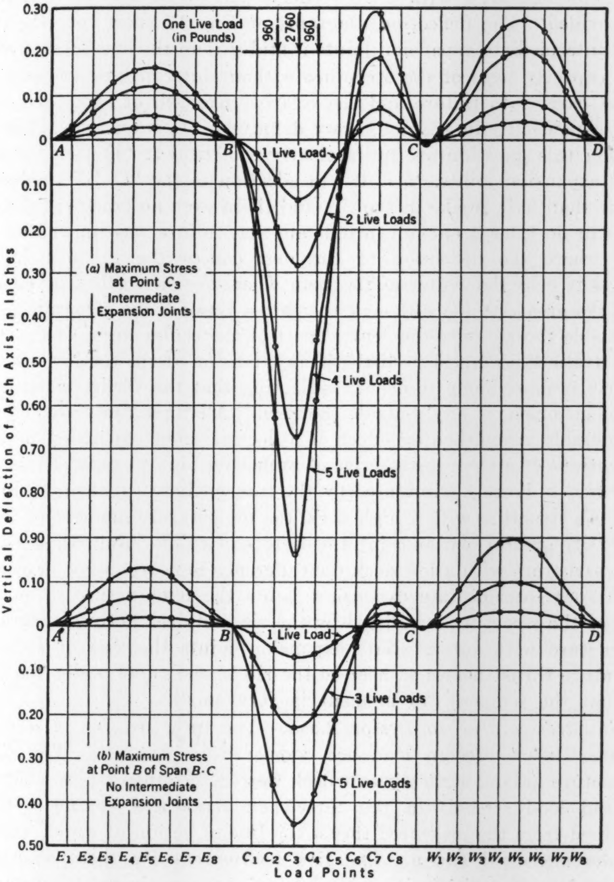

FIG. 17.—VERTICAL DEFLECTION OF ARCH AXIS; CAPACITY TEST FOR MAXIMUM STRESS.

elasticity of the concrete on the dead-load stresses in a multiple-span arch series.

Effect of Intermediate Expansion Joints.—The desirability of using intermediate expansion joints in the deck of an arch depends on whether movement will take place if they are provided and also on the effect they will have on the strength of the structure. The tests indicate that the ratio of movement at an expansion joint to the change in span is 0.25 and 0.11 for the high-deck and the low-deck structures, respectively. If expansion joints are not provided the restraint of the deck will produce a deflection of the spandrel columns commensurate with the movement that would take place if the joints were provided. The deflection diagrams of Fig. 17 show that the structure without intermediate expansion joints is stiffer than the one with joints.

The capacity tests of the structure without intermediate expansion joints were not carried to failure and the relative strength of structures with and without expansion joints is not known definitely. Certain facts, however, that bear upon this question are quite clearly established: (1) For the structure without expansion joints, "5 L. L." in addition to the "D. L." produced nothing more than hair-cracks in the rib, and there were no cracks in the spandrel columns or deck large enough to indicate that failure was impending; (2) the section where the deflection of the pier causes the greatest increase in the stress is near the center of the span where the strengthening effect of the deck is the greatest; (3) although the thrust line for the structure as a whole falls outside the rib over the central part of the center arch, as shown in Fig. 18, the strain diagrams show little, if any, tension at the section where failure of the rib is most likely to occur, indicating that the thrust taken by the rib does not go much, if any, outside the kern. All these facts are indicative of a considerable strengthening effect of a deck without expansion joints at the weak sections of a three-span series of arches on high piers, and this strengthening effect is largely eliminated by the intermediate expansion joints.

For the structure with a high deck, the temperature moment at the springing is 28% greater without intermediate expansion joints than with them. For the structure with a low deck the difference is nearly zero. For the structure without intermediate expansion joints the temperature moment on the middle of the structure is resisted by the rib and deck acting integrally. For the structure with intermediate expansion joints the line of action of the temperature thrust passes so near to the rib in the panel under the expansion joint that the temperature moment is very small.

Unit Stresses Due to Design Load.—The unit stresses in a number of structures due to design load are compared in Table 3. The stresses in the structure having a rib without deck were determined by the elastic theory. The dead load stresses in the three-span structures having a deck were determined from the measured thrust the line of action of which was obtained from the measured strain. The live load stress for these structures was determined by the algebraic method based on experimental constants. The dead load stresses for the single span with fixed ends were determined by the elastic theory, on the basis that the rib carries the dead load unrestrained by the deck. The dead load is shown in Fig. 3 and is the same for all structures. The live load consists of a uniform moving load equivalent to a panel load of 960 lb, with a single concentration of 1 800 lb to be superimposed on the distributed load. For each structure the live load is distributed so as to produce the maximum compression at the critical section of that structure. The critical sections are listed in Column (3), Table 3, and the live load for

* See Table 4 for description of these loads.

maximum stress at that section is referred to by the number in Column (4). The live load corresponding to this number is given in Table 4.

For the structure with a high deck and with intermediate expansion joints, the compression at the extrados of the section at Section C_3, in pounds per square inch, is 1 447, 1 393, and 1 066 for structures having pier heights, in feet, of 20, 10, and 0. A stress of 1 447 lb per sq in. for the three-span series compared with 1 066 lb per sq in. for a single span with fixed ends is of interest; but it should be noted that a considerable part of this difference occurs in the dead load stress. These values are comparable with 1 236, 1 155, and 1 089 for similar structures having a rib without deck. In this case, also, the difference is in the dead load stress. For the structure with a low deck the

15	960	960	2 760	941	308	0	0	0

dead load stresses are smaller and the live load stresses are greater than for the structure with a high deck, but the differences do not exceed possible experimental errors, and the two structures appear to have about the same load-carrying capacity.

The stresses for the structure having a deck without intermediate expansion joints are for the section at the east springing and are very low. Whether danger of failure for these structures is greater over the central part than at the east springing was not definitely determined, but there was nothing to indicate that it is. However, failure in the superstructure followed by failure of the rib is possible and the stress at the springing is not a reliable indication of the likelihood of failure in the deck. Each of the structures having a deck without intermediate expansion joints carried the design dead load plus five times the design live load, the live load being distributed for maximum moment about the axis of the rib on a section through C_4, and there was no indication that failure was impending in either the deck or the rib.

Load-Carrying Capacity of Various Structures.—The results of the capacity tests are very re-assuring. All structures were tested at a pier height of 20 ft. Both structures having a deck without intermediate expansion joints carried "5 L. L." in addition to the "D. L." without indication of impending failure, both when loaded for failure at the springing and also for failure at Section C_4. The structure having a rib without deck carried "4.5 L. L.", and both structures having a deck with intermediate expansion joints carried a little more than "6 L. L.", in addition to the design "D. L." This was true even when the computed stress due to the design load, given in Table 3, was higher than specifications usually allow.

The compressive stress at failure for the three-span structure consisting of a rib without deck was 3 800 lb per sq in., comparable with the strength of the concrete in the control specimens of 3 310 lb per sq in. The compressive stress at failure for the structure having a high deck with intermediate expansion joints, based on measured reactions, was 3 200 lb per sq in., comparable with a strength of the concrete, as determined by control cylinders of 3 412 lb per sq in. The compressive stress at failure for the structure having a low deck was 4 400 lb per sq in., comparable with a strength of the concrete as determined by control cylinders of 4 281 lb per sq in.

The location of the thrust line in an arch is particularly indicative of the ease with which the structure is carrying its load, because flexure in the rib is very destructive. Fig. 15 shows the thrust line at the various load increments of the capacity test of the structure consisting of a rib without deck. The full line represents the position of the thrust line from the elastic theory and the broken line from the measured reactions. The agreement between the two positions is remarkably close, especially at the heavy loads. The rib contained many cracks at three live loads and some of them had attained a width of a few hundredths of an inch at four live loads; and yet, the accuracy of the elastic theory based on the assumption that concrete takes tension, does not seem to be seriously impaired. However, this is really only another way of saying what was stated previously, that varying the elastic constants for a span does not greatly alter the stress distribution. The centers of pressure (the centers of gravity of the trapezoid of strain corrected for the reinforcement steel), fall on the thrust lines with remarkable consistency. The character of the failure of the rib of the structure having a high deck with intermediate expansion joints, is shown in Fig. 19.

Relative Merits of High and Low Decks.—The stresses in the rib of the various structures due to the design load, given in Table 3, indicate that there is not much difference between the load-carrying capacities of the ribs of structures having high and low decks. The temperature moment at the springing, for structures having intermediate expansion joints, is about 64% greater for the high deck than it is for the low deck. For structures without intermediate expansion joints the difference is about 31 per cent.

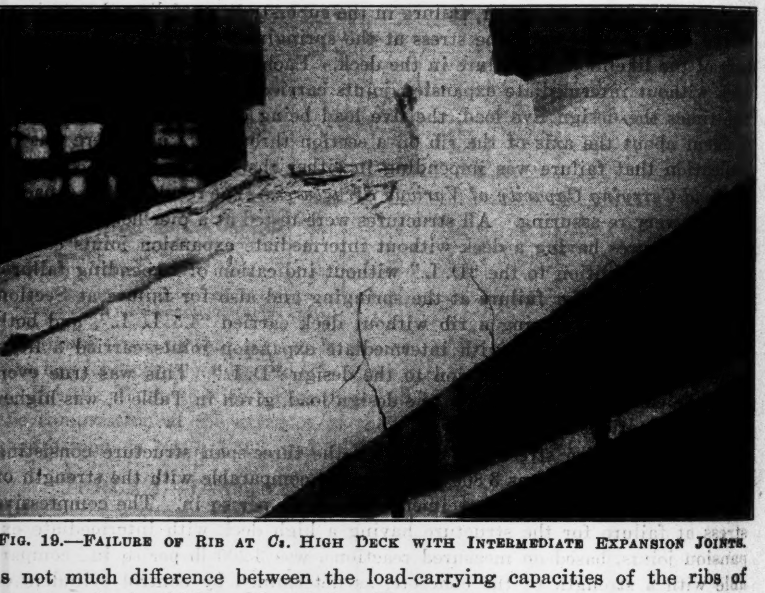

FIG. 19.—FAILURE OF RIB AT C_3. HIGH DECK WITH INTERMEDIATE EXPANSION JOINTS.

The low deck is integral with the rib at the crown, and the probability of a shear failure in the spandrel columns due to gravity loads is less than for a structure with the deck a considerable distance above the rib at the crown. The movement at the intermediate expansion joints due to a change in span is very much less for the low deck than it is for the high deck, making the need for expansion joints less for the former than for the latter structure.

SUMMARY OF RESULTS

Many tests have been made in connection with this investigation and only a small part of the experimental data have been presented in this paper. All the data have been analyzed, however, and this analysis appears to justify the following conclusions relative to the behavior of a three-span arch series on high piers:

For a Structure Consisting of a Rib without Deck.—

(1) The elastic theory based on the usual assumptions gives values for the moment, thrust, and shear at various sections, that agree with the measured values within the tolerance of the tests.

(2) In analyzing a multiple-span arch series, the moment of inertia of a section may be computed on the basis that the concrete takes tension.

(3) Considerable cracking of the arch rib does not greatly alter the position or magnitude of the thrust.

(4) The maximum unit compression due to design load was 13% greater for a three-span series on 20-ft piers than for a similar single span with fixed ends.

For a Structure Having a Deck.—

(5) The influence ordinates for fixed-end reactions is quite different for a structure having a deck than for one consisting of a rib without a deck. The effect of the deck is to reduce the moment at the springing, where it is all resisted by the rib, and to increase the moment over the middle of the span where the deck acts with the rib.

(6) The reactions at the springing can be determined by an algebraic method, using experimentally determined fixed-end reactions and elastic constants for the arch spans. The constants may be obtained from tests of single-span concrete structures or of celluloid models. A considerable variation in the elastic constants will not seriously affect the resulting stresses if the constants are statically consistent, but the fixed-end reactions must be determined accurately if the analysis is used to determine the dead load stresses.

(7) A deck without intermediate expansion joints increases the stiffness and the moment-resisting capacity of the central part of the structure. Intermediate expansion joints reduce both these effects.

(8) The ratio of the movement at each expansion to a change in span is about 0.25 for the structure having a high deck and 0.11 for that having a low deck.

(9) For the structure having a high deck with intermediate expansion joints, the unit compression due to design load was 36% greater for the three-span structure on 20-ft piers than for a single span with fixed ends. For the structure having a low deck with intermediate expansion joints, the difference was 21 per cent. A considerable part of this difference was due to the difference in the dead load stress, a function which would not have been influenced by the flexure of the piers if the specimen had been a symmetrical structure of homogeneous material, symmetrically loaded.

(10) There is considerable evidence indicating that the dead load stress in a multiple-span structure may exceed the corresponding stress in a similar single span having fixed ends.

For All Structures Tested.—

(11) The concrete in the arch developed approximately the same unit stress as the same concrete in 6 by 12-in. control cylinders.

ACKNOWLEDGMENTS

The tests described in this paper are a part of the investigation resulting from the co-operative agreement entered into by the Engineering Experiment Station of the University of Illinois, of which the late Milo S. Ketchum, M. Am. Soc. C. E., was the Director, and the United States Bureau of Public Roads Thomas H. MacDonald, Chief of Bureau. The tests were planned by the writer in consultation with Messrs. E. F. Kelley, Chief of Division of Tests, and A. L. Gemeny, Senior Structural Engineer, both of the U. S. Bureau of Public Roads, and with Professor George E. Beggs, E. H. Harder, A. C. Janni, and Professor Clyde T. Morris, members and Chairman, respectively, of the Special Committee of the Society on Concrete and Reinforced Concrete Arches. The experimental work was done by Ralph W. Kluge, Jun. Am. Soc. C. E., Special Research Assistant in Civil Engineering, assisted by Messrs. F. B. Metterhausen, F. P. Thomas, G. E. Jewett, Jun. Am. Soc. C. E., B. C. Schmeltzer, B. S. Tucker, R. Evans, and W. M. Weidemeyer, all working under the supervision of the writer. The computations involving the experimental data were made by Professor E. C. Grafton, of the Armour Institute of Technology, John N. Pirok, Jun. Am. Soc. C. E., Research Graduate Assistant in Civil Engineering, and Nathan M. Newmark, Jun. Am. Soc. C. E., Graduate Student in Civil Engineering.

The tests were made in the Materials Testing Laboratory of the University of Illinois. The direct expenses of the tests were paid from funds provided by: U. S. Bureau of Public Roads, Engineering Foundation, Universal Atlas Cement Company, Illinois Steel Company, American Bridge Company, Jones and Laughlin Steel Company, Interstate Sand and Gravel Company, Lincoln Sand and Gravel Company, Neal Sand and Gravel Company, Fairbanks, Morse and Company, and the Society.

DISCUSSION

C. B. McCullough,[4] M. Am. Soc. C. E. (by letter).—This presentation of laboratory tests of multiple-span reinforced concrete arch bridges is not only logical and coherent, but also gives evidence of an extraordinary degree of care and precision throughout the research. The section entitled "Description of Specimens and Apparatus," which deals with testing apparatus and equipment, has a value that extends beyond the scope of these particular tests, pointing the way to methods for further experimentation along the line of stress distribution in structures that are highly indeterminate and complex. The method for simulating or reproducing foundation fixity at various pier heights is especially ingenious. A similar comment may also be made in reference to the method of measuring rotations.

The scope of the investigation includes three phases of structural analysis concerning which there appears to be a dearth of published data: (1) An experimental verification of the elastic theory as applied to multi-span arches; (2) a determination of the approximate degree to which a variation in the elastic properties of the materials (or a variation in elastic constants due to any other condition) operates to modify stress distribution and to introduce error in the analysis; and (3), the effect of superstructure restraint and a study of the function of expansion joints. All these are questions that have appeared for some time to merit further investigation and study, and the results of Professor Wilson's researches furnish data which hitherto have been needed badly by every engineer dealing with the design of this structural type.

The influence lines indicated in Fig. 8 check the elastic theory with a degree of accuracy that is reassuring, and the two methods, one based upon pier-top displacements and the other on measured reactions, also check in a satisfying manner. The same comment may be made in reference to Figs. 9 and 10 wherein influence lines have been developed by five different methods.

The analysis of a multi-span arch series, utilizing experimentally determined elastic constants, appears to present far-reaching possibilities. Professor Wilson refers to a method developed under his supervision by Donald E. Larson, Jun. Am. Soc. C. E.,[3] in 1930, but does not go into this question in any great detail. The importance of this phase of the research merits more consideration. It is to be hoped that in closing his paper Professor Wilson will find it possible to present this matter more completely.

The entire research appears to be grouped about two major inquiries—the first having to do with the effect of elastic piers in multi-span arch construction, and the second pertaining to the influence of the deck and spandrel structure.

In reference to the former (the effect of elastic piers of varying heights), an inspection of Figs. 13 and 14 discloses the fact that the general effect of increasing the height of elastic piers is to reduce the horizontal thrust, to reduce moments at or near the pier skewbacks, and to increase stress near the center of the span. In this connection an analysis was made in the writer's office a few years ago embracing a three-span arch structure on elastic piers. Because of certain location studies involved, and as a matter of general interest, analyses were made of three designs, each comprising a series of three 150-ft arches and differing only in the matter of pier heights. Design No. 1 involved a pier height of 45.8 ft; Design No. 2, a pier height of 15.8 ft, and Design No. 3, a pier height of 95.8 ft.

The influence lines for the moment and thrust at three points on Span 1, for each of these three designs, are plotted in Fig 20. These influence lines naturally exhibit the same tendencies as those noted in Professor Wilson's paper; that is, an increase in pier flexibility is accompanied by a decrease in thrust, a decrease in skewback moment at the pier, and a general increase in stress throughout the region adjacent to the crown. It is of interest, however, to note the marked effect of loads in adjacent spans, especially for the two designs involving relatively high piers. Professor Wilson's researches indicate an increase in stress as pier heights are increased, amounting to 13% for the three-span series on 20-ft piers, when compared with a single span of like dimension having fixed ends. When the effect of the deck and spandrel structure is taken into consideration this increase amounts to 17 per cent. A study of the influence lines given in Fig. 20 indicates that a stress increase considerably greater than the foregoing may be expected if the effect of loading in adjacent spans is considered; and, while this fact need cause no serious concern in view of the improbability of simultaneous loading in all spans of a series in such position as to cause maximum stress, such a condition should always be investigated, especially for extreme pier heights.

The second phase of Professor Wilson's paper has to do with the effect of the supported deck and spandrel structure on arch rib strains and stresses. In general, his researches disclose a reduction in horizontal thrust and in bending moment at the springing as a result of the placement of an integrally supported spandrel structure. When expansion joints are inserted in the deck, the same tendencies are exhibited, but to a much less degree. In this connection, certain observations in reference to the effect upon arch rib strains of a spandrel structure and deck, even with the utmost degree of articulation possible, were made by the writer in connection with the operation of decentering the Rogue River Bridge, in Southern Oregon, in 1932. A full report of a co-operative research on this subject has been published for limited distribution by the U. S. Bureau of Public Roads and the Oregon State Highway Commission.[5]

This bridge was constructed after the Freyssinet system[6] which, as applied in this case, consists in the complete severance of the arch rib at the crown, and the introduction at the severed section of a system of hydraulic jacks by which the arch may be raised from its falsework support and adjusted to any

predetermined elastic state. The arch thus handled is converted into two statically determinate cantilever segments, which render it possible to study stress distribution under varying conditions with a considerable degree of accuracy.

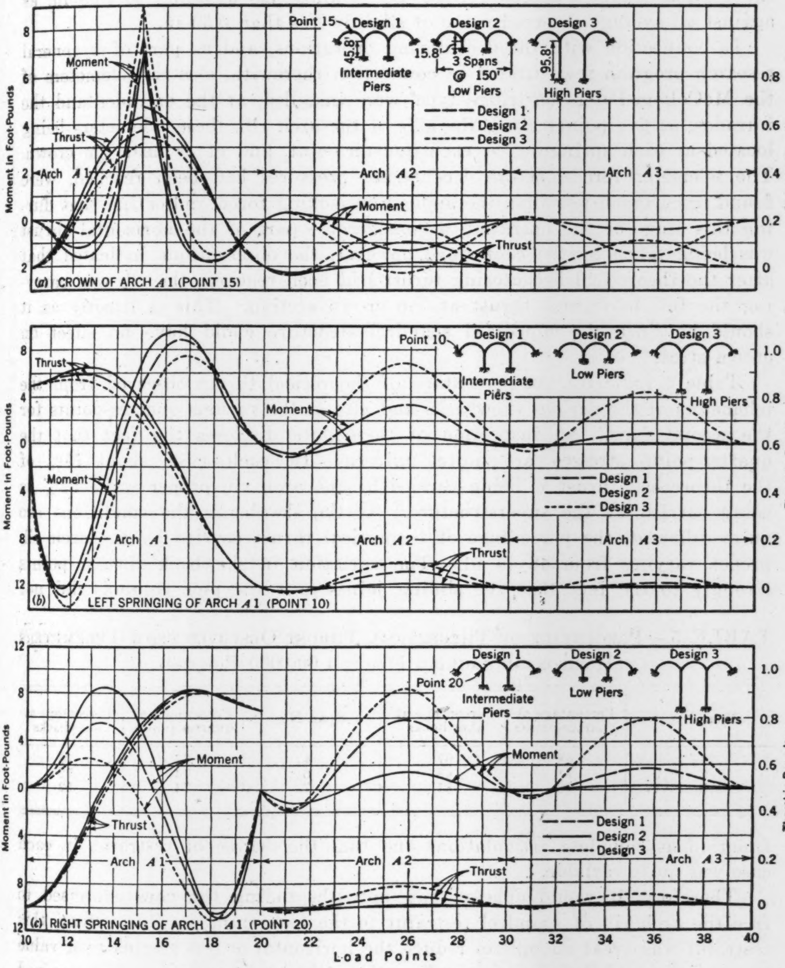

FIG. 20.—COMPARISON OF MOMENTS AND THRUSTS.

The articulation thus attempted[7] was about as thorough as can ordinarily be achieved under construction conditions. In other words, the degree of restraint exercised by the spandrel structure was apparently reduced to as nearly a minimum as is consistent with construction practice. Nevertheless, the observed crown movement was less than one-third of the theoretical for an unrestrained rib. For example, at a total crown-thrust value of 840 000 lb, the computed crown spread for an unrestrained rib amounts to 1.60 in. as against an average observed value of slightly less than 0.50 in.

---

[7] *Proceedings*, Am. Concrete Inst., October, 1932, p. 57.

In connection with the decentering operations, and as part of a general research program inaugurated in connection therewith, electric telemeters of the McCollom-Peters cartridge type[8] were installed, at the extrados and the intrados, at five points along the axis of the arch rib, these telemeters being located at each springing, at each quarter-point, and at or near the crown. The telemeter forces, before decentering pressures had been reached, were found to be much less than the applied or jacking force, indicating that during this stage of the operation a considerable part of the horizontal thrust was being taken by the centering; however, the observations indicated that after the theoretical decentering thrust had been reached, the rib was carrying the full horizontal thrust at the crown section. This is exactly as it should be since the supported spandrel structure could have no effect on crown stress.

Table 5 indicates the percentage of theoretical thrust observed from the telemeters at the various skewbacks and also at the various quarter-points for the second runs. An inspection of these data discloses the fact that the quarter-point stresses are quite uniform. In each case about 75% of the theoretical thrust is being carried by the arch rib proper while 25% is being carried by the superstructure. At the skewbacks the conditions are quite different, the percentage of theoretical thrust carried by the arch rib proper varying from 48 to 81. The variation in skewback thrusts points strongly to the fact that the sliding joints over the pier columns did not function as complete articulations and that the degree of restraint in each case was quite variable.

TABLE 5.—PERCENTAGE OF THEORETICAL THRUST OBSERVED FROM TELEMETERS (HORIZONTAL JACKING FORCE, 1 000 000 POUNDS).

Span No.	Percentage at quarter-points	Percentage at skewbacks	Span No.	Percentage at quarter-points	Percentage at skewbacks
1.........	68	67	4.......	72	76
2.........	71	48	6.......	74	72
3.........	78	81	7.......	74	52

Therefore, it would appear that, notwithstanding the care exercised to free the arch rib of spandrel restraint to the maximum possible extent, this restraint was great enough to reduce the horizontal crown strains to a value less than one-third the corresponding theoretical values for an unrestrained or free rib, and that, furthermore, the spandrel structure absorbed about 25% of the thrust at the quarter-points and an amount at the skewback which was highly variable because of the varying degree of restraint exercised by the sliding expansion joints over the pier columns.

Another interesting fact in reference to the behavior of the expansion joints and spandrel structure articulations is indicated in Fig. 21 wherein are plotted the quarter-point moments as determined from telemeter readings against applied crown thrust. Between Readings 107 and 111 it will be noted that the positive moments gradually increase as crown thrusts are increased. Between Readings 111 and 113, however, a decrease of more than 100 000 lb in applied crown thrust produces no change in moment. Below this point, however, as crown pressures are slacked off, quarter-point moments decrease in accordance with theory. The same characteristic lag is indicated at the bottom of the graph between Readings 101 and 107 and also between Readings 116 and 119. Reading 97 (not shown) is at zero moment and thrust.

FIG. 22.—MECHANICAL ANALYSIS FOR TEMPERATURE STRESSES IN END SPAN.

The same characteristic at the top and bottom of all graphs indicating the relationship between applied crown thrust and arch rib forces and strains at various points persisted throughout the entire test. At first, it was thought that this phenomenon might be explained on the theory of friction in the jacks, but careful calibration and recalibration through a series of test cycles failed to disclose any appreciable jack friction. The only other hypothesis upon which this phenomenon can be explained is that of a frictional resistance to a reversal of motion in the articulations and expansion joints. As long as movement persisted in one direction, superstructure restraint appeared to be more or less uniform and fixed. Whenever motion was reversed, however, there appeared to be sufficient static friction in the articulations to retain the arch in a fixed position, and a considerable increase or decrease in crown thrusts appeared necessary in order to break loose the articulations and permit movement in the reverse direction.

All these results point inevitably to the conclusion that spandrel structure restraint is present to a certain extent even in the most carefully articulated designs; and to the further fact that sliding joints are likely to introduce strain conditions of an exceedingly variant character.

The Rogue River tests were conducted under construction conditions, and certain sources of error were inevitably introduced; however, the persistence, throughout the entire tests, of the results noted herein leaves little room for doubt as to the general tendencies exhibited by the spandrel structure in question. As a result of these researches, it may be logically concluded that the only methods by which the stress distribution in an arch carrying a supported spandrel structure and deck can be determined and controlled accurately, are: (1) By means of a system of articulations much more complete and positive than those ordinarily used heretofore; (2) by means of a system of stress and strain control in the field such as was adopted at the Rogue River Bridge; and (3) by the adoption of a design without expansion joints and a method of calculation that takes into consideration the complete effect of the spandrel structure. In view of the foregoing conclusions, the researches reported by Professor Wilson become exceedingly important.

In connection with the utilization of a spandrel structure without intermediate expansion joints, a word of warning should be sounded against a procedure which carries this idea too far. Fig. 22 is the result of a temperature stress analysis made in the writer's office in 1932. Fig. 22 (*a*) indicates the moments, thrusts, and fiber stresses at the base of spandrel columns supported by a series of three arch spans, no expansion joints being placed throughout any part of the spandrel structure from end to end. Fig. 22 (*b*) indicates the marked reduction in stress at corresponding points when the deck is severed over the intermediate piers. Even in this latter case the stress at the base of the short column exceeds the ultimate strength of the material, indicating the need for a re-design of the spandrel columns or the provision for further articulation.

All in all, the problem presented is rather complex, and the need for the utmost refinement in analyses of large and important structures becomes increasingly apparent as the problem is further investigated. Structural designers have been altogether too prone to neglect spandrel structure effects and to assume a freedom of arch movement under varying stress conditions which was never realized in actual service. The result in many instances is quite apparent in the formation of cracks at column bases, the opening of construction joints, spalling, and disintegration around expansion joints, and other like conditions. Because of the relief afforded by plastic flow and a redistribution of stress, such conditions may not be sufficient to cause structural failure but, nevertheless, they militate against service life and increase maintenance expense.

CARROLL L. MANN, JR.,[9] ESQ. (by letter).—Following parallel with the investigation of concrete arches at the University of Illinois and during the first half of 1933, the writer, working under the direction of George E. Beggs, M. Am. Soc. C. E., built and analyzed by the deformeter gauge method,[10] a precise celluloid model of a multiple-span arch bridge.[11]

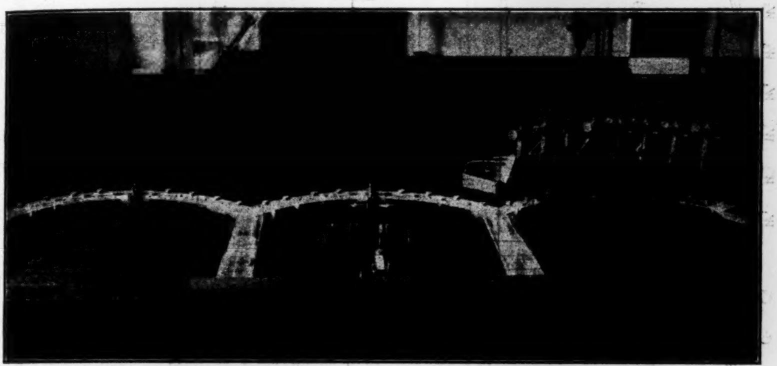

FIG. 23.—CELLULOID MODEL OF THE THREE-SPAN CONCRETE ARCH RIBS ON SLENDER PIERS.

The word, "precise", as applied to these models, has a significant meaning. Throughout the entire analysis of the model various experiments were performed on seemingly unimportant details to determine the best methods

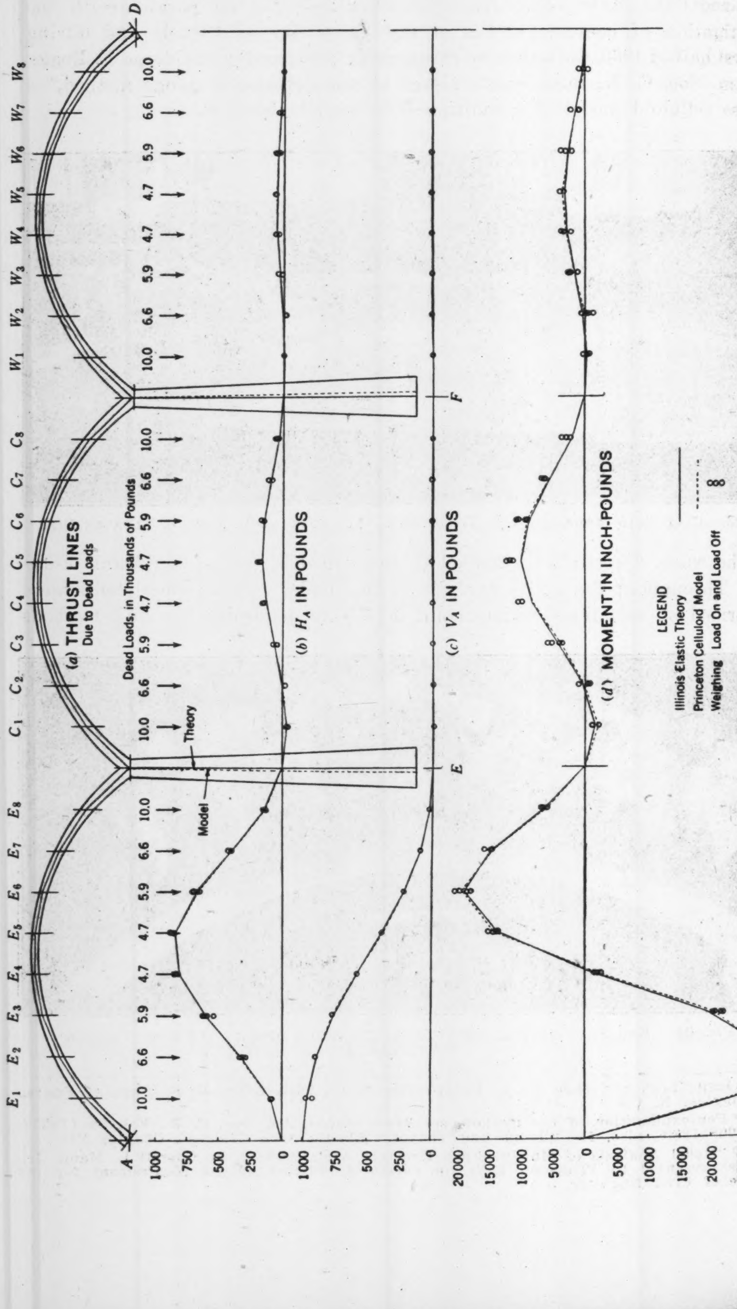

FIG. 25.—INFLUENCE LINES FOR REACTIONS AT A DUE TO 1 000-POUND UNIT LOAD.

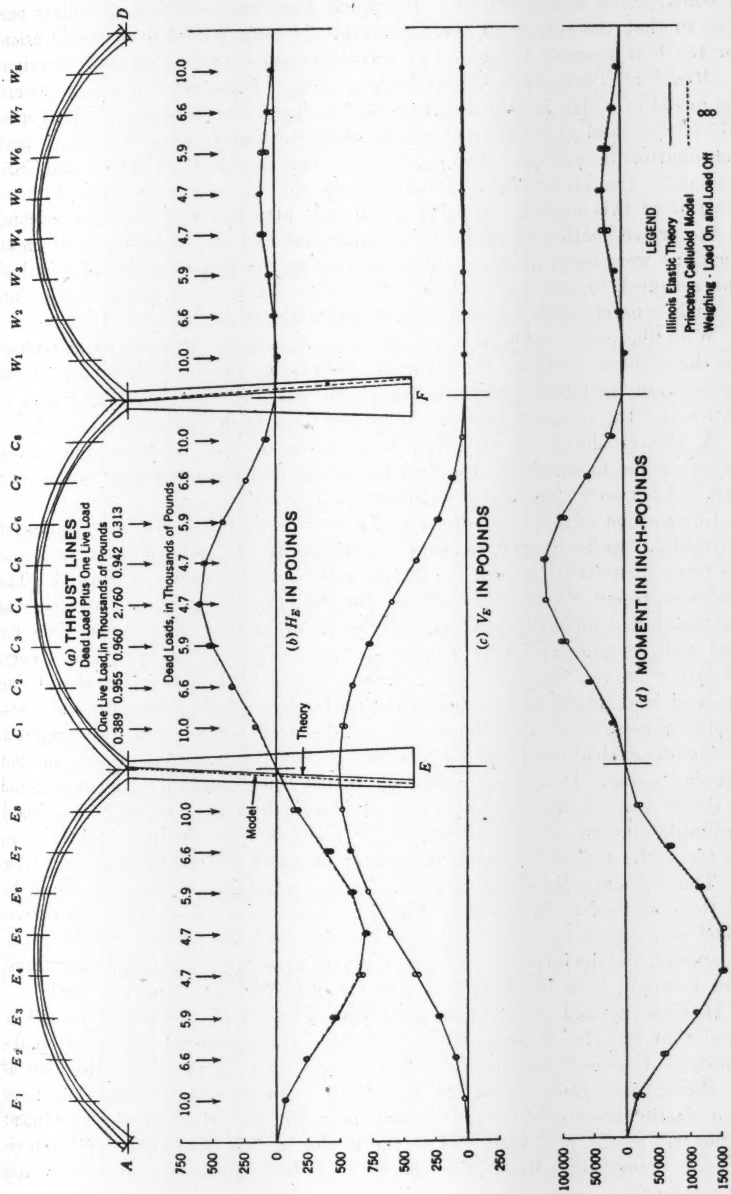

FIG. 26.—INFLUENCE LINES FOR REACTIONS AT *E* DUE TO 1 000-POUND UNIT LOAD.

of construction and operation. The work, therefore, served a secondary purpose in that the results of these observations were recorded as specifications for the best possible technique of precise model construction and operation.

Model of Three-Span Arch Bridge.—The continuous concrete structure, the model of which is shown in Fig. 23, has three arch ribs each of 27-ft span, 6.75-ft rise, and is supported by two abutments and two 20-ft piers. Both the abutments and the two pier bases are assumed as fixed, and, consequently, the structure is indeterminate in the ninth degree. For the analysis of this model, a floating gauge was attached and carefully oriented at the crown section of each of the three ribs and the components of crown reactions were determined at these sections as the 1 000-lb vertical unit load was assumed to move across the structure. There were eight load points on each concrete arch rib, spaced 3 ft apart along the horizontal.

With the components of the forces experimentally determined at each of the three crown sections, the structure became statically determinate. These forces were then transferred to the abutments and pier bases by means of statics and the terminal reaction influence lines so derived.

A clearer detail of the right-hand span of the multiple-arch model, including the microscopes, the floating gauge, and the anchorage of the arch terminal between steel plates, is shown in Fig. 24.

Comparison of Experimental and Theoretical Results.—Influence lines for horizontal, vertical, and moment reactions at the left abutment, *A*, of the three-span structure, for a 1 000-lb unit load, are shown in Fig. 25. The circles represent the results obtained for the concrete structure by weighing the reaction components on very precise lever scales. The thrust lines for dead load, as computed both from the model influence values and by theory, are shown in Fig. 25(*a*). This structure was shaped so that the thrust line for dead load might follow closely the center line of the arch ribs and piers, passing precisely through the centers of the arch crowns and the terminals. In the theoretical analysis, rib-shortening was taken into account, but not pier-shortening. It will be noted that thrust lines determined by model and by theory are for the most part almost identical in the arches, separating a negligible amount at the end portions. The two lines deviate slightly down the piers, the theory following the center line and the model deviating from it. The influence lines for reactions at the left base, *E*, as determined by the three methods, are shown in Fig. 26. The thrust lines as computed from model and theory for dead load plus one live load are plotted in Fig. 26(*a*). In general, the deviation of the model thrust lines from the theoretical thrust lines is small, both for dead load and for dead load plus one live load.

If Figs. 25 and 26 are compared with Fig. 15 of the paper, it will be noted that the thrust lines determined from the measured reactions on the prototype diverge from the theoretical thrust lines in the same direction as the thrust lines found from the model test. In no case are the deviations from elastic theory of practical importance; but, nevertheless, the agreement of the test of the prototype and of the model in this divergence of the position of thrust lines from the theory may be significant; and it excites some interest.

Conclusion.—The small variations between results obtained by the theory, by the model, and by the test of the concrete structure are not of practical importance. The differences may be due in part to experimental errors, but undoubtedly some of them are chargeable to assumptions made in the theory. The theory necessarily includes more assumptions than the model, in which Nature itself works automatically, with few limitations.

M. HIRSCHTHAL,[12] M. AM. SOC. C. E. (by letter).—Of special interest are the effects, described in this paper, of expansion joints in the deck of the spandrel construction on the resistance of the arch ring or rib. There is no doubt that a continuous spandrel system extending from pier to pier, fixed to the arch at its various points, will increase the resistance of the arch rib or ring, to the various stresses to which it is subjected. This is natural, since the structure then becomes a braced arch or a Vierendeel truss with a curved lower chord and laterally supported top chord.

The difficulty lies in the necessity of designing each of the joints of this rigidly connected frame to resist the distortions due to the movement of the arch, particularly under the action of temperature stresses. With a drop in temperature the crown of the arch falls while the haunches rise, which action is transmitted to the deck through the spandrel columns or walls, causing distortions at their junction with the deck. These distortions increase greatly with long arch spans and high spandrel systems and require heavy sections to resist them.

The object in providing intermediate expansion joints in decks, therefore, is not simply to guard against the effect of temperature changes longitudinally, but to eliminate the stresses induced in the deck by the distortion of the arch ring or rib due to changes in temperature in that member. By allowing for free movement in the deck construction for this condition, it is not necessary to design for distortions due to this cause, but to select the proper position for the location of the joints.

There is further danger in the absence of intermediate expansion joints in long span arches, and it lies in the fact that, particularly in railroad bridges, there is superimposed over the open-spandrel construction a heavy parapet as a guard against possible derailment, which then becomes a continuous girder spanning from pier to pier and subject to the foregoing distortions.

The writer wishes to cite an interesting experience in this connection: Between 1908 and 1911, the Delaware, Lackawanna, and Western Railroad Company constructed a cut-off line between Hopatcong, N. J., and Slateford, Pa., in the course of which two concrete arch viaducts were constructed—one over Paulins Kill, at Hainesburg, N, J., and the other over the Delaware River, at Portland, Pa. Both these viaducts were built without expansion joints, except at the piers, the floor systems being of arch construction so that the sections at the junction with the spandrels are quite heavy.

In 1912, preliminary to the design of the proposed structures on the second cut-off line between Clarks Summit and Hallstead, Pa., an examination was made of the parapets of the aforementioned two viaducts to determine whether intermediate expansion joints should be provided in the new structures. These older structures had been in operation a sufficient length of time to have been subjected to several cycles of temperature changes at that time. The examination disclosed vertical cracks in the parapets, particularly in those of the Delaware River Viaduct, possibly due to the fact that the arches had considerably less rise in proportion to span. Although the cracks were not serious, they indicated the effects of the omission of intermediate expansion joints, and it was decided to provide them in the then proposed structures—the Martin's Creek and Tunkhannock Viaducts. These two viaducts have been in operation for more than twenty years, and the expansion joints have functioned so as to eliminate this difficulty.

---

[12] Concrete Engr., D. L. & W. R. R., Hoboken, N. J.

Another interesting phenomenon was observed in connection with the effect of temperature stresses on arch bridges with solid spandrel walls retaining the fill. These arches were of smaller spans, 20 to 45 ft, some of which were constructed early in the progress of the first cut-off line. Before any live load was placed on these arch bridges, the spandrel walls were found to have vertical or nearly vertical cracks at each haunch which, it was decided, were due to the distortion of the arch ring resulting from temperature changes, the high section over the haunch being subjected to greater deformation due to its height. The effect being similar to shear cracks in a beam, it was decided to place shear reinforcement in the spandrel walls in subsequent structures with the result that these cracks have not appeared. Strangely, this difficulty was not experienced with the flat over-head highway arches—probably due to the fact that the height at the haunch is much smaller and the section of the arch ring much lighter. This fact is borne out by the author's conclusion in connection with the relative effects on high and low spandrel construction.

Another point to which the writer would call attention is in connection with Professor Wilson's preliminary statement (see "Description of Specimens and Apparatus: Specimens") that "the weight of the specimen was not great enough to produce a dead-load stress commensurate with the dead-load stresses encountered in the design of a full-sized bridge."

This is significant and emphasizes the care necessary in drawing conclusions from model test results and applying them to full-sized structures. The problem is intricate when the material in both model and prototype is identical; it is more so when the models are of a material having elastic properties entirely different from those of the structure; and it is particularly serious when the structure is an arch and temperature effects are to be considered. In this type of structure, the thrust and moment due to temperature change are proportional to the cube of the depth of arch section and inversely as the square of a function of the rise so that no direct relationship exists between a reduced scale structure and one of full size.

Attention is called to the summary of conclusions, showing an appreciable increase in stress in multiple-arch spans on slender piers over that in arches of single spans with fixed abutments. This should be a warning in the design of multiple-span arch structures of the so-called "rigid frame" type when computing dead load stresses in its members.

It is needless to state that the author has contributed exceedingly valuable information in a field where it is most urgently needed, and his painstaking attention to all the considerations involved cannot be praised too highly. It is to be hoped that similar tests on skew arches will be undertaken to provide the necessary information for such structures.

WILBUR M. WILSON,[13] M. AM. SOC. C. E. (by letter).—In the absence of any considerable disagreement with the interpretation of the data, little appears to be needed in the way of a closure.

Mr. McCullough has mentioned the desirability of a more complete presentation of the combined algebraic-and-experimental method of analyzing multiple-span arch series. This method is presented in the Final Report of the Special Committee on Concrete and Reinforced Concrete Arches.[14]

Quite properly, Mr. McCullough calls attention to the possibility of an increase in stress at the springing of one arch due to live load on adjacent arches. The live load used in the tests is for highway bridges and the single heavy concentration overshadows the smaller distributed load. For a railway bridge, the load on spans adjacent to the one being considered might produce considerable stress thereby increasing the difference between the stress on a multiple-span structure and that in a similar single span. A point that the writer neglected to mention, is the fact that, although the negative live load moment at the springing of the middle span is reduced by the flexure of the pier, the positive moment at that section and the negative moment at the abutments are increased.

Mr. Mann's analysis of a three-span arch series by means of an elastic model is of interest, showing as it does the agreement that may be obtained between values derived from tests of models and from an algebraic analysis when sufficient experience has been acquired to assure skill and accuracy with both methods. However, the experience of the writer is that for a three-span structure consisting of ribs without deck, which are readily susceptible of algebraic analysis, less time is required and the results are more acceptable if the structure is analyzed by the elastic theory than by the use of an elastic model. In the analysis of a three-span structure with a deck, the spans of which are not readily susceptible of algebraic analysis, an experimental analysis involving the use of elastic models appears to be the most acceptable; and comparisons such as Mr. Mann and others have made would appear to indicate that the results of such an analysis are dependable, providing the tests are properly planned and care is exercised to prevent experimentation errors. Whether the model analysis is better accomplished by tests of a model of the entire structure or by tests of a model of a single span, using the experimental data in the combined algebraic-and-experimental method is, to a certain extent, a matter of personal preference. The writer prefers the latter, and for the following reasons.

---

[13] Research Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

[14] This report is included in this volume (Vol. 100), of *Transactions*.

The difference in the time required to make the model—between a single-span and a three-span model—is more than that required to make the algebraic analysis. The results of the algebraic analysis are statically consistent, which is not always true with the results of an all-experimental method. With the combined algebraic-and-experimental method a considerable error in the experimental constants produces only a small error in the stress in the rib computed from the constants.

The three-span structure with the low deck, shown in Fig. 2(*g*), was analyzed by the use of an elastic model, and the results agree closely with those obtained from tests of the concrete specimens.[15] The differences between the results obtained by the two methods are possibly no greater than the differences that might exist between the behavior of two concrete arch bridges built to the same drawings and specifications.

Mr. Hirschthal directs attention to the influence upon the rib of the action of the spandrel columns and deck, and particularly the influence of expansion joints in the deck. These are important questions and questions for which there are as yet no definite and final answers. The early impression was that the interaction of the rib and deck was an asset since it appeared to increase the load-carrying capacity of the structure. More recently attention has been directed to the detrimental effect of the interaction which, although increasing the load-carrying capacity of the rib, may overstress the spandrel columns and deck. Possibly, the final solution (particularly for extremely long-span arches) will be to develop a design having such a relation of rib to superstructure that it will be possible to take advantage of the increase in the load-carrying capacity resulting from interaction without injuriously overstressing the spandrel columns and deck. This is desirable, not so much because of the direct saving in material, but because of the reduction in the dead load, which constitutes almost the entire load in a long-span, reinforced concrete arch bridge. This is an important hoped for development of the future. If the tests, which are the subject of the paper, have contributed to this solution, or if they have demonstrated the desirability of such a design, the investigation will have been profitable.

Mr. Hirschthal relates his experiences with the concrete arches of the Delaware, Lackawanna, and Western Railroad Company and states that cracks occurred in the parapets of two bridges built without intermediate expansion joints and did not occur in the parapets of two other bridges having intermediate expansion joints.

The writer would distinguish between expansion joints in the deck and in the parapet. The horizontal movement that would occur if intermediate expansion joints were provided increases with the distance above the rib. The top of the parapet is a considerable distance above the rib at the crown for these bridges. The cracking of the parapet could have been prevented by providing intermediate expansion joints in it whether or not there were corresponding expansion joints in the deck.

---

[15] See *Bulletin 270*, Univ. of Illinois Eng. Experiment Station, Urbana, Ill.

If the arch barrel, or rib, for an open spandrel arch is extremely heavy so as to overwhelm the deck, as it was for the Delaware River Bridge,[16] referred to by Mr. Hirschthal, the stiffer the deck the more likely it is to crack if intermediate expansion joints are not provided. (Mr. Hirschthal kindly furnished the writer with blue-prints showing the details of the bridges referred to by him.) The deck for all but the Delaware River Bridge was a considerable distance above the rib at the crown, and the bridges fall in the class for which the tests by the writer[17] show that a considerable horizontal movement would occur if intermediate expansion joints were provided. The deck for the Delaware River Bridge was high enough to be not integral with rib at the crown although not so high as for the other bridges. Without having sufficient knowledge as to the interaction between the rib and deck to form a final opinion, it appears to the writer that there are features of this bridge that make it particularly liable to crack if intermediate expansion joints are not provided. Although the deck is not especially high, the parapet is high enough so that some horizontal movement would have taken place at intermediate expansion joints if they had been provided. The arch barrel is extremely heavy. The deck spans are short and, therefore, so stiff that they cannot conform to the flexure of the rib without cracking and yet are not strong enough to prevent this flexure. The situation is further aggravated by the fact that the section of the deck is less at the center of the deck span than at the transverse spandrel walls.

It is possible that the need for intermediate expansion joints in the deck of an arch bridge is not entirely a question of the position of the deck relative to the rib, although that is a vital relation, and both tests and a visualization of the action of the structure indicate that the horizontal movement that would occur if expansion joints were provided is a function of the height of the deck above the rib. The relative stiffness of the deck, spandrel columns, and rib is also important as they probably affect the vertical and angular motion that would occur if expansion joints were provided; they also affect the stress that will result if the movement is prevented or reduced by making the deck continuous.

The studies made to determine the movement at expansion joints[17] were limited to horizontal movement, the opening and closing of the joint. In view of the questions raised by Mr. Hirschthal, further studies to determine the relative vertical and angular movement of the two ends of the deck that meet at an expansion joint, appear to be desirable. This can be done in an acceptable manner with elastic models by methods similar to those used in studying the horizontal movement.

Another question pertaining to the design of multiple-span arch bridges which the writer believes should obtain more attention than it receives, at least in the literature on arches, is the distribution of the vertical distance from the bases of the piers to the top of the roadway. The elevation of the roadway is usually fixed by the approaches, and that of the bases of the piers by the foundation conditions. The difference between these two elevations is usually fixed within narrow limits, but the total vertical distance can be divided into three parts at the discretion of the designer. These parts are: (1) The height of the pier; (2) the rise of the arch; and (3) the distance of the deck above the rib at the crown.

---

[16] *Engineering News*, Vol. 62, No. 26, p. 713.

[17] *Bulletin 226* and *Bulletin 270*, Univ. of Illinois Eng. Experiment Station.

In so far as the limited number of tests show, for a particular rib and a particular deck, the height of the deck above the rib does not affect the load-carrying capacity of the structure, although it does affect somewhat the stresses resulting from temperature changes. Increasing the height of the deck above the crown of the rib also increases the horizontal movement that would take place at intermediate expansion joints if they are provided. This is compensated for, at least in part, by the greater flexibility of the longer spandrel columns. Therefore, it would appear that, structurally, the high deck has no appreciable advantage over the low deck, or the reverse.

If the total available vertical distance is small, the natural design is to make the piers as low as the required flood channel will permit and make the deck so low as to be integral with the rib at the crown, thereby obtaining a maximum rise for the arch rib. If the total vertical distance is ample, or possibly excessive, the best distribution is not so easily apparent.

Increasing the flexibility of the piers of a multiple-span series increases the live-load stress in the rib, but a considerable increase in the flexibility causes a relatively small increase in the stress. Moreover, increasing the flexibility of the piers has a lesser effect on a rib with a large, than on one with a small, rise ratio. Increasing the height of the pier increases the flood channel. Increasing the rise ratio of the arch decreases the horizontal thrust on the piers due to load and decreases the temperature stress in the rib. It would appear, therefore, that there is no advantage in separating the deck from the rib at the crown as the vertical distance can be better disposed of by increasing the height of the pier and increasing the rise ratio of the arch rib. The use of a multiple-span series of flat arches on high piers would appear to be undesirable.

Mr. Hirschthal emphasizes the care necessary in drawing conclusions from tests of a small structure. The writer wishes to repeat this caution not only in applying the results obtained from a small structure to the design of a large structure, but also in drawing any general conclusions from a limited number of tests. Although the investigation included several tests, the results have little statistical value. In general, they are of value because they indicate how the structure functions rather than because of the absolute quantitative values obtained. Those interested are urged to study the detailed reports[18] and make their own interpretation of the data rather than depend entirely upon the writer's interpretation.

RENEWAL OF MITER-GATE BEARINGS, PANAMA CANAL

BY CLINTON MORSE,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. E. S. RANDOLPH, AND CLINTON MORSE.

SYNOPSIS

The equipment and methods of raising and moving twelve miter-gate leaves of the Panama Canal, at Miraflores, are described in this paper. Considerable wear on the vertical bearing surfaces made replacement advisable. The quoin-bearings could be made accessible only by raising the leaves clear of the pintles and moving them from the wall. The largest leaves are 82 ft high and have an estimated gross weight of 790 tons.

Comparisons are made between the experimental equipment and the methods used at Pedro Miguel, in 1929, and the present system. Improvements in technique, suggested by experience gained in raising twenty-two leaves during three over-haul periods, are emphasized.

INTRODUCTION

The Panama Canal was opened to commercial traffic on August 15, 1914. Three lifts are required to reach the summit level, which is normally 85 ft above sea level. Twin chambers, each 110 ft wide, with a usable length of 1 000 ft, permit simultaneous northbound and southbound lockages. A diagram of the Miraflores Locks is shown in Fig. 1. At the time of their construction the lock-gates were by far the largest and heaviest that had ever been built. They contained a number of new features that have been incorporated in later designs. An unusual device was the use of removable nickel-steel plates for the miter and quoin-bearings shown in Fig. 2.

The leaves pivot on hemi-spherical nickel-steel pintles, 16 in. in diameter (Fig. 3). On the gates at the sea end of the lower chambers at Miraflores

and on the lower guard-gates at Gatun, the pintle bushings—twelve in all—are of carbon steel; the others are of manganese bronze. Each leaf is held at the top, by a pin connection, to a V-shaped, vanadium-steel yoke which, in turn, is keyed to anchorages deeply embedded in the concrete walls.

The major dimensions of the gates (of which there are 92) are given in Fig. 4. Their gross weight is 426 to 790 tons each. The design and erection of these gates have been described[2] concisely by Henry Goldmark, M. Am. Soc. C. E., who was in direct charge of the work.

FIG. 4.

In the period between 1924 and 1929, extensive repairs were made to the rising stem and the cylindrical valves.[3]

---

[3] "Lock Valves," Manuals of Eng. Practice, No. 3, Am. Soc. C. E., pp. 54-71.

Present policy requires that each lock be given a general overhauling every four years, the periods alternating between the Atlantic and Pacific locks. Thus, one chamber of the canal is out of service, for about three months during the dry season, once every two years.

Effects of Worn Bearings

The wear on the bearing-plates was first measured during the over-haul at Gatun in 1924. The original sill clearance was $\frac{1}{2}$ in. at the miter end, tapering to zero at the quoin. Inspection showed that the gates rested against the fixed sills and did not meet at the miter point. The measurements were made in an effort to discover the cause of this condition. The total wear on the six bearing surfaces of a pair of leaves was taken to be the space the leaves stood apart at the bottom of the miter when the top plates were in contact. In Fig. 4(*a*) the full lines show the original position of the gate and the dotted lines the position after the bearings had become worn. Measurements made again in 1927 showed the the rate of wear was about $\frac{1}{32}$ in. per yr, but that it varied, depending on the severity of use.

Fig. 5.—Section Through Sill.

The gates act as a horizontal three-hinged arch when they are in position against a head of water. Wear on the vertical bearing surfaces causes rib-shortening and a consequent down-stream movement of the miter point. The movement down stream is 1.10 in. per in. of wear. It is necessary to trim the wood sills periodically (Fig. 5) in order to restore the original clearance.

The result of this trimming has been to increase the tendency of the leaves to warp when in operation. The top of the miter, which showed no wear, remained in its original position, whereas the bottom was forced down stream until the bearing-plates made contact; this caused the leaves to bend along a diagonal line extending from the top of the miter to the pintle. The distortion of the gates is indicated in Fig. 4 (*b*).

The objectionable results of the wear on the bearing surfaces made it obvious that they should be renewed, beginning with the main operating gates and those showing the greatest wear. While the nominal life of the bearing-plates is twenty years, increasing traffic would shorten their life. Twenty-two years would be required to renew all the bearing surfaces if eight leaves were repaired every two years. Even this plan would require that twelve leaves be repaired during one over-haul.

THE TRIAL RAISING

The only way in which the quoin-bearing could be made accessible was to raise the leaf from the pintle and then move it from the wall. Since no attempt had ever been made to raise and move leaves of this size before, the first attempt was largely an experiment to determine the proper equipment and methods to be used for renewing all the bearings. Economy demanded, and the short dry season made imperative, the design of standard equipment and methods which function with production-line efficiency. A proposal to float the gates out of the chamber and to repair them in dry dock was abandoned and E. S. Randolph, M. Am. Soc. C. E., developed a method of raising the leaves within the chamber by hydraulic jacks connected to needle-beams under the leaf, in such a way that the leaves are raised only enough to clear the pintle and then are rolled from the wall.

The first test of this equipment was made in 1929 at Pedro Miguel, when two leaves were raised and replaced successfully. Desirable minor changes in the equipment and mode of procedure were obvious at once. Two years later, eight leaves were raised at Gatun. The speed and efficiency with which the equipment functioned during this over-haul removed all doubts as to the practicability of the adopted design. Additional equipment was purchased and twelve leaves (see Fig. 1) were raised and replaced at Miraflores between January 3 and April 15, 1933.

GENERAL DESCRIPTION OF THE RAISING EQUIPMENT

The small clearance under the leaf (see Fig. 5) made it necessary to place the twelve jacks (grouped in four sets of three jacks each) on the sides. Each set is equi-distant from the transverse center line of the leaf, and the jacks are set with the rams down, bearing against steel slabs grouted in place. The needle-beams under the leaf are arranged in pairs, one beam on each side of a jack; a yoke across the top (closed end) of the cylinder passes through the slotted ends of link bars on each side of the jack; the lower end of each link bar fits between the forked end of a needle-beam; a pin through the fork and link bar completes the connection; and the weight of the leaf is carried on its flange-like bottom edge. Details of the jack-and-needle-beam assembly are shown in Fig. 6, and a typical set of three jacks is shown in Fig. 7.

FIG. 6.—ARRANGEMENT OF JACKS

A mixture of switch oil and transformer oil is the hydraulic medium used to operate the jacks, and pressure is supplied by an electrically driven pump mounted on a detachable platform on the down-stream side of the leaf. The twelve jacks are interconnected to this pumping unit.

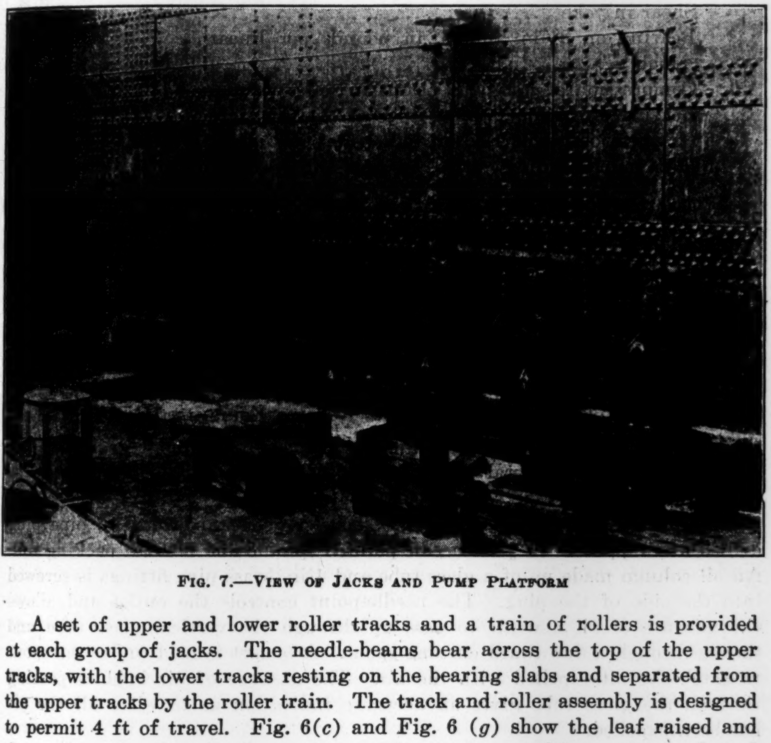

FIG. 7.—VIEW OF JACKS AND PUMP PLATFORM

A set of upper and lower roller tracks and a train of rollers is provided at each group of jacks. The needle-beams bear across the top of the upper tracks, with the lower tracks resting on the bearing slabs and separated from the upper tracks by the roller train. The track and roller assembly is designed to permit 4 ft of travel. Fig. 6(*c*) and Fig. 6 (*g*) show the leaf raised and the tracks and rollers in place. Overturning is prevented by a structural steel guide-frame and four steel cables anchored in the lock-walls.

Some of the principal unit stresses (in pounds per square inch) applying to this problem are, as follows:

	Normal	Maximum
Bearing between bottom of leaf and needle-beam	7 050	10 575
Extreme Fiber Stress in Needle-Beam When:		
Lifted by jacks	20 600	30 900
Resting on shims	26 000	40 350
Resting on tracks	8 000	12 000
Shearing stress in pins	8 300	12 450
Bearing in pins	15 700	23 550
Bending in pins	30 000	45 000

	Normal	Maximum
Tension in link at pin-hole	13 000	19 500
Bearing at top of slot	21 100	30 150
Double shear below pin-hole	8 290	12 425
Extreme fiber stress in yoke	18 850	28 275
Shear in yoke	6 870	10 505
Bearing on 2½-in. rollers, in pounds per linear inch	(1 000)	.....
Compression of web of H-beams in roller nests	3 140	4 710
Bearing on masonry under edge of bearing slabs when load is carried on follow-up blocking	400	600
Maximum bending stress in rams due to all lateral loads	.....	9 220
Oil working pressure in jacks	5 600	8 400

In the foregoing tabulation normal stresses are those caused by all parts functioning perfectly with an even distribution of the load; maximum stresses are those derived by the conditions of design. Due to the high unit stresses anticipated and the lack of clearance for enlarging the sections, the yokes, links, link-pins, and needle-beams were made of forged nickel-manganese steel.

Details of Lifting and Rolling Equipment

Jack Cylinders.—The jack cylinders are medium grade steel castings, made according to Federal Specifications No. 170, with the dimensions as shown in Fig. 6(*c*).

The bleeder valves shown in Fig. 7 consist of a standard ½-in. pipe plug drilled and tapped for a ¼-in. needle-pointed spindle and a small packing nut. An oil column made up of a glass tube and ¼-in. brass pipe fittings is screwed into the side of the plug. The needle-point controls the outlet and allows the mixture of oil and air to pass up through the vertical glass tube and thence through a downward curving spout. A bucket is held under the spout to catch the oil expelled with the air. The absence of air bubbles passing through the glass tube gives an accurate indication as to when all the air has been expelled.

A gag screw, placed near the open end of the cylinder, can be tightened against a Tobin bronze gag plug to prevent the ram from falling out during handling. A felt wiping ring is fastened around the open end of the cylinder to prevent small particles of grit from working up between the cylinder and the ram.

Jack Rams.—The rams (see Fig. 6(*c*)) are of rolled carbon-steel bar stock (Society of Automotive Engineers Standard No. 2315) ground to a diameter 0.008 in. less than the bore of the cylinder, and case-hardened No attempt was made to hold the diameters of the rams and cylinders to an exact dimension, but each ram was required to fit its own cylinder with the specified clearance.

The original jacks were provided with rams 0.005 in. smaller than the bore and were not case-hardened. The cylinder did not have the felt wiping ring and, consequently, small particles of grit entered when the jacks were lowered. When one of these small particles was caught it would raise a small sliver of metal on the ram. As the ram was pushed out, this sliver would gradually roll into a ball and "freeze" the jack. The jacks functioned perfectly at Miraflores and not a single case of scored rams or cylinders was evident.

Pumping System.—Pressure is supplied by a vertical triplex pump having a ½-in. bore and a 4-in. stroke. The driving force is a 5-hp motor acting through a reduction gear giving a speed of 37 rpm. The unit is compactly mounted on a roofed platform which is hooked to the down-stream side of the leaf (a part of this platform is visible in Fig. 7). The high-pressure lines lead through calibrated gauges and flexible couplings to pipe lines, fastened to the leaf and leading to each end; thence they lead through the leaf to the up-stream side. Tee connections and short lengths of pipe lead from the main pressure line on the leaf to stop-valves, and thence through flexible couplings to the individual jacks. The stop-valves at the jacks (see Fig. 7) are normally open and are used only in testing or for cutting out individual jacks in case of their failure.

The pipes on the platform are arranged so that all valves are within reach of one man. The miter end, which is the lighter, tends to raise faster than the quoin so that it is necessary to throttle, slightly, the valves controlling the miter end. A spirit-level fastened to the gate enables the operator to raise both ends at the same rate, approximately 0.3 in. per min. The jacks are interconnected so that no jack can carry more than one-twelfth of the total load.

The high-pressure line is an extra heavy steel pipe, ½ in. in inside diameter, with forged fittings and especially built valves, all of which were subjected to a pressure inspection test before acceptance. The threads were machine-cut on the job, in order to insure a perfect fit and a thick solution of shellac was found to be the most satisfactory medium for sealing the threaded joints. The flexible couplings are of annealed copper tubing, ¼ in. in inside diameter, with brass nipples soldered to the ends. Annealed copper washers were used in all couplings and unions because they had proved more satisfactory than either leather or tin, and little trouble was experienced with leaking connections.

One pump platform and one set of jacks serves two leaves. The jacks are uncoupled and assembled on the other leaf of the pair as soon as one leaf has been raised, but the pump platform is left in place until the leaf has been pushed from the wall. In transferring the platform to the other leaf, it is necessary to uncouple only the flexible joint at the edge and thus leave the fixed piping in place. The original pumping unit was placed on the floor of the sump on the up-stream side of the gates. The maze of pipes interfered considerably with the assembly of the rolling equipment. The present unit is compact, out of the way, and functions perfectly.

Shims.—Banca tin shims were used at all points of bearing in the lifting system, to overcome any uneven bearing and to insure an even distribution of the load by crushing. They were placed between the jacks and the yokes, between the yokes and the link bars, and between the needle-beams and the gate. Their effectiveness was thoroughly demonstrated, some being crushed to one-half their original thickness, while others were only slightly dented.

Banca tin was selected after a number of compression tests had also been made on solid and perforated specimens of aluminum, copper, lead, and type metal.

Roller Tracks.—The roller tracks are centered under the edge of the leaf, which necessitates assembling them around the extended jack rams. To permit this assembly, the inside flanges of the outer beams and the outside flanges of the inner beams are cut back to the web in three places. The upper and lower tracks are alike except for the location of these holes for the jack rams. Hand holes are cut through the webs of the outer beams at each jack location. These holes are necessary to permit the removal and replacement of the rocker disks under the rams. The three inner beams are bolted together in a unit so that the outer beams can be slipped into place quickly. The four upper tracks are made to move as a unit by connecting the up-stream and down-stream tracks to each other, and then connecting the quoin and miter ends by two H-beams.

The original tracks were not provided with hand holes and were only loosely bolted together. The difficulty experienced in assembling the original tracks was overcome by bolting the inner beams together and providing separate bolts for the outer beams.

Bearing-Blocks.—For the lifting and rolling operations the leaves are fixed in a partly open position, so as to allow sufficient room for scaffolds on the miter ends of the leaves after they had been pushed from the wall. In this position, each leaf partly overhangs the sump. A pair of bearing-blocks (made up of plates and angles) was provided under the miter end of each leaf to overcome the difference in elevation. One block in each pair has one corner cut off diagonally, and is slightly shorter, so that it may be placed parallel to the line of rolling and against the arched sill. A leveling screw is placed at each corner of the blocks making it a simple matter to bring them quickly and easily to grade. Punch-marks in the top plates indicate the longitudinal and transverse center lines of the jacks. The larger block of the pair weighs 14 980 lb; the smaller, 12 630 lb.

The original blocks were steel boxes set in place and filled with concrete, which made them so heavy that they were extremely difficult to remove with the available equipment. These old blocks were "scrapped" and the new all-steel blocks are easily placed in approximate position, later to be removed, by two electric cranes.

Bearing Slabs.—A rolled-steel bearing slab, (see Fig. 6(*g*)) is placed at each group of jacks. Three counterbores (Fig. 6(*c*)) are cut in the top of each slab to serve as recesses for the rocker disks under the jack rams. Eight leveling screws, one on each corner, and four along the center line, serve to keep the slab level while it is being grouted in place. The center lines of the jacks are indicated by punch-marks. The two slabs at the quoin end rest directly on the concrete sill; and the up-stream miter slab is supported entirely on the bearing-block, but the down-stream slab bears partly on the bearing-block and partly on the sill.

Guide-Frame and Cables.—The guide-frame shown in Fig. 8 is provided as a safety measure against possible overturning. It is designed in accordance with the specifications for steel railway bridges of the American Railway Engineering Association. The wall end of the frame is pinned to a casting that is held in place by a large jack-bolt and a 4-in. pin through a corbel of the leaf recess cover. The other end, equipped with rollers, rests on the leaf and is provided with a 4-ft slot to permit the leaf to travel as it is pushed from the wall. A casting that holds a spherical-headed pin is bolted to the top center of the leaf. This pin is provided with a square nut, made in halves and bolted together around the spherical head. The nut travels in the guide-frame slot when the leaf is pushed from the wall.

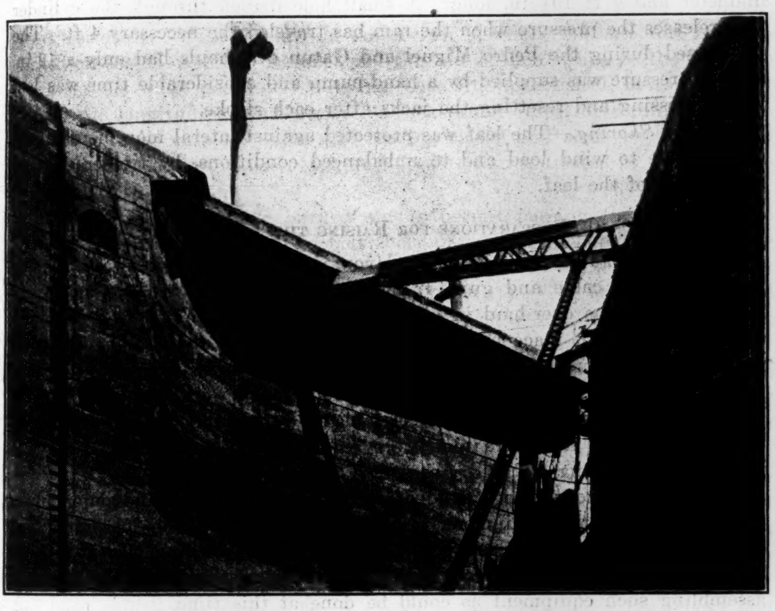

FIG. 8.—GUIDE-FRAME TO PREVENT OVERTURNING.

Four 1¼-in., galvanized, extra strong, plow-steel cables are fastened to the leaf with turnbuckles and anchored in the lock walls, two up stream and two down stream (see Fig. 8). These cables are used to correct slight lateral deflections during raising, lowering, and moving, the guide-frame being depended upon in case of emergency.

Pusher Jacks.—The leaves are pushed from the wall by two hydraulic jacks, one on each side of the leaf, which are suspended from the H-beams that connect the upper miter tracks to the upper quoin tracks. These jacks are interconnected, and pressure is supplied by the same pumping unit used in raising the leaf. The jacks, with rams permitting a 4-ft stroke, roll the leaf the required distance with one continuous movement.

The jack cylinder is a 5-ft section of 3-in., double, extra heavy, lap-welded, steel pipe. It is closed at one end by a plug and a bearing head welded in place. The bore is 2.425 in. in diameter with a solid steel ram, 2.410 in. in diameter and 4 ft 10½ in. long. A small hole drilled through the cylinder wall releases the pressure when the ram has traveled the necessary 4 ft. The jacks used during the Pedro Miguel and Gatun over-hauls had only a 12-in. stroke; pressure was supplied by a hand-pump and considerable time was lost in compressing and resetting the jacks after each stroke.

Timber Shoring.—The leaf was protected against lateral movement at the bottom, due to wind load and to unbalanced conditions, by timber shoring at the ends of the leaf.

Preparations for Raising the Leaves

Layout on the Lock-Walls.—The layout on top of the lock-walls for the location of the cable and guide-frame anchors (see Fig. 8) was made six months before the over-haul in order to allow the anchors to be completely set and grouted in place before beginning the actual work. The line and position of each anchor were referenced carefully to brass plugs grouted into the concrete and center-punched. This preliminary work was done largely by the operating forces in the wet season and during lulls in traffic through the Canal. Very few extra men were required, and no valuable time was lost at the beginning of the dry season.

Other preparatory work included: (*a*) Testing the jacks and pump unit; (*b*) distributing the equipment to its proper place on the lock-wall; (*c*) erecting and stocking temporary tool sheds and time-keeping offices; (*d*) installing field telephones at convenient points along the lock-wall; and (*e*) assembling such equipment as could be done at this time.

The equipment was distributed in an orderly manner by assigning a letter and a color to each pair of leaves. Each piece of equipment was stenciled with its proper mark as soon as it was received. Two electric cranes, converted from towing locomotives, and capable of ascending or descending the ramps, were used for much of this distribution work.

Layout on the Chamber Floor.—As soon as the weather indicated the beginning of the dry season, a floating caisson was placed in position and sunk at low tide. The water remaining in the chambers (approximately 10 ft in the upper lock and 41 ft in the lower lock) was pumped out by four electrically driven centrifugal pumps in the caisson. While the chambers were being unwatered, elevators were placed in position and small jib cranes were erected on the tops of the leaves at the miter and quoin ends.

Work began in the upper chamber as soon as it was dry. The sills were cleaned of mud and the water was pumped out of the sumps. The clapping-sill on the leaf and its lower retaining angle (see Fig. 5) were removed and the bottom and lower part of the leaf scraped and cleaned.

The down-stream face of the leaf served as the base line for the location of the bearing-blocks and slabs. The correct position of the base line was located by swinging the gate to the position fixed for the jacking and rolling operations. This position is determined by a direct measurement from a brass plug that indicates the center line of the guide-frame anchor, to the center of the spherical-headed pin on the gate. The position of the leaf is checked carefully because a mistake in this measurement would delay the work seriously. With the leaf in the correct position, the base line is established on the floor of the chamber and the leaf is then swung to the full open (against the wall) position. With the base line established, brass plugs are set on the longitudinal and transverse jack center lines for reference points. The area to be chipped under the bearing-blocks and slabs is next marked out, and the location of each jack and needle-beam indicated by punch-marks on the leaf.

Certain rivets must be burned out to permit passing the high-pressure piping through the leaf and to bolt the pump platform hangers (Fig. 7) in place. Sections of the sill angle are burned back to allow the jacks to be placed close to the face of the leaf (see Fig. 6(*g*)). The sections of the sill to be "burned" are marked with white paint; those cut from the angle are saved and later welded into place.

The bottom edge of the leaf is milled at each needle-beam location to insure a perfect bearing between the beams and leaf. A horizontal reference line, for the milling machine, is marked on the leaf from a bench-mark established in the sump.

The bearing slabs (Fig. 6(*g*)) are set with their tops only slightly above the level of the concrete sill, making it necessary to chip a recess in the sill for each of the quoin slabs. Because the depths of the sumps vary in each lock, it is necessary to build a concrete mat under the bearing-blocks in order to bring them to their proper elevation. As soon as the leaf layout has been completed, workers begin chipping the areas under the blocks and slabs. After the blocks have been placed in correct position and elevation, the mat is formed by pouring cement mortar between the bottom of the block and the floor of the sump. The mortar consists of 1 bag of cement to 2 sacks of sand, with 2½ lb of calcium chloride for each bag of cement. Three vertical 2-in. pipes through the blocks acted as vents and prevented the formation of air pockets.

The four bearing slabs were carefully leveled (the permissible variation being $\frac{1}{64}$ in.) and checked before and after they were grouted in place. The correct position of the slabs and blocks was easily established by bringing the punch-marks on them to piano wires stretched between the reference plugs.

Assembling and Testing Equipment.—As soon as the slabs were set and the milling was completed, the leaf was swung to the jacking position and the clearance between the milled bottom of the leaf and the slabs was carefully checked. A difference of $\frac{1}{16}$ in. in level would put undue stress in the equipment with the possibility of failure due to: (1) Crushing the edge of the leaf; (2) bending a needle-beam; or (3) crushing the webs of the roller-track beams. The few slight differences were corrected by spot-welding thin steel shims to the bottom of the leaf (see Fig. 6(*g*)). The needle-beams were then placed and connected to the jacks, the pump platform was hung in place and connected to the fixed piping, and the timber shoring set in place. The guide-frame was next placed in position, the cables were attached, and the leaf-operating strut was removed. At this point the jacking equipment was ready for test.

Each pair of jacks on the same needle-beam was tested separately, the pressure being raised gradually to 105 tons per jack, which was equal to a 50% over-load. After this test, each group of three jacks (Fig. 7) was tested to the same pressure, during which levels were taken on the slab under the jacks. Occasionally, a deflection of $\frac{1}{64}$ in. would be recorded with a load of 315 tons on the slab, but in most cases no deflection could be observed. Any leaking connections were tightened and the valve stems repacked if necessary.

The next step was to pull the yoke-pin at the top of the leaf. The jacks were used to lift the miter end slightly which allowed the pin to slip out easily. Then the wedges that key the yoke to the anchorages were removed; some, being very tight, were dislodged with difficulty. Several methods were tried, but the most satisfactory proved to be the following: A pneumatic paving breaker with a square-end bit was held on the wedges until the vibrations had broken the rust film between them, and heavy driving wedges and follow-up blocking were then placed back of the key wedges. The driving wedges were struck with the hammer of a minature pile-driving rig operated by the jib crane on the quoin end of the leaf. The necessary effect was secured by allowing a 150-lb weight to fall approximately 6 ft inside a 4-in. pipe placed over the head of the driving wedge. Ten or twelve blows of this hammer were usually sufficient to start the key wedges. While these wedges were being driven, two-thirds of the weight of the leaf was carried by the jacks and the remainder by follow-up blocking under the ends of the needle-beams. A sling was placed around the yoke and the leaf was ready for raising.

RAISING THE LEAVES

With the standard equipment and the experience gained on previous overhauls, raising and rolling the leaves at Miraflores was largely a matter of routine. The end of each beam was blocked up during raising and lowering so that if the oil pressure failed the leaf would not be dropped more than $\frac{1}{4}$ in. One machinist and two helpers were stationed at each group of jacks while the supervisor assumed a position directly under the leaf so that each group was easily visible. The lifting was started with $\frac{3}{4}$ in. of blocking under the beams, and as the leaf was raised, the blocking was changed at a whistle signal from the supervisor. When each machinist had signaled a clearance of slightly more than $\frac{1}{4}$ in., the whistle was blown and the four groups changed the blocks together, the $\frac{1}{4}$-in. blocks being removed and a $\frac{1}{2}$-in. block put in place, making a total of 1 in. At the next whistle, the $\frac{1}{4}$-in.

block was replaced until another $\frac{1}{2}$-in. block could be added. This procedure was continued until ten $\frac{1}{2}$-in. blocks were in place. A solid 5-in. block was then substituted, one block at a time, for the set of $\frac{1}{2}$-in. blocks. The leaf was then lowered, the pressure released, the wedges back of the jacks were removed, and the jacks reseated by hitting them lightly with a block of wood. A slight pressure was then put on the rams and the aligning wedges were replaced. The raising was continued as before until a total of 15 in. of blocking was in place, thus making a net lift of $14\frac{1}{4}$ in.

The re-alignment of the jacks was important because they are subjected to severe lateral thrusts if their axes of travel are not parallel. The average pressure required to lift the 82-ft leaves was 70 tons per jack (5 900 lb per sq in.), or a total of 840 tons, including the weight of the equipment and friction in the jacks. Fig. 7 shows the leaf partly raised and the follow-up blocking in place.

During the raising, rolling, and lowering operations, the lateral movement was checked with a transit on a line parallel to the down-stream face of the leaf. Observations were taken on targets clamped to webs of the reaction castings and perpendicular to the face. The targets consisted of 6-in. sections of a folding rule fastened to an arm welded to a C-clamp and deflections of $\frac{1}{32}$ in. could be read easily. The unbalanced loads were controlled by proper tension in the stay cables; a signal from the transitman would indicate the direction of any lateral movement to a machinist stationed on the guide-frame who, in turn, would direct helpers, one at each turnbuckle, as to the proper tension in any cable. In this manner, the guide-frame was kept free for any emergency.

Rolling the Leaf

With the leaf raised to its full height, the weight was carried partly by the jacks and partly by the follow-up blocking. The upper and lower groups of inner H-beams and the rollers were next installed. The full weight was then taken entirely by the jacks; the follow-up blocking was removed, the outer H-beams were bolted on, the guide-bars placed over the ends of the rollers, and the beams, tying the upper tracks together, bolted in place.

To make certain that the gate would move away from the wall on the predetermined line, it was essential that the rollers be parallel and their axes normal to that line. The front and rear rollers of each train were omitted and aligning, or dummy, rollers inserted in their place. These were long enough (9 ft 8 in.) to extend through the up-stream and down-stream guide-bars of the roller train, thus insuring that the rollers in opposite trains were parallel. The axes were made normal to the line of rolling by bringing the up-stream and down-stream ends of the dummy equi-distant from the punch-marks which indicate the transverse center lines of the jacks. The dummy rollers were then withdrawn and the regular rollers inserted. Then the leaf was landed on the tracks and preparations were made for rolling it.

With the leaf resting on the roller assembly, the lifting jacks were removed, compressed, and placed near the other leaf of the pair. The pusher jacks were hung in place (see Fig. 9), and connected to the pumping unit, and the timber shoring at the ends of the leaf was removed. Wood-blocking, consisting of 12-in. lengths of 6 by 6-in. timber, was then placed between the lower miter-end tracks and a striking point on the H-beams. These blocks were removed, one by one, as the leaf moved from the wall, thus providing a safety measure against the possibility of the leaf running away.

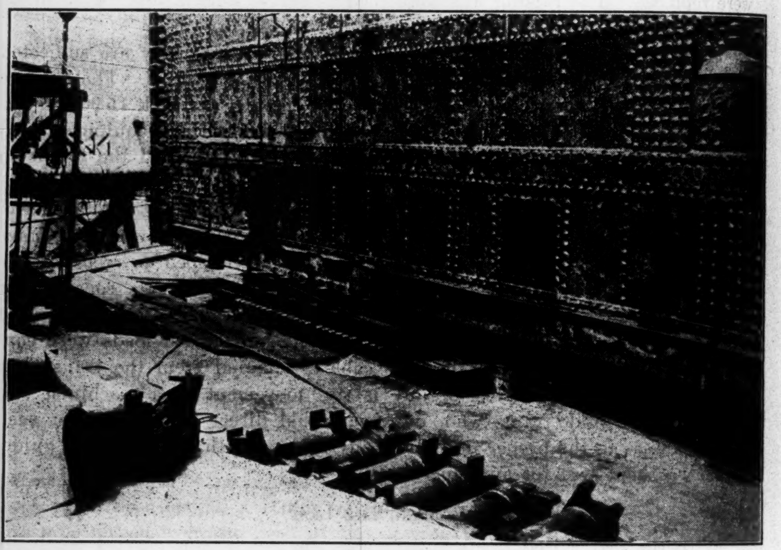

FIG. 9.—DOWN-STREAM MITER END OF LEAF RESTING ON ROLLER TRUCK.

The stay cables were carefully regulated and were arranged so that the arc of travel was divided; that is, when the leaf was 2 ft from the wall, the cables on the opposite sides of the leaf at each end were in line with each other and normal to the axis of the leaf. When the leaf had been rolled the required 4 ft, it was securely blocked in place.

The average pressure required to start a leaf was 5 tons per jack, or 10 tons in all; with the leaf rolling, the pressure dropped to $3\frac{1}{2}$ tons per jack. As an indication of the reduction in time required for raising and rolling, the following comparison is of interest:

	Raising time	Lowering time
Pedro Miguel, 1929	2 hr 55 min	37 min
Miraflores, 1933	1 hr 10 min	10 min

The leaves were rolled back and lowered in the same manner, but in reverse order. During lowering, they were landed on the follow-up blocking every $\frac{1}{2}$ in. of the last 5 in. of lowering. This was necessary because the jacks had to be reseated frequently as the leaf moved slightly away from the wall in settling over the new pintle. Fig. 9 shows the down-stream miter end resting on the roller tracks and the pusher jacks in place for moving a leaf back to the wall.

Removal of Old Bearings

Pintle and Bushing.—The pintles and pintle bushings were removed from their sockets by the use of a cast-steel jacking ring. Two concentric rows of twelve equally spaced holes were drilled around this ring; the outer row was tapped for $1\frac{1}{4}$-in. bolts, used as jacking-screws; and the inner row of $\frac{15}{16}$-in. holes was provided for use in removing the bushing.

This ring was placed over, and welded to, the pintle; two horizontal 1-in. dowels, passed through the ring and into dowel holes in the pintle, helped to hold it in place. Turning the jack-screws against the lower pintle casting (Fig. 3) started the pintle and raised it so that it could be lifted out with the jib crane.

Although the bushings are a shrink fit in the upper casting, no difficulty was found in removing them. The following method was the most efficient: Twelve equally spaced holes were drilled and tapped into the lower edge of the bushing. Short bolts, $\frac{7}{8}$ in. in diameter, passed through the ring and set into these holes held the ring in place. The jack-screws in the outer circle bore against the upper casting (see Fig. 3). A hole was then drilled through the top of the bushing and tapped for a $1\frac{1}{4}$-in. pipe nipple. Flexible tubing was led from this fitting to a hand-operated hydraulic pump. Oil forced between the bushing and casting under a pressure of 600 to 800 lb per sq in. was usually sufficient to start the bushing. The pumping was stopped when the leakage around the bushing became excessive and the removal was completed with the ring and jack-screws.

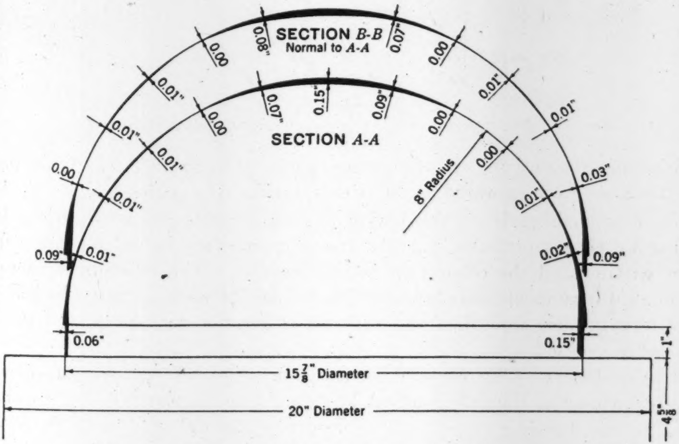

FIG. 10.—SECTION SHOWING TYPICAL WEAR ON PINTLE.

The upper pintle castings were examined carefully for evidence of movement or shearing of bolts. The loose castings were tightened by removing the old fastenings and reaming the holes for bolts and rivets of greater diameter. The old pintles and bushings were marked with the leaf number, and lines were marked on them to indicate planes parallel and perpendicular to the lock-wall. Later, the amount of wear on each pintle and bushing was measured along these lines. Figs. 10 and 11 show typical wear on the pintle and bushing, respectively, in the twenty years, 1913 to 1933. It is estimated that the gates were operated 71 600 times during this period.

FIG. 11.—SECTION SHOWING TYPICAL WEAR ON PINTLE BUSHING.

The new bushing is provided with five oil grooves and is prevented from turning by three vertical $\frac{3}{4}$-in. pins inserted in dowel-holes, one-half drilled in the casting and the other half in the bushing. The new pintle (actually an old pintle re-machined) was not placed in its socket until the leaf was ready to roll back, and then the socket was heavily red-leaded and the ball thoroughly greased.

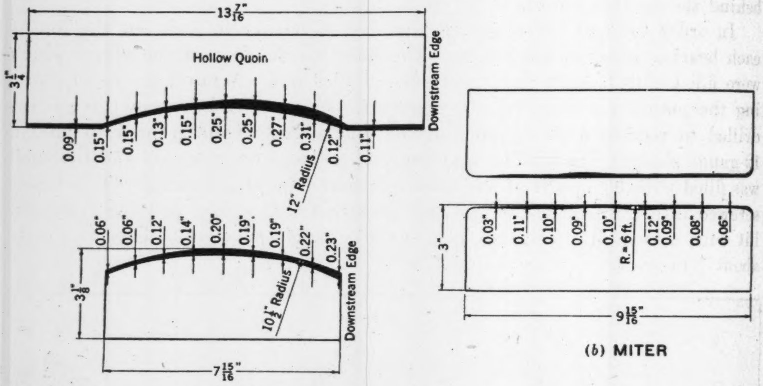
Bearing-Plates.—The removal of the bearing-plates was one of the most difficult features of the first renewal in 1929. This involved: (1) Strongbacks bolted to the bearing-plates; (2) jack-screws through the strongbacks and bearing against the reaction castings; (3) jack-bolts placed between the ends of the stud-bolts and the castings; and (4) hand-driven wedges to remove the plates. It was a slow and laborious method. Details of plate fastenings are shown in Fig. 2.

The bearing-plates on the gates at Miraflores were removed by a vanadium steel wedge 13 ft long, with a taper of $\frac{3}{8}$ in. per ft, which had an offset head keyed to a special driving head in an air-actuated pile-hammer. The wedge and hammer are shown in Fig. 12. By keying the wedge to the hammer, one crane handled both, while another crane handled the plates as they were taken off. The offset on the wedge and driving head permitted the hammer to slide down the face of the reaction castings as the wedge was driven behind the bearing-plates.

In order to start the wedge, it was first necessary to jack out the top of each bearing piece at least $\frac{1}{8}$ in. The holes in the face of the plates which were filled with babbitt metal were also drilled out. A novel means of starting the plates was tried on the last leaf repaired. A heavy pipe plug was drilled to receive a firing-pin and the end slightly counterbored to hold a 12-gauge shotgun shell. The wadding and pellets were removed and the shell was filled with $9\frac{3}{4}$ grains of smokeless powder. The plug holding the shell was screwed into the top hole in the face of each bearing-plate and the firing-pin hit with a swinging weight. The explosion was sufficient to blow the plate about $\frac{3}{4}$ in. away from the babbitt-metal backing.

FIG. 12.—VANADIUM STEEL WEDGE AND HAMMER USED TO REMOVE BEARING-PLATES AT MIRAFLORES

The wedge and hammer were not used in removing the bearing-plates in the wall (hollow quoins) because of the possibility of loosening the reaction castings set in the concrete wall. Heavy strongbacks, made of a 4 by 4-in. bar, drilled and tapped for two capstan head jacking-bolts, were most satisfactory for removing these plates. They were provided with two expanding-jaw clamps, centered to fit into the counterbored nut recesses of the hollow quoin-plates. Although this method was slow, the results were entirely satisfactory. Each bearing-plate was marked and the wear measured at a later date. Fig. 13 shows typical wear on the bearing-plates.



(b) MITER

(a) QUOIN

FIG. 13.—TYPICAL WEAR ON QUOIN-PLATES.

Old Babbitt Metal.—The babbitt metal back of the bearing-plates was removed, the castings were cleaned, and the burrs formed by the original caulking removed by grinding. The new bearing pieces were then loosely bolted in place, preparatory to their final setting.

The babbitt metal is held in place by dovetailed grooves making it necessary to cut it out of the castings. A pneumatic paving breaker with a special cutting-bit proved very efficient in removing it. The bit was a blacksmith forging of T-section drawn to a point and the upstanding stem ground to a knife-edge. With the bit started between the babbitt metal and the casting, it was possible to drive this cutting tool down the full height of the leaf. No one was allowed near the leaf and the babbitt metal was allowed to fall to the chamber floor as it was cut from the casting.

The bearing-plates were removed and reset from double-decked scaffolds which were raised and lowered by the jib cranes. One scaffold, shaped to fit around the reaction castings, was sufficient for the miter end, but three were required at the quoin end; one shaped to fit between the gate and the wall, and one each for the up-stream and down-stream sides when the leaves had been rolled back. The scaffolds were suspended by chains hung from the ends of an H-beam which was fastened to the top of the top reaction casting and extended over the sides of the leaf. The scaffolds could be held at any desired elevation by passing pins through chain-guides on the scaffold and the chains.

Locomotive axles, quills, and car-wheels and lengths of valve stems, which had been salvaged from obsolete equipment, were utilized in building the jib cranes. These cranes, each with a capacity of 3 000 lb, at a radius of 13 ft, could be swung in a full circle and were equipped with a single-drum air hoist. The lower portion of one of them may be seen in Fig. 12.

Adjustment of New Bearing-Plates

The new bearing-plates (the majority of which were old plates salvaged from the Gatun repairs and re-machined) were set in essentially the same manner as in the original construction. The attempt was made to set them within 0.003 in. of their correct position, but no error greater than 0.005 in. was allowed. The plates were set in the following order: Hollow quoins, quoin-plates, and miter-plates.

Hollow Quoins.—The hollow quoins were set by gauges from a vertical piano wire. The correct position of this reference line was established with the aid of a device for centering pintles designed by engineers on the Panama Canal and consists of two parts: The cross-bar center (Fig. 14), which was set in the pintle socket; and the adjustable slide (Fig. 15), which was supported by a bent channel secured in the yoke casting. The slide was drilled with three accurately centered 0.033-in. holes, with a tensioning screw provided near each hole. One hole was at the pintle center; one, 6 in. from the face of the hollow quoins; and the other, 12 in. from the same face.

The steps in setting the device follow: (1) The cross-bar center, or "spider," was centered and clamped in the pintle socket; (2) the lower end of a No. 13 piano wire was fastened in the center of the spider and the upper end passed through the pintle center of the adjustable slide; (3) the piano wire was carefully plumbed, bottom to top, with a transit equipped with a striding level, and it was adjusted at the top by moving the slide; (4) the transit was brought to the top of the lock-wall and set up on a line normal to the chamber axis by transiting-in on the line established by the pintle center of the opposite leaf and the pintle center of the adjustable slide; (5) the center lines on the uprights at each end of the slide were brought to the transit line by revolving the slide around the center wire (this movement controlled the position of the projecting arm of the slide on which are the holes for the reference wires); (6) the reference wire was passed downward through the hole, 12 in. from the face of the plates, and fastened to the end of a projecting arm of the spider; (7) this line was plumbed, from the top to the bottom, and securely fastened (this wire is adjusted at the end of the projecting arm); and (8) as soon as the correct position of the pintle center on the movable slide had been established, reference punch-marks were placed at several points on the yoke casting. These marks were used later in bringing the yoke to its correct position.

Although the hollow quoins may be set from either the 6-in. or the 12-in. wire, the latter was found to give more accurate results. The plates are set with gauges made of sectors of stainless steel, $\frac{1}{16}$ in. thick, and have the arc of the sector cut to the radius of the hollow quoins. Scratch-marks on the gauge indicate the edges of the concave face of the plates and the position of the reference line. The gauge is held horizontally between the face of the plates and the reference wire, and the plates are turned, by temporary set screws on the center line and the permanent stud-bolts along the edges (see Fig. 14), until the center scratch-mark coincides with the reference wire. Due to inaccuracies in the original setting of the reaction castings, it was impossible to set certain plates correctly without first planing the edges.

With the hollow quoins correctly adjusted, the babbitt metal backing was poured (as described later), the set screws were removed, the edges of the plates caulked, the nut recesses filled with concrete, and the plates thoroughly cleaned. The leaf was then rolled back and lowered. The task of keying the yoke and hinging the leaf was carefully supervised and inspected. The jacking equipment was then removed, the operating strut connected, and the leaf was free to swing.

Quoin-Plates.—The quoin-plates were set (by jacking them against the hollow quoins) with the leaf in a position 1 in. up stream from the true miter point. This setting provided a slightly closer contact between the quoin-bearings when the leaf was exactly mitered. The line of contact was centered on the hollow quoins, and the plates were then forced (with short jack-bolts between the ends of the plate studs and the reaction castings) against the hollow quoins until it was impossible to push a 0.005-in. feeler between the faces of the plates. The jack-bolts were essentially a $\frac{3}{4}$-in. hexagonal rod with one end tapped for a conical-pointed nut. The ends of the studs were countersunk to prevent the jacking nut from slipping off. In setting these quoin-plates, it was absolutely essential for the men on opposite sides of the leaf to work together, and they were provided with portable telephones for easy communication. To set the quoin-plates in the exceedingly cramped working space required some of the most arduous work of the entire over-haul. In order to pour the babbitt metal behind the plates, it was necessary to swing the leaf to the full open (against the wall) position.

Miter-Plates.—The miter-plates were set early in the morning, as follows: (1) Both leaves of the pair were brought to the miter point; (2) the top and bottom plates were set so that the thickness of the babbitt metal was the same on each; (3) the leaves were opened partly and a reference wire was stretched from top to bottom and 2 in. from the face of the plates on one leaf; (4) the plates were set by a 2-in. gauge from the reference wire, and the babbitt metal was poured; (5) at the same hour of a following morning, the leaves were mitered again; (6) the bottom plates of the second leaf were brought in contact with those of the first leaf and the top of the top plates was separated by a $\frac{1}{32}$-in. filler; and (7) the plates were set and babbitted. The effect of this setting was to form a V-shaped opening, $\frac{1}{32}$ in. wide at the top, which served to compensate slightly for the effects of temperature expansion and wear.

Pouring Babbitt Metal.—After each set of bearing-plates had been adjusted, the spaces behind the plates were filled with babbitt metal; this work of pouring the molten metal from the small and swinging scaffolds was the most dangerous operation of the over-haul.

The babbitt metal was heated in a double-ended, oil-burning, brick-lined, steel box furnace, placed on the chamber floor. Two openings were provided

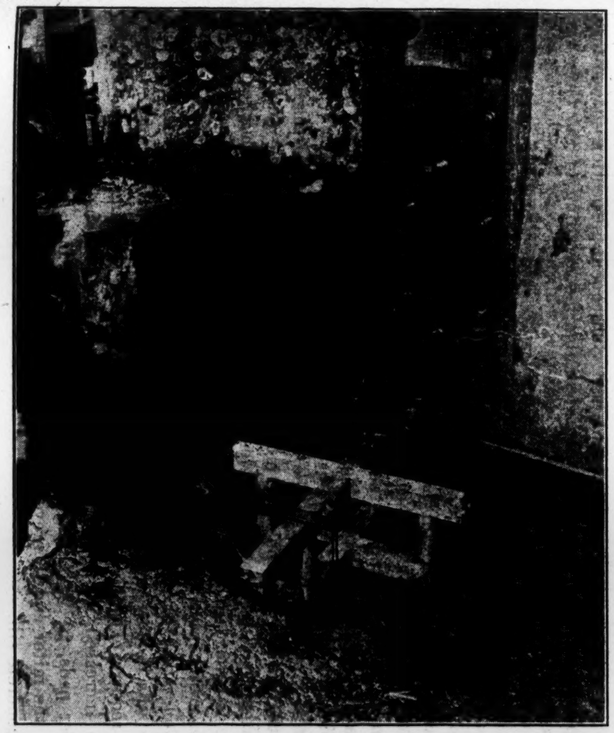


FIG. 14.—CROSS-BAR OF PINTLE CENTERING DEVICE SET IN PINTLE SOCKET.

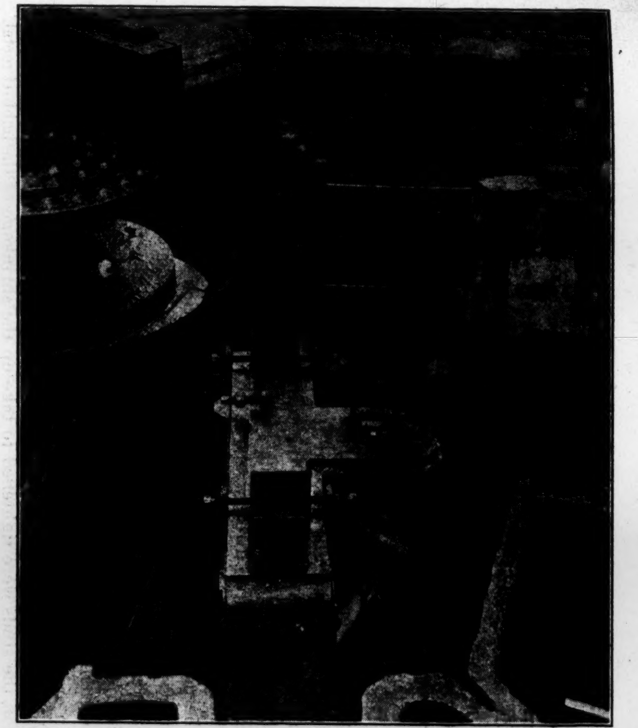

FIG. 15.—ADJUSTABLE SLIDE FOR PINTLE CENTERING DEVICE, SUPPORTED BY A BENT CHANNEL SECURED IN A YOKE CASTING.

in the top for the pots, the compartment under each pot being fired with separate air-oil burners, with the smoke flue in the center of the furnace.

The spaces behind the plates were heated by compressed air to dry out any moisture and to prevent the molten metal from cooling too rapidly. The air circulated through the coils in the flue and was conducted through a 1-in. pipe to another vertical pipe near the edge of the plates. The vertical pipe extended about 25 ft above the bottom plate and was provided with branches leading to tapped holes in the face of the bearing-plates. The lower plates were heated for about two hours before the workmen began pouring. Experience showed that it was necessary to pre-heat only the lower two or three plates rather than the entire height, as was done on the previous over-hauls. The heat from each pour was sufficient to increase the temperature, in the plates directly above, to a higher degree than was possible with hot air.

The metal was heated until a dry wooden stick thrust into it would ignite instantly. Four men were required on the scaffold during the pouring. A helper poured a small quantity of kerosene into the funnel just previous to pouring, and he was provided with a supply of wet clay for stopping leaks. The signalman and the crane operator were equipped with telephone head-sets in order to minimize the danger of a misunderstood hand signal.

When the plates had cooled, the asbestos caulking was removed, and the nuts on the studs were tightened to take up the shrinkage of the babbitt metal. The edges of the plates were then caulked with lead, and lead plugs driven into the holes in the face of the plates. Subsequent inspection showed that the plates had been set in so accurately that no grinding of the faces was necessary.

Changes to Original Gate Design

Automatic Pintle-Oiling Device.—In the original design no provision was made for oiling the pintle. The new bushings are provided with five oil grooves leading to an oil passage drilled through the bushing and upper pintle casting. An extra heavy 1-in. brass tube leads from this oil passage to an oil pump on top of the leaf, which is placed so that the plunger is actuated by the leaf-operating strut when the leaf approaches the miter position.

It is a question whether the life of the bearing-plates is increased by oiling the pintle. The bushing must yield with the wear on the quoin-plates in order that the leaves may close to secure the necessary arch effect when there is a head of water behind them. However, with oil on the pintles the leaves swing more smoothly.

Concrete Sills.—The fixed wooden sills (Fig. 5) were replaced with concrete sills because the wooden ones were subject to the attacks of the teredo and require expensive replacement. The wooden clapping sills on the gate were increased in thickness to allow for the additional trimming. Two rubber pads, $1\frac{1}{2}$ in. thick, were set 1 in. into the face of the clapping sill near the miter end to prevent the leaves from slamming too forcibly against the concrete sill.

Sealing Bead on Bearing-Plates.—To secure a truly water-tight bearing, projecting beads of babbitt metal were poured into small dovetailed grooves in the faces of the miter and quoin bearing-plates. This was the last operation before the water was let into the chamber. At the miter end, two grooves were located 2 in. each side of the center line of the plates on one leaf only. At the quoin end, one groove was placed 2⅜ in. down stream from the center of the quoin-plates on each leaf.

General Observations

This paper describes the various operations in reference to one leaf only. It should be understood, however, that three complete sets of equipment were provided, and that the bearings were renewed simultaneously on six leaves in each chamber. The work was done continuously by three 8-hr shifts, six days per week. Numerous flood-lights provided ample illumination for all night work with the exception of raising or lowering the leaves, which was done only in daylight.

Each group of leaves was in direct charge of a foreman, with a general supervisor responsible for the three groups. Engineers and inspectors on each shift were responsible for the correct layout, proper use of the equipment, and the final adjustment of the new bearings.

The following non-related comments are worthy of attention: (*a*) Extensometer readings, taken during the gate-raising, gave results that checked closely with the computed stresses; (*b*) the average cost per leaf (labor and material), was $14 340.77; and (*c*) at the conclusion of the Miraflores over-haul, the equipment was repainted, re-marked, and shipped to Gatun for storage until the next over-haul on those locks.

The equipment and methods for renewing the bearings on the Panama Canal gates have become practically standardized, and only very minor changes in detail are probable.

Acknowledgment

The plant and equipment for overhauling the gates were originally designed by E. S. Randolph, M. Am. Soc. C. E., and many of the improvements are due to his recommendations, made at the conclusion of the trial raising at Pedro Miguel. The unit stresses, as given in this paper, and other supporting data, are taken from Mr. Randolph's report to the Assistant Engineer of Maintenance of The Panama Canal, in 1929. The writer, as Junior Engineer, was in charge of engineering and inspection on one of the 8-hour shifts.

DISCUSSION

E. S. Randolph,[4] M. Am. Soc. C. E. (by letter).—The subject has been so well covered in this paper that there is little comment to offer. The first, or experimental, repairs conducted under the technical supervision of the writer, were reported in 1930.[5] It is gratifying to the engineer of the original equipment that much of it was still in use in 1933, after being previously used in 1929 and 1931. An important event in the 1931 operation was the test that was run as a preliminary drill and exercise for the apparatus and crew before attempting to lift a gate. Had not this test been run, there would have been serious trouble.

The preliminary test was made with all equipment for one gate assembled and a load of structural material instead of the gate. The test load was much lighter than the gate. It was noted that the travel of the jacks was at uneven rates. Examination showed scoring of the rams and cylinders in seven of the twelve jacks; one had a groove $\frac{3}{8}$ in. wide and $\frac{3}{32}$ in. deep; furthermore, foundry sand and some metal chips and cuttings from drilling and tapping operations were found in the cylinders of the jacks. New rams of case-hardened material were made; the cylinders were thoroughly cleaned; and felt wiping washers were provided at the end of each cylinder so as to fit tightly against the rams. The improved jacks were finally assembled in the machine shop and kept in a locker until used; not the least trouble from scoring was experienced thereafter.

Another preliminary test was made by placing two jacks with rams in opposition. Yokes and links, as provided for regular operation, were used, and additional double links completed the tension members. The jacks were then loaded to 110 tons of 2 000 lb without any signs of distress.

While being constructed, more clearance under the gates would have facilitated their removal; and wider sills would have made special foundations for the jacks unnecessary. The gates were erected in a raised position, moved against the lock-wall, lowered over the pintle bearing, and yokes were fitted to the top. While being erected and moved, each leaf was supported on two steel falsework frames, one on each side. These frames were supported on wedges for lowering the leaves, and the wedges rested on roller nests for moving the gates to the walls. Consideration was given to re-assembling these frames for repairing the gates with jacks instead of wedges, but this was found to be too laborious for the work intended. A description of the gates and their erection was published[6] in book form in 1916.

Clinton Morse,[7] Assoc. M. Am. Soc. C. E. (by letter).—An item that was not clearly emphasized in the paper was the low cost of the gate-raising equipment. The total cost to date (1935) of the three sets of equipment is

$151 656.94. This amount includes the cost of such minor changes as were considered necessary in the interests of safety and economy. Since the equipment will be used in raising all the leaves, 92 in number, it is proper to pro-rate this cost against each leaf, making a cost per leaf of $1 648.44.

The writer wishes to express his appreciation of Mr. Randolph's comments concerning the preliminary drill and tests of equipment which were made previous to the 1929 gate-raising.

WATER-POWER DEVELOPMENT OF THE ST. LAWRENCE RIVER[1]

By Daniel W. Mead,[2] Hon. M. Am. Soc. C. E.

With Discussion by Messrs. T. H. Hogg, Theron M. Ripley, W. S. Lee, Frank E. Bonner, Rufus W. Putnam, James W. Rickey, Walter M. Smith, J. W. Beardsley, L. F. Harza, Adolph J. Ackerman, and Daniel W. Mead.

Synopsis

An analysis of the proposed official plans for the development of water power along the International Section of the St. Lawrence River, is contained in this paper. Since the Wooten-Bowden Report in 1921 on the development of the proposed St. Lawrence Waterway, there has been controversy between the United States and Canadian members of the various engineering boards that have made reports on the development of the International Section, in regard to the relative merits of a single-stage and a two-stage plan of development of the water-power resources. The American engineers have consistently advocated a single-stage plan, and the Canadian engineers have consistently advocated a two-stage plan.

In December, 1931, the Joint Board of Engineers (United States and Canada), consisting of an entirely new membership of the United States Section and of the original members of the Canadian Section, was reconvened and in March, 1932, was instructed to reach an agreement on a plan for early execution. On April 9, 1932, the Joint Board submitted the "Reconvened" Report on which the treaty now under consideration is based.

If this analysis is correct, the value of the two-stage plan will be nearly $95 000 000 less than the alternate Joint Board plan for a single-stage development at Barnhart Island, and at least $154 000 000 less than the New

---

[2] Prof. Emeritus, Hydr. and San. Eng., Univ. of Wisconsin; Cons. Engr., Madison, Wis.

York single-stage plan. The advantages of the various plans are not adequately discussed in the report of the Joint Board, and no reference is made in the Joint Board Reconvened Report as to why the two-stage plan is recommended. The reasons set forth in the Conference Report (Canadian) seem entirely inadequate to offset the aforementioned disadvantages. If the reports and this analysis is correct, it will be a very serious mistake and a misfortune to both the United States and Canada, in the writer's opinion, if the treaty now pending is ratified on the basis of the Joint Board Reconvened Report.

INTRODUCTION

With his limited knowledge of the International Rapids Section of the St. Lawrence River, the writer, ordinarily, would not have presumed to discuss this important question. As a disinterested engineer familiar with water-power development, he was requested by the Power Division of the Society to examine the various reports on this subject and to analyze the comparative values of the principal plans on the basis of these reports.

A proper report should be so prepared that it will give any intelligent engineer, familiar with the character of the work considered, fair understanding of the reasons for the recommendations made in the report. As an American citizen, and especially as an hydraulic engineer interested in water-power development, the writer believes that it is his right to know, in the case at hand, the reasons for the recommendations, on the basis of which an important treaty is expected to be consummated, and to judge of the validity of such recommendations from the information furnished in these reports.

If his interpretation of the conditions is faulty or if his conclusions are in error, he believes that he is entitled to have such conditions explained and such errors corrected. His mind is entirely open on the entire subject, but he believes that the people of the United States and Canada who are asked to spend hundreds of millions of dollars on this project are entitled to something better than an opinion, no matter from how distinguished a source, and to consider this project on the broader economic basis on which the writer has attempted to examine it.

The investigation leading to the treaty, now (1933) before the United States Congress, began with the work of Col. W. P. Wooten, Corps of Engineers, U. S. A., M. Am. Soc. C. E., and Mr. W. A. Bowden, Canadian Government Engineer, in 1920–21. The results of their investigation were outlined in their report to the International Joint Commission, dated June 24, 1921.[3]

This Board was so restricted in time that it was unable to go into the subject in great detail, but submitted a set of recommendations on which its members were able to agree, and pointed out certain others on which they differed. This report was considered by the International Joint Commission in 1921, together with certain alternate suggestions, submitted by or on behalf of the Hydro-Electric Power Commission of Canada, The New York and Ontario Power Company, Hugh L. Cooper and Company, of New York City, and Mr. S. M. Lovelace, of Montreal, Que., Canada.

[3] See Senate Doc. No. 179, 67th Cong., 2d Session.

The Commission accepted the plans of the Engineering Board as a basis for the recommended improvements of the St. Lawrence River with the suggestion that both the plans of the Engineering Board and the alternate plans should be referred to a larger board for final determination.[4]

In 1924 a Joint Board of Engineers was appointed, consisting of six members, three from the United States and three from Canada. This Board was asked to review the Wooten-Bowden Report and to extend its inquiries to certain additional matters relevant to proposals made by the International Joint Commission in its report dated December 19, 1921. The studies of this Joint Board extended over several years, and its report was submitted in 1926. Most of the engineering questions were cleared up by this report, and a large number of questions of fact and opinion which were referred to it, were definitely answered, but the Board failed to agree on the best method of developing power and navigation in the International Rapids Section.[5]

The Canadian Section favored a two-dam plan (see Fig. 1 (*A*)) with the upper dam at Ogden Island, and the lower near the foot of the Rapids. The American Section, however, favored a single dam (see Fig. 1(*B*)), near the foot of the Rapids. Both Sections agreed that both plans were feasible from an engineering standpoint, and suggested that the choice between them be determined by constructing agencies at a later date; they also agreed that the two-dam plan would cost about $30 000 000 more than the single-dam plan.

After several years, in which the subject was studied further, a Conference Board of Engineers was appointed in Canada. This Board recommended moving the upper dam in the two-dam plan from Ogden Island to Crysler Island, farther down the river.[6] By this change the difference in first cost between the one-stage and the two-stage plans was increased to about $40 000 000. The change in location also resulted in raising the proposed water level along the Iroquois-Morrisburg Section to such height that the problem of protecting this section, which had been in controversy before, became substantially the same in the two plans proposed.

In 1930, the State of New York established a Commission which was instructed to report on "a comprehensive plan for the development and operation of the water power resources of the State on the St. Lawrence River. * * *" This Commission reported[7] under date of January 15, 1931, and its engineers advised:

"A modification of the one-dam plan which eliminates the unusual serious hazards of the previous plans and makes possible the development of a somewhat increased amount of power. The estimated saving in first cost under

this plan as compared with the two-stage Crysler Island plan was increased further to about $70 000 000.

"In December, 1931, the Joint Board of Engineers was instructed to meet and report on a mutually satisfactory plan for the improvement of the International Rapids Section.[8]

"In March, 1932, the Board was instructed to reach an agreement on a plan for early execution that would provide effectively for navigation and power requirements."[9]

It should be noted that the Canadian members of the Joint Board of Engineers were appointed in 1924 and consisted of Mr. Duncan W. McLachlan, of the Department of Railways and Canals, of Ottawa, Olivier O. Lefebvre, M. Am. Soc. C. E., Chief Engineer, Quebec Streams Commission, of Montreal, and Charles H. Mitchell, M. Am. Soc. C. E., of Toronto. They have continued unchanged from the time of their appointment to the present (1933). The original United States members of the Board consisted of the late Lt.-Gen. Edgar Jadwin, U. S. A., M. Am. Soc. C. E. (then Chief of Engineers, U. S. A.), Col. William Kelly, Corps of Engineers, U. S. A., M. Am. Soc. C. E., and Brig.-Gen. G. B. Pillsbury, U. S. A., M. Am. Soc. C. E., (then Colonel, Corps of Engineers, U. S. A.); while the United States members of the Reconvened Joint Board of 1930 consisted of Col. H. B. Ferguson, Corps of Engineers, U. S. A., *Chairman*, Col. E. M. Markham, Corps of Engineers, U. S. A., M. Am. Soc. C. E., and General Pillsbury. In June, 1930, Maj. Eugene Reybold, Corps of Engineers, U. S. A., was detailed to replace General Pillsbury.

It is unfortunate that the same members of the Board of United States Engineers were not employed continuously on this project. New board members appointed to co-operate with others who have served for many years on a project as involved as that of the navigation and power development of the International Section of the St. Lawrence River, are at a great disadvantage. The various plans that might be adopted are so numerous and the possible method of effecting the same results are so involved that only long and continued contact with the problem will insure the familiarity necessary to secure the best results. Such conditions, together with the instructions under which the Board was working, necessitated coming to a conclusion on a "mutually satisfactory plan" which could "provide effectively for navigation and power requirements" and did not involve either the "best" or the "most economical" development for navigation or for power.

It is also unfortunate that the economic desirability of river and harbor improvements is usually determined by legislative bodies or by non-engineering fact-finding boards. The engineering boards appointed to plan such improvements are seldom expected to look into the economic phases of such problems in their broader aspects. First cost, while always of importance, must yield to various questions of safety, expedience, and influence. Apparently, for the foregoing or for similar reasons, none of the engineering reports considered, except that of the New York Board (which is confined principally to the question of water-power development), discusses the projects involved from an economic standpoint either as to navigation or water-power development, except as to the items of first cost.

---

[8] See Rept. of Joint Board of Engrs. (Reconvened), p. 4, Paragraph 16.

[9] *Loc. cit.*, p. 4, Paragraph 7.

As navigation works are seldom if ever constructed from the avails of bond issues, but from annual or occasional appropriations, the matter of interest during construction is almost never considered. In the case at hand, it is expected that the water-power development will be undertaken by the State of New York and the Province of Ontario, Canada, and will involve bond issues and a considerable expense of interest during construction. Other economic considerations, such as cost of maintenance, operation, depreciation, amortization, etc., also become of importance quite equal perhaps to the matter of first cost. It would seem, therefore, that those interested in this project, which involves so great an expense and which is of such great importance to thousands of citizens of both the United States and Canada, are entitled to some knowledge of the economic relations of the project recommended in the "Reconvened" Report to other plants which seem equally or more economically feasible.

The writer has analyzed the problem of water-power development on the International Section of the St. Lawrence River on the basis of the plans and estimates presented in the various reports and on the assumption that such plans are adequate for the purpose and that such estimates are reasonably correct, or at least fairly comparative. He has found certain discrepancies between some of the detailed estimates and the summaries, but such differences are of minor importance and in no material way do they affect the ultimate results of the analyses. The costs, estimated on a higher market than prevails at present (1933), are believed to be fairly comparative; any attempt to correct prices or details to meet the writer's ideas would involve confusion and would destroy the values of the analyses and comparisons made.

The writer has confined his discussion to the three most important plans proposed in the several official reports that have been issued by various boards of engineers appointed by the United States, Canada, and New York State to report on the St. Lawrence Waterway and the incidental water power to be developed in the International Section of the river. So far as the plans and estimates of cost are concerned, they are taken unmodified from the official reports or, if modified, the reasons for such changes are discussed.

In this paper the writer has analyzed the comparative advantage of three official plans, as follows: First, the two-stage Reconvened Plan; second, the single-stage Conference (Barnhart Island) Plan; and third, the single-stage New York (Massena Point) Plan.

The plan referred to in the "Reconvened" Report on which the treaty under consideration is based, is the two-stage plan advocated by the Canadian engineers and apparently accepted by the United States engineers, not on its merits, but because the engineers were instructed to agree by a certain date on a feasible plan for power development and navigation (see Fig. 1(*A*)).

Concerning the plan, the following statement[10] was made by President Hoover: "The cost is slightly more (for the two-stage development) but the Canadian officials have felt that the two-stage development is desirable for many reasons * * *."

‖ Twelve months.
¶ Three winter months.
** Reduced for loss by power; see Table 1 (*k*).
†† Increased for extra winter power; see Table 1 (*k*).

An examination of the official reports,[11] shows that the slight difference in first cost of the two-stage plan over the single-stage (Barnhart Island) plan is $38 324 000 (see Fig 1(*B*)).

Further consideration also shows that the two-stage plan is: (1) Deficient in output and, therefore, in earning capacity; and (2) more expensive in cost of operation. The consideration of these two items makes the relative cost of the two-stage plan much greater than is represented by the first cost.

TABLE 2.—OPERATING CHARGES (ONE PLANT, CANADA OR UNITED STATES) FROM NEW YORK REPORT, APPENDIX A.

Salaries	Single-stage		Extra for two-stage		Total two-stage
Direct Operation Staff:					
Chief engineer (1)	$12 000				
Electrical engineer (1)	8 000				
Hydraulic engineer (1)	8 000				
		$28 000			
Draftsmen (4)	$12 000		(2) $6 000		
Accountant (1)	4 000		(1) 4 000		
Clerks (4)	8 000		(2) 4 000		
Telephone operators (3)	3 000		(3) 3 000		
		27 000		$17 000	
		$55 000			
Power-House Operation:					
Station superintendent (1)	$6 000		$6 000		
Assistant superintendents (3)	12 000		12 000		
Dispatchers (3)	11 000		11 000		
Group chiefs (7)	17 500		(6) 15 000		
Operators (14)	28 000		(12) 24 000		
		$74 500		$68 000	
Outside Operation:					
Regular and extra help on dam	$30 000		$25 000		
Sub-station	6 000		6 000		
Oil and waste	4 000		3 000		
		$40 000		$34 000	
Maintenance and Repairs:					
Chief electrician (1)	$3 000		$3 000		
Master mechanic (1)	3 000		3 000		
Mechanics (4)	8 000		8 000		
		$14 000		$14 000	
Total payroll (one plant)		$183 500		$133 000	
Total payroll two-stage (four plants): 2 ($183 500+133 000)					$633 000
Materials and Supplies:					
Regular and extraordinary at $3 000 per unit		$72 000		$54 000	
Regular and extraordinary at $3 000 per unit for two-stage (four plants) 2 ($72 000+$54 000)					$252 000
Total for single plant		$255 500		$187 000	
Total for two-plant		$511 000		$374 000	
Total for four-plant (two-stage) ($511 000+$374 000)					$885 000
Estimated annual operating cost	New York Plan (Single-Stage)				$511 000
	Conference Plan (Single-Stage)				511 000
	Reconvened Plan (Two-Stage)				885 000

Fig. 2 is a map of Plan *C*, the single-stage, Massena Point development, and Fig. 3 shows the profiles of all three plans, for comparison.

CONTROLLING PHYSICAL CONDITIONS

In all computations in the various reports involving stream flow it has been assumed that the summer flow (for nine months of each year) will be

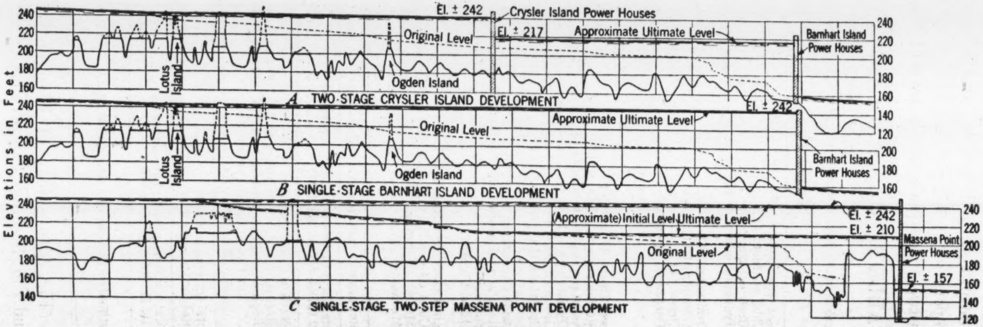

FIG. 3.—COMPARATIVE PROFILES, PLANS A, B, AND C.

235 000 cu ft per sec, and that during the three months of winter the flow will be reduced to 210 000 cu ft per sec.

The estimated head available in the three plans considered is shown in Table 1(*a*) and the horse-power years calculated on the basis of the stream flow are given in Table 1(*b*). Table 1(*c*) shows a summary of official estimates of the total cost of the three combined navigation and water power projects.[13]

In neither the Reconvened Report nor in the Conference Report does the writer find any estimates of operating costs. Therefore, he has based his estimates (see Table 2) on the New York Report, Appendix A, and while he would personally change these estimates in some respects, he believes that the official figures used are comparatively correct and suitable for this analysis.

FIRST ANALYSIS

In the first analysis the writer used the official figures as given in the official reports, without exception, taking operating charges from the New York Report. The cost figures for each water-power project are made up of: (1) The official estimate of the cost of works to be used solely for power; and (2) one-half the official estimate of the cost of works common to navigation and power.

While it is possible that some other proportion of this cost of the work common to navigation and power may be charged to the cost of power, such change in cost will apply to all plans and will not seriously affect the comparisons made.

In Table 1(*e*) are given the official estimates of the cost of the plans subdivided into depreciable and non-depreciable elements for the purpose of calculating the annual expense for each plan. In Table 1(*f*) are given estimates of the annual expense, of each of the three plans, made on the basis used in the New York Report, except that annual depreciation is taken at $1\frac{3}{4}$% of the value of depreciable property and annual amortization is calculated on the basis of 1% of the total capital cost.

In Table 1(*g*) are given; (*a*) The capital cost (Item No: 35), installed capacity (Item No. 19), and the estimated horse-power years output (Item No. 45); (*b*) the capital cost per horse-power year (Item No. 48); (*c*) the annual earnings based on $15 per hp year for firm power and $10 per hp year for secondary power (Item No. 50); (*d*) the excess capital costs per horse-power year of the two-stage plan over the single-stage plans (Item No. 49); (*e*) the earning capacity of each plant (Item No. 52); (*f*) the excess earning capacity of the single-stage plans over the two-stage plan (Item No. 53); and (*g*) the capitalized value of the excess earning capacities (Item No. 54).

Based on the unchanged estimates of the official reports, Table 1(*g*) shows that when the full financial conditions of power development are considered the relative cost of the two-stage plan is: (*a*) Almost $69 000 000 more than the single-stage Conference Plan; and (*b*) almost $125 000 000 more than the New York Plan.

---

[13] Reconvened Rept., p. 9; Conference Rept., p. 11; and, New York Rept., p. 50, respectively.

Second Analysis

In the first analysis official estimates have been used so as to make the comparisons as far as possible independent of the writer's interpretations of these reports.

There are, however, certain estimates in these reports which the writer believes to be clearly in error, and which should be corrected to make the plans truly comparative:

(*a*) In the Conference Plan, $4 149 000 of capital cost is included to secure 5 000 sq ft more cross-section in the area between Lotus Island and Morrisburg.[13]

The writer understands that the Canadian engineers consider 95 000 sq ft as entirely adequate in this section for the two-stage plan, but that the single-stage plan will require a further increased section due to the manner of its operation, its pool fluctuations in winter, and certain ice conditions which might change the gradient so as to reduce the section between Ogden and Lotus Islands sufficiently to increase velocities above the limit necessary to permit the formation of surface ice and prevent the formation of frazil ice.

With his limited knowledge of the local conditions, the writer is unable to concede the probability of any such occurrence. In the two-stage plan the fall to Crysler Island must be equal to the head necessary to produce the flow through the section.

At Crysler Island a certain head is utilized, and a head of from 1.3 to 1.5 ft will be lost in passing the water through the power-house and turbines. In the same way a head sufficient to cause the flow through the lower section will be required from the Crysler Island tail-water to the power-house at Barnhart Island.

If the Crysler Island power-house is eliminated there will be an increase of 25 ft in depth for the 18-mile reach from the Barnhart Island plant to Crysler Island, thus reducing the head necessary to create the flow in the lower reach of the river, and eliminating also the head lost in the two-stage power-house at that point. Certainly with any reasonable operation the tendency should be to increase rather than to decrease the depth of water in the reaches above Crysler Island. Truly, ice troubles may follow mismanagement with either plan, but would seem more likely to occur with the two-stage plan and its exceedingly limited pondage. With proper design and proper operation, trouble with frazil ice will be confined to the early period of winter just before surface ice is formed, and should be far less with the single-stage plan at or near Barnhart Island with its extra depth and consequent lower velocities. If there is any valid reason for including this extra expense in the single-stage and not in the two-stage development, it is not obvious. This amount, therefore, is added to the cost of the two-stage development.

---

[13] See Conference Rept., p. 5, Paragraph 16 (*b*).

(*b*) In the estimate of installed horse-power of machines, the single-stage Conference Plan is penalized by adding 87 740 hp in machine equipment above that used in the two-stage plan, and 87 700 hp more than is provided in the New York Plan.

This extra capacity may be desirable for the equipment of the plant in question but if so there would be a necessity for increased capacity in the two-stage and New York plans. For the purpose of comparison, the equipment of the plants is equalized on the basis of a total capacity of 2 200 000 hp.

The estimated cost of installation per horse-power is shown in Table I of the Joint Report (page 281) and is segregated as follows:

Item 1 (*b*) Power-house substructure.........	$24 000 000
Item 1 (*e*) Tail-race excavation............	3 799 000
Item 1 (*g*) Superstructure and machinery....	53 571 000
Total	$81 370 000
Overhead, 12.5% (see Joint Report, page 287).	10 171 000
Total cost of 2 287 000 installed horse-power..	$91 541 000
Approximate cost per horse-power........	$40

The cost of the 40 hp additional equipment, which is recognized as quite insignificant, is added therefore to the two-stage plan, and the cost of 87 700 hp extra equipment (at $40 per hp) is deducted from the cost of the single-stage Conference Plan to make the plans fairly comparative The foregoing corrections to the official estimates is shown in Table 1(*h*).

The annual expense involved is calculated in Table 1(*i*) on the basis of data in Table 1(*h*). The comparison of the three plants based on these partly corrected capital costs is shown in Table 1(*j*), which also shows that, based on the estimates corrected for the two errors mentioned, the cost of the two-stage plan is: (*a*) $79 000 000 more than the single-stage Conference Plan; and (*b*) almost $130 000 000 more than the New York Plan.

Third Analysis

In the second analysis, official estimates have been corrected for certain errors which seem to the writer beyond reasonable question. In this third analysis, these same errors are corrected and certain other errors are considered which the writer thinks should also be taken into account. These errors are:

(*a*) It seems certain that the extra loss in head due to the use of the water through two plants over the loss due to the use in the single plant of the single-stage plan has not been allowed for in the official estimates of the power which can be generated in the two-stage plan. A correction for this loss in the quantity of power and in the resulting net income, therefore, has been deducted in the estimates of power for the two-stage plan (see Table 1(*k*)).

(*b*) It seems equally clear that an error has been made in the estimate of the winter head in the single-stage Conference Plan. This error has been estimated by the writer at 1.5 ft (although it would probably be greater than this amount) and a correction has been made in the estimated output of power and corresponding net income for the single-stage Conference Plan (see Table 1(*k*)).

Based on the four corrections discussed, the three plans are compared in Table 1(*l*). These data show that the relative cost of the two-stage plan is: (*a*) Nearly \$93 000 000 greater than the single-stage Conference Plan; and (*b*) more than \$138 000 000 greater than the New York Plan.

In the three analyses previously discussed the writer has considered only the estimated cost of the water-power development, including in such cost one-half the estimated cost of works common to navigation and power. It will be noted from Table 1(*m*) that, in addition to the difference shown in the cost of power plans, there are also differences in the cost of the navigation works plus one-half the cost of works common to navigation and power, which must be added to the differences previously shown, in order to ascertain the entire difference in capitalized values.

Taking the excess cost of navigation into account (Table 1(*m*)), as well as the capitalized costs of the power plants, the difference in the complete plans for power and navigation will be as shown in Table 3. In considering the data in this table, it should be noted that in none of the reports (with the exception of the New York Report) has interest during construction been considered; and that without definite plans of comparative construction procedure no such estimates are practicable. If interest during construction were considered, as well as depreciation and amortization of navigation works, the difference shown in Table 3 would be considerably increased.

TABLE 3.—DIFFERENCE IN VALUE OF PLANS, BASED ON CAPITALIZED NET INCOME AS PREVIOUSLY DETERMINED, CORRECTED FOR DIFFERENCE IN NAVIGATION COSTS

Item No.	Analytical comparison	DEFICIENCY IN VALUE OF TWO-STAGE PLAN COMPARED WITH:	
		Single-Stage Conference Plan (B)	Single-Stage New York Plan (C)
1	Based on official estimates (Table 1 (*g*))	\$68 795 560	\$124 705 920
2	(*a*) Extra cost of navigation work (Table 1 (*m*))	1 974 500	15 911 500
3	(*b*) Total difference (Items Nos. 1 and 2)	\$70 770 060	\$140 617 420
4	Estimates corrected for excavation and extra capacity (Table 1 (*j*))	\$79 301 600	\$129 686 860
5	(*a*) Extra for navigation work	1 974 500	15 911 500
6	(*b*) Total difference (Items Nos. 4 and 5)	\$81 276 100	\$145 598 360
7	Based on corrected estimates and heads (Table 1 (*l*))	\$92 701 980	\$138 357 240
8	(*a*) Extra for navigation work	1 974 500	15 911 500
9	(*b*) Total difference (Items Nos. 7 and 8)	\$94 676 480	\$154 268 740

It will justly be claimed that such analyses as have been made are not conclusive because there may be elements of greater importance than relative financial comparisons.

One claim of advantage for the two-stage plan is that it can be developed in two steps while the single-stage Barnhart Island development must be built in one step, and the development charge on the latter during the time necessary to develop a market may exceed the difference in first cost, $38 324 000. (See Table 1(*c*), Plan *B*.)

The Joint Board of Engineers may not have found it feasible to develop the single-stage Barnhart Island plan in two steps, but its members evidently did not consider the fact that the single-stage plan at Massena Point could be developed in two steps. This matter is discussed in the New York Report (pages 46-47), but is here tabulated (see Table 4), in order to show the comparison of the two two-step plans.

TABLE 4.—INITIAL DEVELOPMENT TWO-STAGE CRYSLER ISLAND PLAN WITH INITIAL SINGLE-STAGE NEW YORK PLAN

Item No.	Comparison	Crysler Island Plan (A)	New York Plan (C)
1	Head, in feet	24	50
2	Proposed installation, horse-power	593 000	660 000
3	Available horse-power years for sale	504 000	600 000
4	Capital cost (exclusive of navigation)	$93 423 000	$82 502 000
5	Excess in cost of Plan A over Plan C	....	$10 921 000
6	Capital cost per horse-power year available	$185	$138
7	Capital cost advantage of Plan C over Plan A per horse-power year	....	$47
8	Capital cost, navigation works	$46 137 000	$887 000
9	Excess cost of navigation works, Plan A over Plan C	....	$45 250 000
	FIRST STEP (14-FOOT NAVIGATION)		
10	Power works	$93 423 000	$82 502 000
11	Navigation works	46 137 000	887 000
12	Sub-total	$139 560 000	$83 389 000
13	Difference	$56 171 000	
	SECOND STEP (27-FOOT NAVIGATION)		
14	Power works	$93 080 000	$42 796 000
15	Navigation works	42 102 000	78 040 000
16	Sub-total	$135 182 000	$120 836 000
17	Total	$274 742 000	$204 225 000
18	Difference in total first cost	$70 517 000	
19	Capitalized difference (Table 3)	$154 268 740	
	SALEABLE HORSE-POWER YEARS		
20	First step	504 000	600 000
21	Difference	96 000	
22	Second step	1 386 100	1 392 000
23	Total	1 890 100	1 992 000
24	Difference	101 900	

It is evident from Table 4 that the two-stage plan has a distinct disadvantage in comparison with the New York Plan, because Items Nos. 5, 7, 9, 13, 18, 19, 21, and 24 are uniformly to the advantage of the New York Plan as to both the first and second step.

Other reasons for favoring the two-stage plan are given in the Conference Report (see page 8) as follows:

> "It will be noted, by reference to the estimates given, that the single-stage project apparently costs about $38 000 000 less than the double-stage project. The difference in cost is compensated for by the earlier date that power may be made available from the double-stage project, the extent of the economic losses to the country from the flooding of additional lands, as well as the prime considerations mentioned in paragraph 9 of the Report."

(*a*) It has already been shown that while the two-stage plan will cost over $38 000 000 more than the single-stage Barnhart Island Plan and over $70 500 000 more than the single-stage Massena Point Plan, the comparative cost of the two-stage plan based on the official estimate will be about $70 770 060, and probably about $94 676 480 more than the single-stage Barnhart Island Plan, and about $140 617 420, and probably about $154 268 740, more than the Massena Point Plan. (See Table 3.)

(*b*) That the difference in cost of the two-stage plan will be in any degree compensated for by the earlier date at which power may be available is more than questionable.

The time of completion of both the first step of the two-stage plan at Crysler Island and the first step of the Massena Point Plan is estimated as five years.

The Crysler Island plans require coffer-dams aggregating about 9 000 ft in length, to be built in water up to 40 ft in depth, across the St. Lawrence River channel, and maintained during long winters with heavy ice running, and are likely to involve many contingencies and consequent delays.

The spillway and power-house at Massena Point will be founded in excavation on land "at a safe distance from the water's edge" and will be constructed "in the dry," thus avoiding the hazards of river construction. Certainly the chances in favor of early completion are much in favor of the Massena Plan.

(*c*) "The economic losses to the country caused by the flooding of additional lands" mentioned in the foregoing quotation, involves 5 760 acres extra in the United States and 9 600 acres extra in Canada, or a total of 15 360 acres, the value of which at any reasonably assumed price is entirely insignificant when the greater advantages of the single-stage development are considered.

In the Conference Report (page 4, paragraph 9), it is stated:

> "If, as an alternative, the International Rapids Section be improved by a single-stage project then control of flow must be secured by operation of gates and turbines at a power plant which will develop about 2 000 000 horse power. This is not regarded favorably by the down river interests, since this single plant would serve a large and populous territory both in Canada and the United States, and operation restrictions would be difficult to impose in view of the fact that it would be a dominant interest in the territory served. Again, the additional flooding of land and the extent of the embankments, along with some adverse effects at the end of the navigation season, make the single stage project undesirable."

(*a*) It is understood that in any plan the primary control of the flow of the river will be accomplished by means of control works at Galop Island. That such control is anticipated for the two-stage plan is shown by the "Reconvened" Report (page 5, paragraph 19 (*d*)) which refers to:

"A free open channel south of Galop Island for navigation, together with a diversion channel through Galop Island capable of discharge control in the interest of both navigation and power."

Such works are also applicable to any other plan. Secondary control must take place at the power-house and spillway under any plan of development. In all cases the river must flow in its normal volume either through the turbines or sluice-gates, or both, as occasion may require. The capacity of the plant will have little bearing on the matter of control as in each case the entire river flow must be balanced between the turbines and sluice-gate discharge at all times, and such control is not influenced by the head available below the structure. This control can be accomplished by automatically controlled sluice-gates as recommended by the New York Commission.[14]

(*b*) If the proposed works are operated so as to assure normal flow of the river, "down river interests" can have no valid complaints.

It is scarcely possible that any "dominant interest" of "the populous territory" of the United States and Canada will be able to affect operating restrictions injuriously to the paramount object of navigation. If the power authorities of the State of New York and the Province of Ontario can be influenced to ignore navigation interests in favor of power users, it is safe to assume that the Federal Authorities of the United States and Canada can be relied upon to enforce all necessary restrictions.

It can scarcely be demonstrated that complicating the situation by increasing the number of power plants, which in any case must be operated in parallel, would simplify operation, management, or control.

SAFETY OF MONTREAL AND COMMUNITIES ADJACENT TO EMBANKMENTS

While the safety of the City of Montreal and the communities adjacent to the embankments is not specially discussed in the reports, it is incidentally referred to as a matter of importance, which it certainly is.

In all plans herein considered the normal pool level above Crysler Island will be at Elevation 242. In either of the single-stage plans, considered, the water above the proposed dam will be raised to this same elevation, which will necessarily involve longer and higher embankments.

The Barnhart Island single-stage plan will require about 20 miles of embankment below Crysler Island, as compared with about 4 miles in the two-stage plan. The depth of water against the embankment in any single-stage plan will generally be less than 20 ft, and much of it will be less than 10 ft. The maximum depth for a short distance is 40 ft. The large quantities of suitable material which must be excavated for navigation purposes, and the exceptionally large cross-section for the embankment proposed by the Joint Board gives an assurance of safety the degree of which can be increased to almost any limit desired at very reasonable cost. (The embankments shown on Plate 5 of the Conference Report have a top width of 50 ft; a water slope of 4 to 1, heavily riprapped above normal water level; a land slope of 5 to 1, with a very heavy rock-fill toe and a free-board of 20 ft.)

---

[14] See New York Rept., p. 44.

As to the safety of Montreal, it should be noted that if any of the dams proposed in the single-stage plan could be removed instantaneously, the water in Montreal Harbor would be raised no more than a few inches. As the level of water has frequently been raised at Montreal from 10 to 15 ft, or more, by ice jams, there can be no question of trouble of this nature.

CONCLUSION

In conclusion, the writer would say that if the reports and estimates considered are correct, there can be no question that the single-stage Barnhart Island Plan, is at least $70 000 000 greater in value than the two-stage Crysler Island Plan, and that the single-stage New York Massena Point Plan exceeds the two-stage plan in value by at least $140 000 000. (See Table 3, Item No. 3.)

The New York Plan, which apparently received no consideration by the Joint Board, seems to be not only much less expensive in first cost, but also much less hazardous in construction, and to be an improvement from a navigation standpoint by eliminating one lock, greatly reducing the necessary length of canal.

The writer can see no valid reasons to justify the two-stage plan which can outweigh the millions of dollars of value in favor of other plans. If the reports are in error or if the reasons for advising the two-stage plan cannot be made manifest, the writer believes that this project should be further and completely investigated before the United States and Canada are asked to make the great permanent investment involved by this project.

DISCUSSION

T. H. Hogg,[15] M. Am. Soc. C. E. (by letter).—Before considering the paper under discussion, the writer wishes to state that in his opinion the choice of a single-stage or a double-stage plan cannot be settled satisfactorily solely on engineering or economic grounds. He would like to make his standpoint clear in regard to the entire question of the proper means of developing the International Reach of the St. Lawrence River. That part of the river under discussion forms the boundary between the United States and Canada. New York State, on the American side, and the Province of Ontario, on the Canadian side, border on the river, and by virtue of their position and ownership of the water power incidental thereto, are vitally interested in the proposed development. It is obvious, therefore, that National, State, and Provincial opinions must be given consideration. For these reasons the question of the relative suitability of a single-stage as against a two-stage plan of development is not a simple one. With these conditions in mind, a treaty, between the United States and Canada, has been negotiated, signed, and now (1933) awaits ratification.

General.—Because of the magnitude of the undertaking and its international aspects, the development of the St. Lawrence Waterway has occasioned the most widespread interest and discussion on the part of the general public and those interests particularly affected. From an engineering standpoint, it has been the subject of wide discussion, since it has occupied attention in one form or another for more than three decades. At the turn of the century, the Board of Deep Waterways issued an exhaustive report on the navigation features. Following the publication of this report, the Long Sault Development Company and the allied Canadian company—the St. Lawrence Power Company—made studies of the power possibilities of the Long Sault Rapids and secured a charter to develop power at that point; but owing to the fact that its charter was found to be unconstitutional, the Company did not go on with the work.

In 1918, the Hydro-Electric Power Commission of Ontario began its studies, which have been carried on practically continuously since that date. In 1920, the International Joint Commission referred the question of improving the International Section of the St. Lawrence River to an International Engineering Board. This was followed by investigations on the part of various private interests and by New York State. It will be realized, therefore, that many plans must have been studied and discarded. This, in all likelihood, accounts for what may appear to be lack of sufficient detail in the later reports.

Naturally, when dealing with such a project, there must be differences of opinion as to the proper method of handling the problem presented, and, for these reasons, it is evident that the determination of the proper course to follow cannot be based on purely engineering grounds. Neither, when it comes to the economic side, can the intangible values (which occupy positions of widely varying importance in the view of those studying the problem), be lightly brushed aside.

---

[15] Chf. Hydr. Engr., Hydro-Elec. Power Comm. of Ontario, Toronto, Ont., Canada.

In considering the entire question of the development of the St. Lawrence River, the fact that it is an international river cannot be ignored. Each country must deal with the problems that arise, in the way best suited to itself. What may appear as an obvious solution of a domestic question to one may not be at all suitable when dealt with by the other. These matters only add to the difficulty of securing a proper solution of the problem.

In his very interesting paper, the author has given a general outline of the latest studies, and has indicated quite clearly that he does not agree with the report of the Joint Board of Engineers. He also shows a marked preference for the plan of development presented by the Engineering Board of the St. Lawrence Power Development Commission for the State of New York, and uses it as a basis for comparison with other plans.

Discussion.—The project referred to as Plan *A*—the "Two-Stage Reconvened Plan"—is the Crysler Island Two-Stage Project, with the upper dam and power-houses at Crysler Island and the lower dam and power-houses respectively, at the upper and lower ends of Barnhart Island (see Fig. 1(*A*)). Plan *B*—the "Single-Stage Conference Plan" (Fig. 1(*B*))—is essentially the Barnhart Island, Single-Stage, 242 Project presented in the report of the Joint Board of Engineers. It was presented subsequently, with minor changes, in a report by the Conference of Canadian Engineers, a board made up of the Canadian members of the Joint Board and two engineers representing the Province of Ontario. Plan *C*—the "Single-Stage Massena Plan" (Fig. 2)—is that project which was reported on favorably by the Engineering Board of the New York State St. Lawrence Power Development Commission.

A comparison of the relative merits of a single-stage as against a two-stage project involves questions other than those of engineering import, and, since the author has indicated a certain preference, it is proposed to deal with it in the following way: First, examine the two single-stage methods of development; and, second, discuss the reasons which led up to accepting the two-stage plan and its relative merits compared with other proposed plans.

Professor Mead has undertaken a comparison of the various plans on the basis of the estimated costs. It is of prime importance, therefore, that each estimate be on the same basis. In so far as Plans *A* and *B* are concerned, they are strictly comparable, since great care was exercised to insure that the estimates of the Conference and of the Joint Board were on the same basis. In respect to the estimates of these two projects and that of the Massena Point project (Plan *C*), there is good reason for taking exception to the comparison.

Capital Cost.—In Table 1(*c*), the author shows that the total capital costs of Plans *B* and *C* are \$236 418 000 and \$204 225 000, respectively, indicating apparently a balance in favor of the latter, of \$32 193 000. An examination of the detailed estimates of the two projects discloses that the estimated costs of comparable items and unit prices are not on the same basis. It is found that $15 403 000 should be added to the estimate for Plan *C* for land damages, rehabilitation, etc., on the Canadian side, $1 250 000 for contingencies on "land damages", and $12 477 000 for power-house machinery and equipment, etc.

If the unit prices for work to be done in the same or similar locations are equalized, the estimate should be increased by $5 006 000, and a further sum of $11 340 000 should be added to cover a supply weir at the head of the Massena Canal, the excavation of an additional 5 000 sq ft in the channels between Lotus and Ogden Islands, and to provide for a double flight of locks. These additions bring the total estimated cost of Plan *C* to $249 701 000, as against $236 418 000 for Plan *B*. It is not contended that the equipment cannot be purchased or the work cannot be done for the prices given, but the foregoing adjustments are required in order that the estimates of all three plans may be on the same basis.

Head Developed.—With regard to the head that may be developed under Plan *C*, the official report states (page 5), that "the head will vary therefore from 84 to 88 feet, and is expected to average 85 feet". This variation in head corresponds to the fluctuation in tail-water level due to the variation in discharge, and does not take into account the fluctuation in the head-water levels due to the same cause. For a flow of 235 000 cu ft per sec, and a regulated Lake Ontario level of 246.32, the head-water level at Massena Point would be 242.15. Due to the fact that the total flow of the river will be discharged into the pool at the south end of Polly's Gut, and considering the channel improvements provided in the estimates, the water level will be from 0.8 ft to 1.5 ft higher than under natural conditions, giving a tail-water level of 156.0 and a corresponding head of 86.15 ft, instead of the 88 ft used by the author in computing the power output for open-water conditions.

The head that may be secured under winter conditions should also be corrected. The loss in head above the plant in winter, due to increased slope, will be as great as that in Plan *B*, and would amount to 4.3 ft. In addition, there will be a loss, due to higher tail-water levels. In an ordinary winter, the water level below Polly's Gut averages between 10 and 15 ft above normal water level. The flow of ice will be reduced, but during the latter part of December, or early January (depending on the season), some packing will occur between the Lake St. Francis ice sheet and Polly's Gut, as this channel will always be open. Under these circumstances, a rise of from 5 to 6 ft is to be expected. The head at the Massena Point plant, corresponding to the winter flow of 210 000 cu ft per sec, would be 76.65 ft.

Power Output.—In reference to the output that may be expected from the plants, the writer is unable to agree with the figures used by Professor Mead. Primary power is continuous power and, therefore. is limited by the winter head and flow. Secondary power is that which is available in addition to primary power during the remainder of the year. Expressing the output in horse-power years, based on a winter flow of 210 000 cu ft per sec (three months), and a summer flow of 235 000 cu ft per sec (nine months), and using the corrected heads, it will be seen from Table 5(*b*) that the total horse-power years available are reduced for each of the plans, but that the greatest change is for the Massena Point project (Plan *C*). Instead of an output of 1 992 000 hp-yr (Table 1(*b*)), it should be 1 852 605 hp-yr, a reduction of 139 395 hp-yr (see Table 5(*b*), Item No. 9). The output for Plans *A* and *B* should be corrected by deducting 67 380 hp-yr and 68 110 hp-yr, respectively, from the figures given in Table 1 (*b*), Item No. 8.

Hazards of Construction.—The elimination of the hazards of construction in the Massena Point project, when compared with the projects proposed by the Joint Board and the Conference, has been stressed by its proponents and also by the author. An examination of the results of borings at the site proposed for the Massena Point power-houses and spillway shows that the over-burden varies in depth from 65 to 120 ft. To open such an excavation in the materials to be encountered, with adjacent water levels 65 ft above the rock-surface elevation, is certainly not less hazardous than that involved at the sites at the foot of Barnhart Island, where the over-burden is a maximum of 50 ft in depth and varies down to a few feet, and the unwatering is a very minor problem.

The main dam above Hawkin's Point, proposed in Plan *C*, is a rock-fill structure with a blanket of sluiced material on the up-stream side. No provision is made for diverting any of the flow while the structure is being built in the main channel for a water level above the dam lower than Elevation 200. Above this elevation the water would be diverted over the sluice-ways at Massena Point. The cribs carrying the construction trestle must be placed in water 35 to 40 ft in depth, in velocities up to 15 ft per sec, with a flow of from 215 000 to 280 000 cu ft per sec; and, since it is not proposed to clear off the rock surface, there is likelihood of underscouring. Not only is this proposal very hazardous, but there is great uncertainty as to the quantity of material required in the blanket because no one can foretell what slope the materials will take when placed under water by sluicing methods.

The location of the concrete dam proposed in Plan *B* is such that at least 70% of it can be built in still water, a great part of which is quite shallow, and where the rock is lying at a depth varying from 15 to 25 ft below the water surface. By building this section of the dam up to the surface of the river bed, the remainder can then be put in by diverting a large part of the flow, after which the entire dam can be raised a section at a time to its final elevation. This proposal is considered by those intimately acquainted with the river, as much less hazardous than the one suggested by the proponents of Plan *C*.

Summary of Comparisons of Single-Stage Plans.—To summarize, then, a comparison of the single-stage plans shows that, after the estimates are made strictly comparable, the capital cost of Plan B is $13 283 000 less than that of Plan *C*. Correcting for slope and loss in the tail-race, the summer heads on the two plants for a flow of 235 000 cu ft per sec would be 86.1 and 86.2 ft, respectively, and, in winter, for a flow of 215 000 cu ft per sec, the heads would be 76.4 and 76.65 ft, respectively. In respect to hazard, Plan *B* is more free from that objection than Plan *C*, and the quantities, especially in the dam, are capable of being estimated much more closely. From the Canadian standpoint it is more satisfactory because the Canadian power-house can be placed on Canadian territory.

In the report of the Board of Engineers, New York State, it is stated that "they [the Board] do not feel that so strong a position can be taken as to the superiority of the Massena Point one-stage plan over other single-stage plans." Apparently, the plan was finally presented for consideration, not because its authors were convinced of its overwhelming superiority, but as an alternative which might help in a final determination of a satisfactory scheme of development. The report states:

> "It is appreciated that the choice of the exact location of the dams and power houses must be determined along with other negotiations which, of necessity, remain to be made with the Canadian interests."

Comparison of Plan A with Plans B and C.—In considering the two-stage Crysler Island plan contained in the "Reconvened Report," it is pointed out that to state "the Canadian engineers have consistently advocated a two-stage plan of developing the International Rapids Section," is erroneous. In the first report the Canadian engineers were not convinced it was desirable or feasible, on account of ice conditions, to raise the pool level at Barnhart Island to Elevation 242.0, but they favored a single-stage plan with a lower level, namely, 232.0, with a control dam at Ogden Island. In presenting the Ogden Island two-stage, as an alternative to the single-stage plan, the Canadian engineers were endeavoring to meet the wishes of the power interests, to make available for power as much of the total fall in that section of the river as possible.

Following the 1921 report, both the Hydro-Electric Power Commission of Ontario and the Department of Railways and Canals (which organization secured all the field data on the Canadian side and carried on the office investigations for the Canadian representative) made further intensive studies of the winter conditions on the river. The viewpoint of the Canadian Government officials was that, with the open-water reaches that would exist under any single-stage plan studied to that time, serious ice jams were certain to occur, similar to those conditions which have been observed from Weever's Point up stream under natural conditions. The down-river interests looked on these possibilities with great apprehension; they considered that it would inevitably lead to disaster and insisted that in any plan of development their interests must be amply safeguarded.

Ice Conditions.—It is emphasized that the seriousness of the ice problem in relation to the development of the St. Lawrence River cannot be too greatly stressed. Under natural conditions there is a stretch of river, more than fifty miles long, in which ice in its various forms—board, frazil, anchor, and slush—is formed on a colossal scale. This accumulating under the ice sheet at the upper end of Lake St. Francis has caused shoves and packing to occur all the way from Summerstown up stream to Lock 21, and on numerous occasions it has resulted in raising the water level at the foot of Polly's Gut and the lower end of Barnhart Island from 15 to 25 ft above normal level. Jams have formed below Weever's Point, which have caused the ice to pack up stream to Morrisburg, resulting in a rise in water level of 12 to 15 ft at the latter point. Study of the river during the winter season has engendered a wholesome respect for the problem of providing safe winter operating conditions.

Reasons for Crysler Island Two-Stage Plan.—In order that the objections of the down-river interests might be met, the Canadian officials proposed a control dam at Ogden Island, so that the flow could be throttled if a jam began to form. This led to a demand on the part of the power interests of Ontario that the control dam should be designed to develop power.

To raise the pool level to Elevation 242.0, without disturbing present lake levels, requires very heavy channel improvements from the head of Galops Rapids down stream. Coupled with the studies of winter conditions, it was considered that the only safe way to deal with the situation was to enlarge the channels until an ice cover could be secured, and to make provision for the control of the flow to prevent ice gorging, since the velocities could not be reduced in the entire reach to the point where ice would form in place, as the formation of an ice cover is dependent to a considerable extent upon the packing of ice carried in from the open reaches above.

While these studies were being made, the communities on the Canadian side of the International Rapids Section of the St. Lawrence River were deeply interested and, through their parliamentary representatives, discussed the effect to them of the different methods of development proposed; so there was built up, through various organizations, a tangible and strong public opinion for the adoption of a two-stage plan. The expressed public opinion finally had to be given serious consideration. The grounds for the stand taken by these communities were as follows.

The north shore of the St. Lawrence River constitutes the oldest settled section of the Province of Ontario, and, in many cases, the land is still held and occupied by descendants of the original holders. This area was known as "the Front," from which the back townships were settled; and the river towns and villages were, and still constitute, the marketing and trading centers for a distance half-way to the Ottawa River. The objection of these communities to disturbance is strenuous and continuous, so much so that it has come to be recognized by both the Provincial and Dominion Governments; strengthened by the objections of the down-river interests, it is a real and insurmountable obstacle to securing the single-stage plan. It may be pointed out that Plan *A*, the two-stage plan, has also been objected to on the score of disturbance, and while there are some grounds for these objections, still the single-stage plan would result in disturbance to, and the elimination of, the entire tier of communities from above Cornwall to the head of Galops Rapids, a distance of forty miles; in the two-stage plan, on the other hand, the disturbance would be confined to one-half that distance and would not extend any appreciable distance back from the river.

In a two-stage plan, with the upper plant at Ogden Island taking the place of a control dam at that point, an ice cover could only be secured below the plant by very heavy work in the channels as far down stream as Crysler Island for any water-surface elevation below 225.0. After numerous borings had been made to determine the elevation of the rock surface, it was decided that the proper position for the upper plant in a two-stage plan was at Crysler Island. This was the reason Plan *A* was finally proposed by the Canadian engineers; and the Joint Board agreed that, "all things considered, the scheme was feasible from an engineering standpoint."

The foregoing is a brief outline of the steps followed by the Canadian engineers in reaching the position as to the desirability of a two-stage plan, and indicates the engineering problems.

Table 5(*a*) gives a comparison of the three plans for the heads which would obtain under winter and summer conditions. In regard to the power produced under the three plans of development, each is expressed in horsepower years. With the corrected heads and using 85% efficiency in each case, Table 5(*b*) gives a comparison of the power output under the three methods of development.

Comparison of Plans of Development on Basis of Capital Cost.—Table 5(*c*) gives a comparison of the three plans on the basis of capital cost after they have been placed on a comparative basis by corrections to the unit prices and other items, as outlined in a preceding paragraph. The corrections to the estimates of Plan *C* do not entirely adjust the differences. When studying the plan of the New York State Board after the report was presented, the layout shown therein was accepted, but the quantities were taken off and estimates were prepared in the same way as for Plans *A* and *B*. It was then found that the capital cost was $273 822 000 as compared with $236 418 000 for Plan *B*. In view of this, it was considered that Plan *C* was distinctly inferior to other single-stage plans that had already been studied.

In Table 5(*d*), the costs are subdivided in order that the annual expenses may be calculated. The values for Plan *C* are corrected in accordance with the revised capital costs for that project. Table 5(*e*) shows the estimated annual expenses which would be incurred in the operation of the three projects. These are based on the experience which the Hydro-Electric Power Commission of Ontario has had in operating its plants. The rates used are neither the highest nor the lowest, but are considered to represent, fairly, the operation costs of these plants. Item No. 28, Table 5, includes management, engineering staff, superintendence, record staff, stenographers, telephone operators, operating payroll and supplies, maintenance and repairs, liability insurance, and the operation and maintenace of the dams.

The estimated cost of maintaining and operating the plants is given in Table 6.

A comparison of the power plant costs of the three plans, based on corrected capital costs and equalized installed capacity is given in

TABLE 5.—Writer's Comparative Data Pertaining to Plans *A*, *B*, and *C*

Item No.	Description	Plan *A*; Two-Stage, Crysler Island, "Reconvened" Plan		Plan *B*; Single-Stage, Barnhart Island, Conference Plan		Plan *C*; Single-Stage, Massena Point, New York Plan

It is confidently asserted that in so far as Plan *C* is concerned, the tremendous difference in capital value presented in Table 3 would vanish entirely if, as was indicated in an earlier paragraph, the plan were placed on the same basis as the others as regards safety, freedom from operation hazard, and navigation facilities, and if the questionable proposal of placing a rock-fill structure in a river of the nature of the St. Lawrence and at the point proposed were eliminated.

Reasons for Not Accepting Author's Set-Up.—For the reasons given in the discussion of capital costs, no further reference has been made to Professor Mead's "First Analysis" of the three plans, but what is considered to be the correct comparison is given in Tables 5 and 6. It is proposed now to give the reasons for not accepting the corrections made by the author in his second and third analyses. Before doing so, attention is called to the fact that the Canadian organizations studying the problem have been living with the river for a number of years, and that practically the same personnel has been engaged on the work throughout. While these organizations have been working independently, they have conferred and discussed the problems freely. Furthermore, the Hydro-Electric Power Commission of Ontario, has discussed these questions with organizations from the United States side of the line, and has furnished, freely, whatever information they might desire. On the United States side, while the personnel has not been so continuously on the problem, the United States Government organization (the Army Engineers, and, through them, the Lake Survey) has been engaged on the river more or less continuously for a number of years.

In contrast to these conditions, the New York State Engineering Board reported in a little more than three months after its organization and, as a Board, never had the opportunity to study winter conditions, first hand, which is probably the greatest problem of this development. Surely then, its plan should scarcely be used as a measuring stick to judge the other methods of development from the point of view of cost, etc. The author has acknowledged that, in making the analysis, he has been handicapped by his lack of knowledge concerning local conditions, and his difficulties are fully appreciated. The writer wishes to emphasize his belief that the plan recommended, and on which the treaty between the United States and Canada has been negotiated, has been arrived at after careful and long study, and, all things considered, represents the best solution of the problem.

Necessity for Increased Cross-Section in the Single-Stage Plan.—In his capital cost comparisons (Table 1(*c*)), Professor Mead has added the sum of \$4 149 000 to Plan *A* to provide an additional 5 000 ft to the cross-sectional area in the reach between Lotus and Ogden Islands, similar to that in Plan *B*. This addition is not considered necessary. In explanation, the additional cross-sectional area was considered necessary in the single-stage plan to reduce the danger from ice gorging. This danger is greater under the single-stage plan for the following reasons: The control dam at the head of the Galops Rapids is situated in an artificial channel and provides only partial control. Due to changes in atmospheric pressure, surges are set up on Lake Ontario which will cause a rise in gauge height of 2 to 3 ft in a few hours at Prescott, or at the head of Galops Rapids, resulting in a relatively material increase in slope in the pool above the power plant, with a consequent increase in velocity and flow.

Occurring at a time when the ice on the pool is forming, as these surges frequently do, could result in the formation of an ice gorge, with serious results to the power output during the remainder of the winter season. These surges can be anticipated, and in Plan *A* there is time, by closing the sluice-gates in the upper dam, to raise the pool level and counteract the increased slope; and, at the same time, by transferring part of the load to the lower plant, it is possible to reduce or eliminate any reduction in power output during the period that the flow is being manipulated. In the single-stage plan, with its much larger pool, it would be impossible, in most cases, to reduce the slope in time to meet the emergency. It was considered that the extra cross-sectional area would provide the additional safeguard to reduce this hazard.

Heads at Crysler and Barnhart Islands.—It is not considered that the head on the Crysler Island plant should be reduced by from 1.3 to 1.5 ft (Table 1(*k*)), any more than the heads on the plants at Barnhart Island or Massena Point. The loss through the plant is taken care of in the efficiency used in computing the power output. The necessity of providing an extra 5 000 sq ft in the channels below Lotus Island has been explained. The apparent excess loss in head of 1.5 ft on the Barnhart Island plant in winter (Table 1(*k*)), is due to the extra accumulation of ice in the tail-race in any single-stage plan.

Power Costs, Barnhart Island.—If the installed capacity of the plants at Barnhart Island and Massena Point is equalized, the cost of the Barnhart Island development should only be reduced by the cost of the electrical equipment, since there would be no reduction in the spacing of the units, or in the size of the turbines, to take care of the 87 700 hp, considering the number and size of the units. This reduction in cost would not amount to more than $1 045 000.

Navigation Costs.—With reference to the navigation costs, the estimates in the Massena Point plan provide for a single flight of locks on Barnhart Island; the fact that the tonnage capacity was not the same in each case, was not considered. In both the other plans, the capacity of the locks is 16 000 000 tons, while that of the single-flight locks in Plan *C* is only 12 000 000 tons. In order that the capacity may be increased, the estimates were increased to provide for double-flight locks.

Comparison of Initial Developments.—The author has compared the upper development of the two-stage plan with the first-stage of the Massena Point project (Table 4), and, while of interest, it is not expected now that the need will arise for such a program of construction. In considering the relative output of the Crysler Island plant and the Massena Point initial development, it is contended that all the 600 000 hp available from the latter plant will be prime power; in other words, the head of 50 ft will be available throughout the year. For an elevation of 210 at Massena Point, the upper end of the pool would be about at Morrisburg. With the natural slope in the river above that point, there would be twenty miles of open water from which ice would be carried down into the pool during the entire winter. This would certainly result in an increased slope and reduced head-water level. The tail-water level would be increased by the accumulation of ice in the channel below Polly's Gut.

It is estimated that during the latter part of December, and during January, February, and the early part of March, the head will be reduced by 20 to 25 ft in an ordinary winter, so that the net head on the plant would be between 25 and 30 ft, instead of the 50 ft assumed in Table 4. The net head on the Crysler Island initial development—owing to the fact that natural levels would obtain below the plant—would be from 28 to 30 ft. The power output of each plant is also incorrect. The available continuous power from the Crysler Island plant would be 568 000 hp, and from the Massena Point plant, 506 000 hp, or 62 000 hp less than from the two-stage Crysler Island plant.

The capital cost of the initial development of the Crysler Island plant is given as $93 423 000, or $185 per available hp, in Table 4. This capital cost includes one-half the cost of works common to power and navigation, amounting to $37 918 000. A large part of this sum is chargeable to channel improvements, which are as valuable to the Barnhart Island plant as to the Crysler Island plant. It has been considered as fair that only one-third the cost of channel improvements above the plant should be charged against the upper plant, and the remaining two-thirds against the lower plant. This division is on the basis of installed capacity, approximately. The capital cost, therefore, of the Crysler Island plant, as given in Table 4, should be reduced by $14 360 000.

The total capital cost of providing 25-ft navigation in the upper pool is charged against the initial development of the two-stage plan, although Table 4 includes the sub-title, "First Step (14-Foot Navigation)", while, in the Massena Point plan, only the cost of providing a lock for the continuance of the present 14-ft navigation is included. The cost of providing similar navigation facilities in Plan *A* is included in the estimates of the cost of works common to navigation and power for the upper pool, and amounts to $1 205 000. The total shown in Table 4 to cover the cost of navigation, therefore, should be omitted. With these corrections, the capital cost of power for the Crysler Island initial development becomes $79 063 000, and that of the initial Massena Point development becomes $89 284 000, and the corresponding cost per available continuous horse-power would be $139.25 and $176.50, respectively.

In Table 3, Professor Mead summarizes his comparison of the three plans, and the conclusion he reaches is that Plan *C* is from $140 600 000 to $154 268 000 better than Plan *A*. It has been shown that these comparisons do not give the proper picture because compared with Plan *B*, when the difference in income is capitalized, the balance against the two-stage plan is $63 600 000 (see Table 5(*f*), a fact that has always been known and taken into consideration. In so far as Plan *C* is concerned, instead of being superior to Plan *B* by $60 000 000 (Table 3), on the basis of capitalized earnings, it is inferior by about $14 900 000, leaving out of consideration the fact that from an engineering standpoint its proponents were not at all certain that it was superior to Plan *B*, and that there is good reason to doubt that it is as free from construction hazard.

The author has made reference to the probable effect on the water level in Montreal Harbor if, by some mischance, the dikes were breached. His statement that, in such an event, the level would only be raised by a few inches is undoubtedly correct; but he has lost sight of the fact that in Quebec, above Montreal, there are industrial centers and areas that are not in the fortunate position of Montreal. In the event of such a disaster, they would suffer great damage, and there is the possibility that a new channel might be created for the St. Lawrence south of the new Beauharnois Power Canal. These communities cannot help but be apprehensive, and their apprehension takes the form of serious objection through their political representatives.

Conclusion.—In conclusion, it is pointed out that the comparison drawn, using Plan *C* as a basis, is incorrect, because the plans as presented in the official reports are not comparable.

Revising the estimates of the official report by using the same unit prices and adding certain items that are omitted, but not altering the quantities, would bring them more nearly in line with those of Plans *A* and *B*. The capital cost of Plan *C* would then be (Table 5, Item No. 14) $249 703 000, instead of $204 225 000 used by the author in Table 1(*c*). If the estimates of quantities and costs are prepared in the same way as those of Plans *A* and *B*, the capital cost would be $273 822 000.

As between Plans *C* and *B*, it has been shown that when placed on the same basis, Plan *B* is distinctly superior as regards total capital cost, cost of power, revenue, annual charges, freedom from construction and operation hazard, and capacity and superiority of navigation works. If objection is taken to placing the American power-house on Barnhart Island, it is quite possible, with little increase in cost, to place a concrete dam below the head of Barnhart Island, alter the navigation route by leaving the river above Robinson's Bay, build twin-flight locks at the mouth of Grass River, and place the American power-house on the main shore below Hawkin's Point, where the rock is much higher than at the proposed Massena Point site.

Considering hazards of construction, a careful analysis of the proposed methods of construction and a knowledge of the physical conditions, the hazards in the two-stage plan are not as great as those to be expected in the Massena Point plan. The capital cost is practically the same when the estimates are prepared on the same basis, and, in addition, there are those advantages in its favor which are associated with reduced disturbance and satisfied communities below the developments.

A comparison of Plan *A* and Plan *B* indicates that, both from the standpoint of capital cost and the annual costs which would be chargeable against power, the latter is preferable, although both plans are sound from the standpoint of the engineering problems involved and from the broad economic viewpoint. After years of study of all aspects of the development of the International Rapids Section of the St. Lawrence River—during the course of which it has been abundantly evident that there are a great many factors of other than an engineering, or a purely economic, character which have had a profound influence upon the problem, and to which as a consequence it was necessary to give due weight—Canadian engineers have reached the conclusion that the two-stage Crysler Island plan is the most suitable method of meeting, satisfactorily, all the varying conditions involved.

THERON M. RIPLEY,[16] M. AM. SOC. C. E. (by letter).—In considering this paper the reader is left in almost as confused a state of mind as has been the condition in the past from the reading of the various estimates put out by the Government engineers and other engineering organizations. Moreover, all these various reports and papers are devoted principally to the estimated cost of the construction of one or other of the various plans, and little or nothing is said about their economic justification. There has come to the writer's desk only one of these numerous reports that contained much information on this question of economics and in which the statement seemed to be based on estimated figures of costs of power delivered where there might be some probability of its use.

---

[16] Cons. Engr., Buffalo, N. Y.

The "Report of the St. Lawrence Power Development Commission; Submitted to the Governor and the Legislature of the State of New York, January 15, 1931," contains an estimate of the cost of steam generated in, and of St. Lawrence power transmitted to, New York and up-State cities. It contains, also, extensive tabulations of the cost of electricity now furnished to many up-State municipalities and to New York City.

The Marketing Board, after submitting the aforementioned estimates and tabulations, completes its report to the Commission with these words:

> "A further source of electric development appears in railway electrification. It seems probable that within a ten-year period enough of the railroads of the State will be electrified to require 1 000 000 000 kilowatt-hours per year.
>
> "In view of the past increases in power required and in view of the special developments that are likely to take place, we conclude there will be an ample market for St. Lawrence power and that there will be sufficient continuous load to take the entire St. Lawrence output available to New York within a brief period after the completion of the plant."

There is no doubt but that contracts for a large portion or all of the St. Lawrence power could be secured providing said contracts were on a basis of guaranteed delivery with the resources of the State of New York behind such guaranty.

With the knowledge that the report on the New York Plan was made by a Commission appointed by a Governor who was known to be sympathetic to the proposition of the State developing its water powers, and, further, in view of the fact that the Commission was careful to confine itself to the realm of possibilities rather than probabilities, one is still left in doubt as to whether the findings should be accepted as conclusive economically or whether there were other political and social reasons for the conclusions stated.

In other words, the question is: Can electricity be furnished to "possible" users for a less expenditure of time and money than by the development and transmission of St. Lawrence power?

During the three decades that this problem has been a subject of widest discussion the cost of producting electric power by steam has undergone radical changes in the following major lines: (*a*) The development of steam turbines; (*b*) the development of the mechanically fed boiler (which is best illustrated by the change from a grimy man with a coal scoop to the white-collar man in front of an instrument board); (*c*) the construction of the high-speed generator with a capacity of 100 000 hp; and (*d*) the transmission of the power at voltages never dreamed of at the beginning of the Twentieth Century. In spite of all these changes, power development on the rapids of the St. Lawrence still holds a position in the public conscience which the writer believes is due in a large measure to the magnitude of the undertaking.

In Tables 1 and 2, Professor Mead shows operating charges and net income. The former is based on a capacity factor of 100% and, therefore, the power would have to be used at the point of generation continuously throughout the year. Justly, the author was not concerned with the economics of power use; nevertheless, this question must be a main issue at all times. It is believed that no one is so optimistic as to believe that 1 000 000 hp, even if available, would be used along the banks of the St. Lawrence River in New York State within any time that can be predicated. The moment this power is put on the transmission line its quantity at the receiving end diminishes and its price rises.

Relative to whether the Reconvened Plan, the Conference Plan, or the New York Plan should be the one constructed, it would be interesting to learn the estimated value of this power when distributed to those parts of the Eastern United States that would be able to utilize it, and the cost of generating steam power in the same communities. In making such an estimate the class of use would be a major consideration and a conservative load factor would have to be assumed for the estimate to be fair either to the St. Lawrence power or to the steam power.

The writer understands that steam-electric power can be produced to-day in the principal cities of New York State for a fraction of a cent per kilowatt-hour and that mechanical and electrical engineers admit that further economies are possible; in fact, they state that such economies will come. If steam-electric power can be put on the low-tension bars for 3 or 4 mills per kw-hr, it may be difficult for St. Lawrence power to compete with it over any long-distance transmission and with a normal load factor.

W. S. LEE,[17] M. AM. SOC. C. E. (by letter).—This paper is extremely pertinent and interesting to the American as well as to the Canadian Engineering Fraternity. The subject is very important and should not be criticized in an unfriendly manner by either one side or the other; the entire Engineering Profession should enter into this discussion in a spirit of determining the best possible development that can be made. This development forms part of the boundary between two great friendly nations, and they will always be mutually interested in it and will have friendly interest in one another. American engineers have too many friends in Canada and *vice versa* for this matter to be discussed in any other way except for the best interests of all concerned; therefore, any discussion that would tend to enlighten the situation before the public as well as the Engineering Profession, aiming toward the development of the best possible plan in this project is, of course, very pleasing to every one.

---

[17] Vice-Pres. and Chf. Engr., Duke Power Co., Charlotte, N. C. Mr. Lee died on March 24, 1934.

If this project is carefully studied (as it should be) and properly developed it will be a great acomplishment. If it is poorly developed and mistakes are made, such mistakes will stand out always, and the work will be a poor presentation of the ability of American and Canadian engineers. The writer urges the Engineering Profession to join in a most careful study of the best laid plans, in order to decide on the most economical and enduring construction, so that it may be not only a great advantage to the two countries, but the embodiment of good engineering.

Frank E. Bonner,[18] M. Am. Soc. C. E. (by letter).—Proposals for the utilization of the St. Lawrence River present several complex questions. None is more important to the people of the United States than that relating to the merit of the single-stage plan as compared with the two-stage plan for improvement of the International Section of the river for the combined purposes of navigation and power production. Professor Mead's paper reviews this issue with admirable sagacity and candor.

The subject is of timely interest and searching examination by the Engineering Profession constitutes a high public duty. Several years ago, while dealing with various plans presented to the Federal Power Commission for the development of the St. Lawrence, the writer became keenly impressed with the probable danger of wasteful and extravagant improvement should the program be guided by professional politicians rather than by competent engineers. It is true, of course, that some other elements must be considered, but, primarily, the entire problem is one of engineering in its broadest aspects.

If the St. Lawrence project is to be launched in the near future by joint effort of the two nations, it is vital that the partnership be based on complete and sympathetic recognition of the rights and problems of each. In order to reach equitable agreement, concessions should be expected on both sides, but in so far as humanly possible these concessions must be evenly balanced or the proposed project will fail for want of public support in one country or the other.

Preliminary negotiations of the past decade (1923–33) have developed that the chief item of disagreement concerns the single-stage plan advocated by representatives of the United States *versus* the two-stage plan preferred by the Canadians. The precipitate acceptance of the Canadian contention in 1932 without adequate explanation naturally provokes a question as to whether the surrender might have been influenced by some temporary political expediency, or whether compensating advantages have been granted the United States in other respects. A satisfactory showing that the proposed treaty does not impose inequitable burdens on the United States should be a necessary prerequisite to unconditional ratification by the Senate.

Professor Mead's analysis clearly demonstrates that the single-stage development is far more favorable than the other from the standpoint of the United States. The original cost will be about $40 000 000 less than the cost of the two-stage plan while at the same time power production is increased, operation costs are reduced, and navigation is served fully as well. The modified single-stage plan proposed by the State of New York offers promise of even larger advantages, but because of uncertainty as to whether the estimates are strictly comparable, definite appraisal cannot be made with assurance. However, in view of the high standing of the engineers responsible for the New York plan, it may safely be assumed that the single-stage plan considered by the Joint Board can be further improved with consequent widening of the margin of advantage over the two-stage plan.

---

[18] Cons. Engr., Piedmont, Calif.

In the face of these established facts it is difficult to understand the Canadian preference for the two-stage plan. The reasons advanced seem rather vague and indefinite. Apparently, they relate mainly to local prejudice against marginal flowage and fear by some interests of aggravating ice conditions along the lower river. Although sentiment favoring the two-stage plan may be of sufficient weight to justify preference for the more costly development by Canada, it is not evident that the actuating factors are of such a character as to warrant the United States assuming a greatly increased burden.

If early development of the St. Lawrence is more urgently needed by the economic requirements of the United States it might be desirable to undertake more than a proportionate share of the obligations in order to expedite completion. Apparently, however, such is not the case. Available information shows no pressing need for proceeding with the project at present in so far as the United States is concerned. Doubtless, it will be a desirable improvement eventually, but under present conditions the enterprise is more likely to be a liability than an asset.

The project will provide only two things—a new transportation facility and a huge block of electric energy. These will be useful only to the extent that they may either supply requirements which cannot be met by present equipment or furnish service at a sufficiently lower cost to displace existing competitive facilities to the general public benefit. Active agitation for the St. Lawrence Waterway began during the post-war period, when existing transportation systems were heavily overloaded; but the situation has completely changed and there is now a great surplus of transportation. The same is true of electric power. Under the circumstances, the St. Lawrence project will have to meet the test of competition, and construction will be justified only when it can serve much more economically than the facilities it will displace.

The navigation project involves considerably more of course than the items included in Professor Mead's summary, which is confined to the International Rapids Section. The many ramifications of the entire navigation enterprise are too complex for more than incidental attention in connection with the present discussion. It should be observed, however, that an outlay of several hundred million dollars will be required of the United States, exclusive of extensive harbor improvements, and comprehensive analysis[19] shows that if tolls are placed on the traffic, as they ought to be, sufficient to cover the interest, maintenance, and operation charges, the venture offers little hope of reducing present charges for transportation between Lake ports and the Atlantic seaboard.

---

[19] "The St. Lawrence Navigation and Power Project," pub. by the Brookings Inst., 1929.

It is realized that Professor Mead's analysis relating to cost and net income of power production was intended merely for the purpose of comparing the relative values of the different development plans, but it is possible that the method of presentation may convey some misapprehension regarding the margin of profit possible from this feature of the project and may thus lead to the conclusion that the United States can afford to deal generously with Canada.

The available output will be subject to considerable seasonal variation. Due to the combined effect of low water and reduced head during the winter months, the production will be lowest at the time of highest demand in the electric market. Under the circumstances the continuous primary power will be represented by the winter capability of the generating plant.

Under natural conditions the winter discharge from Lake Ontario occasionally diminishes to about 175 000 sec-ft but, with the moderate regulation planned, the flow will seldom fall below 190 000 sec-ft. Discharge of 200 000 sec-ft may be maintained approximately 90% of the time and for 64% of the time 210 000 sec-ft would be available (50-yr period, 1881–1930).[20] For this same period a flow of 235 000 sec-ft would be available about 48% of the time. In some years this would extend through 10 months of the year, but during dry cycles the discharge may be considerably less for as long as 33 consecutive months. During the period, 1923–1927, the controlled flow would exceed 225 000 sec-ft in only 11 of the 60 months. In view of the irregularity of the higher flows it is clear that part of the potential power is of very poor quality and of doubtful usefulness.

Taking 76.4 ft as the average winter head (Barnhart Island Plan) and the discharge at 190 000 sec-ft, the dependable primary power will amount to 1 402 158 hp. The secondary power of good quality will be represented by that excess which may be produced from discharges up to 210 000 sec-ft. This block may be estimated as follows. Let T_1, T_2, and T_3 represent the proportional time elements, respectively, of (*a*) summer power (9 months), from discharges of 200 000 to 210 000 sec-ft; (*b*) the winter power (3 months), from discharges of 190 000 to 200 000 sec-ft; and (*c*) the winter power from discharges of 200 000 to 210 000 sec-ft. Then, from the foregoing time-flow percentages:

$$T_1 = 0.75 - \frac{(0.75 - 0.64)\,\dfrac{0.75 - 0.64}{0.90 - 0.64}}{2} = 0.72673;$$

$$T_2 = 0.25\,\frac{1.00 + 0.90}{2} = 0.2375; \text{ and } T_3 = \frac{(0.90 - 0.75)\,\dfrac{0.90 - 0.75}{0.90 - 0.64}}{2}$$

$$= 0.04327.$$

---

[20] Plate 19, of Appendix B (revised to November, 1930), Joint Board Rept. of 1926.

The good quality secondary power from discharges up to 210 000 sec-ft equals $[86.1\ (200\,000 \times 0.75 + 10\,000\ T_1) + 76.4\ (190\,000 \times 0.25 + 10\,000\ T_2 + 10\,000\ T_3)] \times 0.096594 - 1\,402\,158 = (13\,540\,714.73 + 3\,843\,508.28)\ 0.096594 - 1\,402\,158 = 277\,054$ hp (average). Similarly, the poor quality secondary output produced from discharges ranging from 210 000 to 235 000 sec-ft may be computed, as follows: $25\,000 \times 86.1 \times \frac{(0.48 + 0.64)}{2} \times 0.096594 = 116\,429$ hp (average).

The estimated average annual production is summarized in Table 7.

TABLE 7.—AVERAGE ANNUAL POWER PRODUCTION.

Class	Horse-power	Kilowatts	Kilowatt-hours
Primary	1 402 158	1 046 010	9 163 000 000
Secondary-good quality	277 054	206 682	1 810 500 000
Secondary-poor quality	116 429	86 856	760 900 000
Total	1 795 641	1 339 548	11 734 400 000
United States' share (50%)	....	....	5 867 200 000

The construction cost of the works chargeable to power, as adjusted by Professor Mead for an installation of 2 200 000 hp at Barnhart Island, amounts to $146 645 500 (Item No. 59, Table 1). This is based on the assumption that the cost of the dams, dikes, channel excavation, etc., useful and necessary for both navigation and power, will be apportioned equally, 50% to each. Power may be called upon to bear a heavier share of the burden, but for present purposes the more optimistic proration will be adopted. Interest during construction amounting to 12½% (5 years at 5% × ½), or $18 330 700, will bring the total outlay to $164 976 200 or, say, $165 000 000, by the time the plant is ready for operation. The investment of the United States in the construction, therefore, may be taken as $82 500 000.

The annual cost of the power development facilities of the United States estimated on a commercial basis for comparison with competitive sources is, as follows:

Interest ($82 500 000 @ 5%)	$4 125 000
Amortization (40 yr @ 5%; factor, 0.0083)	684 750
Depreciation ($50 000 000, 33 yr; factor, 0.0125)	625 000
Operation and maintenance (60 cents per hp installed)	660 000
General expenses, legal and management (15 cents per hp installed)	165 000
Federal license fee (90% capacity 669 000 hp @ 25 cents)	167 400
New York State charges @ 1.5%	1 237 500
Total	$7 664 650

The foregoing financial set-up assumes the development undertaken by some form of a public corporation probably financed by revenue bonds and with obligation to pay the customary Federal charges and State fees equivalent to taxes.

An important additional item of cost in a large development of this kind arises from the idle investment during the years immediately succeeding completion while the market is being built up to the full capacity of the project. Contracts for the Boulder Canyon power were negotiated on a basis of a 4-yr absorption period, but it is now evident that a considerably longer time will be required for the growth and adjustments of the tributary markets to utilize the available output. In the report of the New York State Commission eight years was assumed as the absorption period[21] for the St. Lawrence power. On account of possible savings by means of progressive partial installation it seems reasonable to assume five years and estimate the added capital charge to the project by taking one-half the annual costs for such period. This amounts to $19 161 625 and increases the total investment at the time the plant reaches full operation to $101 662 000. Interest and amortization on the added capital charges increase the annual costs to a total of $8 781 800.

One-half the primary output that will be available to the United States amounts to 4 581 500 000 kw-hr. This presumes discontinuing the diversion of approximately 20 000 sec-ft which supplies the existing Massena Plant and instead serving equivalent energy amounting to about 80 000 hp of peak and 400 000 000 kw-hr per year from the main plant. The primary output available for disposal is thus decreased to 4 181 500 000 kw-hr. At the same time, by crediting proportionate operation, maintenance, and other appropriate costs amounting to $207 800, the annual cost of the generating project is reduced to $8 574 000.

Forecast of the probable revenue from the sale of power opens up a complicated subject which can be treated here in broad outline only. Obviously, the secondary power, if utilized at all, will have to be sold at very low rates for seasonal industrial purposes in the immediate locality of the plant. Under present conditions, such demand would be negligible, but eventually substantial fractions of these irregular energy blocks might be salvaged by new industries attracted by low-cost power. The share of the United States of the secondary output of good quality averages 905 250 000 kw-hr, and of the poor quality blocks, 380 450 000 kw-hr. Disposal of 70% of the former at 1.0 mill and 50% of the latter at 0.5 mill would probably represent about the maximum expectation. The gross return on such basis would average about $725 000 annually.

The primary power production will have to be marketed at high load factor by wholesaling the large industries induced to migrate to the river, or by transmission to the distant metropolitan load centers. The Boston, Mass., and the Newark, N. J., Districts probably offer the most promising prospects. Transmission in either case would be about 325 miles. New York

---

[21] Rept. of the St. Lawrence Power Development Comm. (State of New York). January 15, 1931, p. 59.

City could be reached with about the same length of line, but in competition with local steam-generated energy the value of the imported power would be considerably less due to the costly underground cable facilities required for access to the city sub-stations. Present dimensions and characteristics of the load of the Boston and Newark Districts might cause some question about the capacity of these markets to utilize the St. Lawrence primary energy as base load at high load factor about ten years hence. It is recognized that the reputations of most authoritative prognosticators relative to the probable growth of electric load have suffered heavily during the past few years, but nevertheless the assumption is made that in due course the Boston and Newark Districts, with taps serving some of the secondary load centers en route, could each absorb about one-half the St. Lawrence primary energy at 85% utilization factor and with minimum load factor of 80 per cent. This combination imposes peaks about 6% in excess of the average primary output, but it is considered that the resulting fluctuation of discharge would be within the permissible limits during the non-navigation season and, under the more severe requirements for constant flow during the summer, the variation of output could be accomplished without seriously affecting the characteristics or value of the secondary power. Without going into details, it may be assumed that the cost of generation by local steam plants at 80% load factor will be approximately 4½ mills per kw-hr as developed by the report of the New York State Commission.[22] This rate, therefore, represents the maximum market value of the imported power delivered at load centers.

For transmission of the primary output of 4 181 500 000 kw-hr (477 340 average kw) with a utilization factor of 85%, load factor of 80%, and transmission efficiency of 87% (line, 9.5%; step-down, 1%; and synchronous condensers, 2.5%), the necessary peak capacity at delivery terminals will total 441 241 kw. This will require four 220-kv circuits (two each to Boston and Newark), with delivery capacity of 110 000 kw each. At $25 000 per circuit-mile, including right of way, the lines will cost $32 500 000. Terminal sub-stations with synchronous condensers at $16 per kw and sectionalizing and switching stations will cost $7 500 000 more, thus making the total investment in transmission facilities $40 000 000. The annual cost on a 9% basis (interest, 5%; amortization, 1%; and depreciation, operation, and maintenance, 3%) will amount to $3 600 000, not including taxes which, if estimated at 1.5% of the investment, would increase the total annual cost to $4 200 000.

Steam stand-by, equivalent to 50% of the delivery capacity, or 220 000 kw, will be necessary to assure reliability of service comparable with local production. If estimated at $80 per kw the investment will be $17 600 000 and the annual cost, exclusive of taxes, $2 436 500 (interest, 5%; amortization, 1%; depreciation, 3%; operation and maintenance, $2.25 per kw; general expense, 50 cents per kw; and, stand-by fuel, 0.25 ton @ $4.50 per kw). Taxes at 1.5% will increase the annual stand-by cost to $2 700 500.

---

[22] Rept. of St. Lawrence Power Development Comm. (State of New York), January 15, 1931, pp. 80-82.

The cost of the delivered energy amounting to 3 092 219 250 kw-hr (4 181 500 000 × 85% utilization factor × 87% transmission efficiency) is summarized by the following tabulation:

	Including taxes	Without taxes on transmission facilities
Production cost ($8 574 000 less $725 000 return from secondary)	$7 849 000	$7 849 000
Transmission and sub-station cost..	4 200 000	3 600 000
Stand-by cost....................	2 700 500	2 436 500
Total delivery cost.........	$14 749 500	$13 885 500
Cost per kilowatt-hour delivered, in mills	4.77	4.49

It is apparent from these general figures that in competition with equivalent local steam-plant generation, at approximately 4½ mills, the introduction of St. Lawrence power into the large metropolitan districts fails to provide a very favorable possibility even though the transmission lines, sub-stations, and stand-by plants should be relieved of taxes. In any event, it will be clear that there is no hope of obtaining any large profits or extensive public benefits from the enterprise.

The alternative of endeavoring to market the output in the immediate vicinity of the generating plant by building up large electro-chemical and electro-metallurgical works, although largely speculative, seems to offer a somewhat beter chance of accomplishment. The development of such a project, however, will require time, a vast expenditure of money, and the closing of industries in other sections. The feasibility will depend largely on the cheapness of the power rates. In order to attract large industrial load, it is doubtful whether the average rate can be higher than 2¼ mills per kw-hr ($14.70 per average hp). Disposal of the primary output at such rate, with 85% utilization factor, would produce revenue of $7 997 119. This would cover the generating cost by only a slender margin after taking credit for the possible return of $725 000 from secondary power.

From the foregoing, it will be evident that the situation offers no assurance of power revenue in excess of that needed to meet the bare carrying charges. Substantial increase in the capital outlay as involved with the adoption of the two-stage plan can easily thrust the project from the border line of financial feasibility into the outer zone of economic impractibility. Hence, the importance of this question of development plan to the United States. In Canada, the situation is different on account of large load centers being close to the power site. The extra cost of about $40 000 000 for the two-stage development is chargeable mostly to the power facilities and would raise production costs approximately 25 per cent. With such an increase, the marketability of the output would be extremely doubtful. Under the circumstances, it would appear that if the two-stage plan is adopted, Canada, in all fairness, should be willing to assume the additional cost.

RUFUS W. PUTNAM,[23] M. AM. SOC. C. E. (by letter).—Reference is made in this paper to a few of the navigation aspects of the power developments under consideration; furthermore, in the tables showing comparative costs, items appear for costs of navigation features embodied in the three plans. This discussion proposes to set forth the writer's views on the relative merits of these plans for water-power development as affecting the navigation interests involved.

Factors affecting the utilization of the waterway by vessels include channel dimensions and curvature, cross-currents, ice conditions, and lockages. Table 8 sets forth some of these factors.

TABLE 8.—FACTORS AFFECTING UTILIZATION OF THE WATERWAY BY VESSELS

	Plan *A* (Crysler)	Plan *B* (Barnhart)	Plan *C* (New York)
Length of canal, in miles	9	8	0
Number of locks	3	2	2*

* In flight.

Channels.—As to channel widths, depths, and curvature, the same specifications have been followed in each plan and, therefore, no differences exist. Plan *A* and Plan *B* are about equal as to length of restricted channel, but they have a disadvantage compared with Plan *C*. A ship will require about an hour more to navigate the channels available with either the Crysler two-stage project, or the Barnhart single-stage project, than it will with the New York single-stage project. Assuming the ultimate capacity provided for in Plans *A* and *B*, as 24 000 000 tons per year, with average cargoes of 5 000 tons per vessel, the vessel-hours lost would be 4 800. At a cost of $30 per hr the annual loss becomes $144 000, which, capitalized at 5%, represents a capital advantage in favor of Plan *C* of $7 200 000. This represents a minimum loss based on capacity tonnage for Plans *A* or *B*, for if smaller average cargoes are assumed the number of vessel-hours lost increases proportionately, but the hourly vessel cost does not decrease in like proportion.

Lockages.—Plan *A* will require three lockages per trip per vessel, while Plans *B* and *C* will require only two. It is customary to allow an average of 1 hr per lockage, even though many passages are made in much less time. The records at the locks at Sault Ste. Marie bear out this conclusion.

The New York Plan (*C*) has two locks in flight, while the locks provided by Plans *A* and *B* are separated sufficiently to have no added influence on time of transit. The Joint Board of Engineers estimates the annual capacity of a single dock development at 24 000 000 tons, but places that of an improvement involving a set of flight locks at 16 000 000 tons per year. The average time of 1 hr per transit through a single lock, therefore, becomes 1½ hr for each lock in a set of flight locks. For comparative purposes, therefore, lockage times are as follows: Plan *A*, 3 hr; Plan *B*, 2 hr; and, Plan *C*, 3 hr.

Using the same assumptions as to size and costs of vessels and annual capacity of the waterway as before, Plan *B* has a capitalized advantage of $7 200 000 as regards Plans *A* and *C*. Combining the capitalized value of lock delays with those involved in channel transit, it appears that Plan *A* entails a loss of $7 200 000 as compared with Plans *B* and *C*, while Plans *B* and *C* are of equal value in these respects.

---

[23] Director, Chicago Regional Port Comm., Chicago, Ill.

Capacity.—A further consideration involved is that of the ultimate capacity of the three projects which is 24 000 000 tons per year for Plans *A* and *B*, and 16 000 000 tons per year for projects involving flight locks, according to the report by the Joint Board of Engineers. If Plan *C* is followed, it will be necessary to install a parallel flight of locks in order to obtain the same capacity as that afforded by Plans *A* and *B*. This will involve an expense of between $7 000 000 and $8 000 000. As far as ice conditions and cross-currents are concerned, it does not appear from any of the plans available that any difference exists between Plans *A*, *B*, and *C*.

Summary.—The writer considers that, from the point of view of the interests of navigation alone, Plan *B* is superior to both Plans *A* and *C* which are of about equal ultimate value.

JAMES W. RICKEY,[24] M. AM. SOC. C. E. (by letter).—Engineers are under a moral obligation to advise the public and to assist in forming an enlightened public opinion on such matters as the development of water power along the International Section of the St. Lawrence River, which they are particularly qualified to discuss.

The author's analysis points unmistakably to the conclusion that the development of this section of the river in a single-stage plan is superior in every engineering aspect to its development in a two-stage plan. This raises the question as to why the two-stage plan was incorporated in the Treaty, now (November, 1933) awaiting ratification. A study of the various reports apparently provides the answer, namely, that an agreement between the Canadian and the American Sections of the Joint Board of Engineers must be reached before any development can be undertaken, and that the Canadian Section would agree to the two-stage plan and no other, notwithstanding the less satisfactory navigation facilities, the reduced power output, and the greatly increased cost of the two-stage plan.

It is vitally necessary that the people of both countries and their responsible representatives be fully acquainted with all the facts before adopting a definite plan for the public development of this great national resource. The facts clearly made evident by the paper are that, when using the same unit prices in both estimates of cost, the single-stage Plan *B* will be worth about $94 000 000 more and will cost about $38 000 000 less than the two-stage Plan *A*; and, that when similar comparison is made between Plan *C* and Plan *A* the corresponding sums will be very much greater. (See Table 3, Item No. 9, and Table 1, Item No. 18.)

The author is to be congratulated highly upon his clear, unbiased analysis of the facts set forth in the various published Government reports. The paper and the discussion incident thereto should be of great assistance in securing the early execution of this project and in accordance with the best interests of all concerned.

[24] Chf. Hydr. Engr., Aluminum Co. of America, Pittsburgh, Pa.

WALTER M. SMITH,[35] M. AM. SOC. C. E. (by letter).—The canals at the International Section of the St. Lawrence River, are somewhat analogous to the Sault Ste Marie Canal, although the class of boats passing through it will be quite different. As about 60% of the freight carried through the "Soo" Canal is iron ore, a type of vessel not sufficiently strong for ocean going, has been developed for this traffic. Therefore, conclusions drawn from traffic through the "Soo" Canal can only be applied in a very general manner to the International Section of the St. Lawrence River.

Table 9 shows statistics of traffic through the "Soo" Canal from which some general conclusions may be drawn. It will be seen from Table 9(*a*), Item No. 11, for example, that in 1929 in moderately heavy traffic the speed in the canal was about 2 miles per hr, whereas in Table 9(*b*), Item No. 23, it is shown that in maximum traffic through each lock it was from 0.8 mile to 1.4 miles per hr. Thus, it will be seen that as traffic increases the speed is cut down and all vessels lose more time in transit. The canal at the "Soo" is 300 ft wide against 200 ft proposed for the canal in Professor Mead's study, and yet the engineers in charge claim that it is not sufficiently wide for two-way traffic. It will be seen that the average size of vessel in the

[35] Chf. Engr., State Dept. of Public Works and Bldgs., Div. of Waterways, Chicago, Ill.

"Soo" Canal in 1929 was 6 250 dead weight tons (Table 9(*a*), Item No. 5, Column (6)); therefore, this size of vessel will be used for a comparison in this study.

The Poe Lock at the "Soo" Canal is the same length as the proposed locks on the canal being discussed, but is 100 ft wide instead of 80 ft as is proposed for the locks in question. It will be seen from Table 9(*b*) (Item No. 16, Column (3)) that 43 083 490 tons of freight passed through the Poe Lock in 1906, but it will be noticed that there was an average of 1.7 vessels per lockage, and making a correction for an average of only a single vessel of average size per lockage would give a traffic of about 26 000 000 tons per year, which is double the estimate of the Joint Board of Engineers for the capacity through the locks in question, as long as they are single locks. It will also be seen that if there had been open-water approaches to the Poe Lock the capacity would be much higher because the average time per lockage was only 34½ min, which would give 42 lockages per day mathematically possible, whereas the number was only 16, or about 40% of capacity. It will also be seen that it took 2 hr to navigate the 1¾ miles of canal, or three and one-half times as long as to go through the lock.

The data for the Davis and Sabin Locks are not comparable with the proposed locks as they are 1 300 ft long, although they are the same width (80 ft) as the proposed locks. On account of the great increase in traffic in the "Soo" Canal these locks were built to accommodate two of the largest lake steamers at the same time. It is interesting, however, as showing what capacity may be reached in locking. No other canal in existence has ever passed more than 60% of the traffic of one of these locks.

It will be noted that the great traffic through the Poe Lock was in 1906 long before either of the other two locks were built, the Davis Lock having been put in commission in 1914 and the Sabin Lock in 1919. After the completion of these two locks the passenger traffic was turned over to the Poe Lock and the two large locks turned over to freight traffic almost exclusively. Therefore, the 14 684 835, shown for the Poe Lock in 1929, is registered tonnage; in all other cases, it is dead weight tonnage.

It will be noted that as the tonnage fell from 43 000 000 to 14 700 000 the locking time decreased from 34.5 to 22.8 min, and the speed in the canal increased from 0.8 mile to 1.94 miles per hr. This shows vividly the bottleneck effect of any narrow canal in slowing down traffic as the volume of traffic increases.

Assume that passing places will be made in the proposed canal sufficiently close together for a vessel to pass from one to the other in the same time as it takes to go through the lock. In this case the mathematically possible maximum traffic would be 1 vessel every 25 min through the lock; but every vessel will be waiting one-half the time throughout its passage through the canal.

Assume next the existence of an ideal condition of a series of standard-sized vessels, 6 250 tons, moving with clock-like precision, one going through the lock every 25 min. This would give 58 lockages per day, or a capacity of 58 × 6 250 = 362 500 tons per day, or 132 000 000 tons per year. Assume also that it is possible to attain 33% of this tonnage as was done at the Poe Lock in 1906. It will then be seen that it is not the lock that is the bottle-neck, but the canal. At the Poe Lock with a canal 300 ft wide, only an average speed of 0.8 mile per hr was attained in the canal; therefore, assume a speed of 1 mile per hr in the canal. The upper canal at Crysler Island is 2.5 miles long and the lower one at Barnhart Island, 7.5 miles long; a total length of 10 miles. Therefore, it will take a vessel 11 hr, including the time through lockages, to get through the canal.

In the Massena Point scheme there is a proposed channel, 450 ft wide, leading up to the lock down stream for 2 miles, and open-lake navigation on the up-stream side so that vessels can come and go at open-river navigation speed except for the 2 miles, where the speed will have to be reduced somewhat, although vessels can pass at moderate speed. To pass through the flight of two locks having a lift equal to the three locks in the other scheme will require about 1 hr. This would give 24 lockages per day, or 24 × 6 250 = 150 000 tons per day, or 54 750 000 tons per year. As there is no bottle-neck canal here, these locks can certainly pass more than the canals and locks in the Crysler Island Plan. The vessels approaching these locks could certainly run 10 miles per hr in the open river, and at least 8 miles per hr in the 450-ft channel; therefore, it will require only 2 hr to go 10 miles, including the lockage. This will be a saving in time of 9 hr.

It costs about $64 per hr to operate a vessel of 6 250 tons; thus, the extra expense for each vessel in the Crysler Island Plan will be $64 × 9 = $576 and 19 vessels will be $576 × 19 = $10 944 per day, or $10 944 × 365 = $3 994 560 per year. This amount capitalized at 5% gives $79 891 200. Therefore, under the foregoing assumptions, other things being equal, an additional expenditure of about $80 000 000 would be justified on the Massena Point Plan over and above what the Crysler Island Plan would cost for navigation alone.

In studying the advisability of building a sea-level or lock canal in 1906, the Board of Consulting Engineers for the Panama Canal estimated that the time it would require a vessel of the size used herein would be from 8.6 hr for 10 vessels per day, to 11.1 hr for 30 vessels per day, to pass through the sea-level canal, with passing places 2.5 miles apart. The same size of vessel could pass through the 85-ft level lock canal, including the six locks, in 9.5 hr for 10 vessels, and 10.0 hr for 30 vessels, per day. This was a speed of from 7.7 to 7.1 miles per hr in the lock canal, allowing 3 hr for lockage, and an average speed of from 5.7 to 4.5 miles for 10 vessels per day per hour, with an average of 30 vessels per day, for the sea-level canal with passing places 2.5 miles apart. The dimensions assumed for the two canals are given in Table 10.

It will be noticed that even with only 12.4 of the 49.7 miles of the lock canal, with a bottom width of less than 500 ft, the speed of vessels, with 10 vessels per day, including lockages, was 7.7 miles per hr, and for 30 vessels, 7.1 miles per hr, in the canal.

The high speed of vessels assumed for the lock canal at Panama is explained by the fact that 75% of the canal is 500 ft, or more, and 50%, 1 000 ft, or more, wide. Therefore, 50% of the distance is practically open-lake navigation. In channels 500 ft wide, vessels of the size herein assumed can pass each other at full speed. With channels 300 ft wide they can pass at reduced speed without stopping; but at 200 ft, or less, in width one vessel will have to stop and the other greatly reduce its speed.

TABLE 10.—DIMENSIONS OF SEA-LEVEL AND LOCK CANALS PROPOSED FOR PANAMA CANAL

Item No. (1)	Bottom width, in feet (2)	Length of sea-level canal, in miles (3)	Length of 85-ft level canal, in miles (4)
1	150	21.1	....
2	200	18.8	4.7
3	300	3.9	7.7
4	340	0.3	....
5	350	0.5	....
6	500	....	8.2
7	800	....	3.8
8	1 000	....	19.5
9	Unlimited	4.7	5.8
10	Total....	49.3	49.7

Even if it is assumed that the vessels passing through the canals in the Crysler Island Plan can average 2 miles per hr, including time lost at meeting places, it will take each vessel about 6.5 hr to pass through the 10 miles of canal and locks, or 4.5 hr more than in the Massena Point Plan. This is as favorable an assumption as can be made and even under these conditions the time lost will be valued at about $2 000 000, and capitalized at 5%, about $40 000 000.

When the traffic is increased sufficiently to require an enlargement of the canals and locks the capacity of the Massena Point Project can be doubled approximately by building an additional flight of locks alongside the other at a cost of about 70% of the cost of the original flight of locks and appurtenances. As the cost of the original flight of locks and other work solely for navigation is estimated at $21 138 000, this increase will be $21 138 000 × 70% = $14 796 600. To increase the capacity of the Crysler Island Project in the same proportion will require an increase of probably nearer 65%, and as the estimate of cost of work purely for navigation is $34 138 000, the increase in cost would be $34 138 000 × 65% = $22 189 700, or an increase of $7 393 100.

It is evident from the foregoing analysis that, other things being equal, the Massena Point Plan is far preferable to the Crysler Island Project from a standpoint of economy. In the Barnhart Island Project there is a moderate gain over the Crysler Island Project, but as the length is about the same as that of the lower canal in the Crysler Island Project, the gain would be only about 25% as great as for the Massena Point Project.

J. W. BEARDSLEY,[26] M. AM. SOC. C. E. (by letter).—The author has presented a critical study of the three St. Lawrence River projects submitted to him for comparison, and has arranged his finding in exceptionally convenient form for ready reference. He states that his knowledge of the rapids of the river is limited. He implies that there are phases of the problem other than the engineering that should be considered. He also implies a compliment to the Canadian Government on account of its policy of re-appointing the members of its Commission, and, possibly, a criticism of the United States in not following a similar policy. If these implications had been clearly stated, the writer would have agreed heartily.

The report of the Deep Waterways Commission (1900)[27] relates specifically to navigation problems and estimates of cost for channels, 21 and 30 ft deep. In that report, the writer discusses the geology of this section.[28] Broadly, the rapid St. Lawrence River flows along a ridge and the sluggish Grass River in a valley, 50 ft lower and 3 miles distant.

In one case while inspecting wash drill borings, the writer noted that the overlying boulder clay was being penetrated with difficulty. The drill broke through it, and the following 70 ft in blue clay was drilled in about 30 min, or as rapidly as connections could be made. Similar formation was found at Massena Point and along the southeast shore of Cornwall Island. It was this formation that caused the failure of one of the piers during the construction of the Ontario and Western Railway Bridge. The foundations were on a thin layer of boulder clay through which the increased velocity of the stream cut down to the clay formation. Boulder clay, found previously when making sub-surface explorations, had been discovered resting on rock in place. To find it resting on a considerable body of blue clay was a new experience to the writer—a condition that may be explained if secondary clay deposits from a prior glacier had been bridged by the ice-cap of a subsequent glacier.

In another case, the formation of frazil in the forebay was creating an anchor-ice barrier in the tail-race, which reduced the head by one-half. During past years the northern water-power companies have had considerable trouble in maintaining a free tail-race under such conditions—an important item when continuous electrical service is financially necessary.

These facts have been stated to indicate that at least several years of critical observation of the St. Lawrence is needed to estimate properly the effects of ice-jams, anchor ice, frazil, water-stages, etc., and to counteract them. In general, the northeastern part of the United States is well provided with electrical energy. New electrical devices for household use are appearing almost daily, and the various systems are constantly soliciting consumers for surplus power.

A circle described about Massena Point as a center, with a radius of about 300 miles, will include Boston, Mass., New York, N. Y., and Buffalo, N. Y. The principal systems with their subsidiaries operating in New York State are the Niagara Hudson, the Associated Gas and Electric, and the New York

---

[26] Cons. Engr., Syracuse, N. Y.

[27] H. R. Doc. No. 149, 56th Congress, 2d Session.

[28] *Loc cit.*, Appendix 11, p. 398.

Edison. Of these three systems, the Niagara Hudson serves the greater area (and probably the greater population, excluding New York City) of the State and more definitely the northern half, including the area adjacent to the St. Lawrence River. It is interconnected with systems serving contiguous territory. A few facts regarding that system will illustrate the points the writer wishes to make.

More than 60% of the total capacity of the Niagara Hudson Company, (1 695 000 kw), is in water-power plants. The load factor on the day of maximum demand in 1932 was 78 per cent. The number of farms estimated within the franchise area is 74 374 (the total in the State was 159 806 in 1930); the number of farm consumers is 27 184, or 38% of the farms in the franchise area. The annual report to stockholders (1932) shows an average farm rate, in cents per kilowatt-hour, as follows: 1929 = 7.384; 1930 = 6.764; 1931 = 6.229; and 1932 = 6.059. (The average rate for residence customers was similarly reduced from 5.028 cents per kw-hr in 1929 to 4.658 cents in 1932). Due to unfavorable location, or greater distance from existing transmission and distribution lines, the rate for many of the remaining farms wishing electrical service would be considerably higher even if no charge were made for the energy supplied.

In 1932, the number of shareholders of common stock was 98 300, and dividends were paid to the amount of $10 471 878, but reductions have been made in the 1933 dividends. It seems reasonable to assume that many consumers of all classes are holders of common stock, and that any sharp competition or undue volume of surplus energy will cause a considerable reduction in dividends, offsetting any practical reduction in rates. It is generally conceded that even if power was furnished free, the reduction in rates in many cases would be nominal because of the total costs of distribution.

The proposed development of the St. Lawrence River in the near future would throw into a field, already amply supplied, nearly 2 000 000 hp of energy. Can practical use be made of it without the serious depreciation of existing plants? A complete plan should show how this block of power will be marketed at a benefit to the entire State and community.

The sum of the cost of Plans *A*, *B*, and *C* given in Table 1, Item No. 35 (or Item No. 85), divided by the sum of primary and secondary horse-power, Table 1, Item No. 9 (or Item No. 59), gives an average development of about $80. In view of the continuing improvements in steam power with its advantages of location favorable for transportation, markets, labor, and fuel, this average cost is not financially attractive.

On the St. Lawrence River the development of power and of navigation are closely related and interdependent. When navigation is possible for vessels of about 25-ft draft, the benefits to Canada and to several of the Northern Central States will be large. The effect on the Barge Canal and the industries of New York State and New England will doubtless be harmful. In any case they will require broad re-adjustment.

There is no doubt about the ultimate development of the St. Lawrence. However, present conditions throughout the nation, with large electrical projects under way on the Colorado River, the Tennessee River, and in the Columbia River Basin, suggest at least that the St. Lawrence development can be postponed advantageously to both countries. Reduced utility rates is a popular slogan—a vote getter. Electrical appliances are no longer luxuries in American homes. If the excessive rates and unfair practices charged[29] against some companies are true, they can be regulated by equitable laws far more economically for the average citizen than by throwing a huge block of power, without definite plans for its utilization, into an area now provided with surplus power. The writer has made no study of conditions in Canada. If they are similar to those in the United States, the safest plan would be to delay construction until the profitable use of the additional power arises.

It is an enticing vision to plan great power developments, interconnected throughout the nation, technically and financially operated at reasonable profits, furnishing energy to consumers at fair rates, reducing drudgery, and making more profitable the increasing hours of leisure. Such a plan seems to be the goal of at least a few of existing operating and holding companies. Some have exploited the public until faith is lost in all. Will plants operated by the Government reach the desired goal? Does the history of Muscle Shoals prove it? The possibilities of the St. Lawrence project will remain "available assets without depreciation" until utilized.

Conclusion.—The writer's conclusion is a repetition of the last sentence of Professor Mead's "Synopsis," with a modification of his final words, namely, it will be a serious mistake and a misfortune to both the United States and Canada, if the treaty now pending is ratified on the basis of the construction in the near future of works controlling the major hydro-electric power of the St. Lawrence River.

L. F. HARZA,[30] M. AM. SOC. C. E. (by letter).—The author has done a great service to the taxpayers and power users of both Canada and the United States by his analysis of the proposed official plans for developing water power along the International Section of the St. Lawrence River. Since he has had no previous connection with any of the St. Lawrence River investigations, his analysis is unbiased by preconceived ideas. On the other hand, the analysis may have fallen into error if the unit prices or other basic assumptions of Plan *C* are not comparable with Plans *A* and *B*, a question regarding which a difference of opinion exists.

The excess cost and its equivalent, of the two-project plan over either of the single-project plans, is so great, even after allowing for possible error, that exceedingly momentous reasons of absolute vital concern to the success of the project would need to be advanced to justify the extra cost and equivalent capitalized excess operating expense.

It is important to realize that the best navigation facilities, in combination with the best power development, are of paramount importance to Canada and the United States. Although power development is secondary in general to navigation, it is the prime requisite to Ontario and New York. The "best plan" is that which provides, with maximum economy, the most satisfactory combined navigation and power facilities, giving due consideration to: Physical conditions, capital charges, cost of operation, maintenance, renewals and repairs of structures, navigation, amount of primary power developable, reliability and cost of power, etc.

---

Navigation.—It would seem that navigation merits far greater consideration than it has received in the published reports. Under Plan *A* the ships must pass through about 10 miles of canals and 3 locks as against 8 miles of canals and 2 locks in Plan *B* and only 2 locks—there being no canals—in Plan *C*. For fair comparison, it would be necessary to add to the cost of Plan *A* the capitalized value of the lost time per year of all vessels expected to navigate this waterway. Competent authority has estimated that 3 hr more, or 6 hr per round trip, is required to navigate the 10 miles of canal and 3 single locks of Plan *A*, as compared with the double lock without canal of Plan *C*. If anticipated traffic in this waterway is to be realized, the capitalized value of this time might well be a deciding factor in favor of Plan *C*.

Arguments Against the Single-Stage Development.—In the last paragraph of his paper, the author states that he can see no valid reasons to justify the two-stage plan which can outweigh the millions of dollars of value in favor of other plans. It would seem proper, therefore, to analyze the arguments advanced against a single-stage development.

The following objection is stated[22] in the Conference Report:

> "If, as an alternative, the International Rapids Section be improved by a single-stage project, then control of flow must be secured by operation of gates and turbines at a power plant which will develop about 2 000 000 horsepower. This is not regarded favorably by the down river interests, since this single plant would serve a large and populous territory both in Canada and the United States, and operation restrictions would be difficult to impose in view of the fact that it would be a dominant interest in the territory served. Again, the additional flooding of land [15 360 acres, of which 9 600 acres are in Canada] and the extent of the embankments, along with some adverse effects at the end of the navigation season, make the single-stage project undesirable."

The "control of flow," as noted in the preceding paragraph, was referred[23] to by a member of the Canadian Section, when testifying before the Canadian Special Committee on the St. Lawrence River development:

> "We insist that the control of the flow from Lake Ontario be not connected with a power plant having a capacity of several million horsepower. The ideal plan would be the construction of a control dam for the flow only. But as this plan would involve the loss of a certain quantity of power which may become very valuable, and which has an important value to-day, we agreed to connect this dam with a hydroelectric plant of much less proportions, and which can be operated as a basic plant with a uniform load 24 hours a day. * * * For this reason we favor concentration at two points—'the two-stage development.' The control dam for Lake Ontario would be at Crysler Island, a few miles below the town of Morrisburg."

---

[22] See Conference Report, 1929, p. 4, paragraph 9.

[23] See First Annual Rept. of the Power Authority of the State of New York, p. 23.

The safety of the City of Montreal is referred[33] to in the Treaty as follows:

> "The Canadian project of a 2-stage development in the International Section has been adopted instead of the original American project of a single-stage development. The cost is slightly more, but the Canadian officials have felt that the 2-stage development is desirable for many reasons, amongst others for the complete assurance of the safety of the City of Montreal."

In analyzing the foregoing arguments against the single-stage development, it is enlightening to consider carefully the 2 000 000 hp. partly completed (fall of 1932), all-Canadian, single-stage development on the St. Lawrence River near Beauharnois, Que., and much closer to (in fact only about 28 miles above) Montreal. In order to make this development efficient, economical, and in accordance with the latest and best engineering practice, practically every feature of general arrangement was incorporated in it that is so strongly objected to in a single-stage international development, with the result that it stands for the "best plan" from the standpoint of engineering design, of capital costs, of sustaining charges, and of cheapness of product to the Canadian power consumer.

The 83-ft fall between Lake St. Francis and Lake St. Louis is developed at Beauharnois[34] by a single-stage project, where the "control of flow must be secured by the operation of gates and turbines at a power plant that will develop about 2 000 000 hp." and hence "a dominant interest in the territory served." The power house is at the end of a canal, 15 miles long, embanked by dikes on both sides throughout its entire length. The entire normal flow of the river will be used to carry the ultimate load and, when part load is carried, the surplus water will be passed through the sluice-gates yet to be built across the main river channel at a distance of more than 15 miles from the power house.

Since the general physical conditions obtaining at Beauharnois are substantially the same as those obtaining in the International Section of the river (except in respect to loss of land by submergence), it would seem that the Beauharnois development stands in mute refutation of the foregoing arguments against a single-stage development under Plan *B* or Plan *C*.

Adoption of the Two-Stage Plan.—The Reconvened Report forms a part of the proposed Treaty between the United States and Canada, now (November, 1933) awaiting ratification. Upon this Treaty depends the joint expenditure of $543 000 000,[35] of which sum, $274 742 000 is allocated to the two-stage development, termed Plan *A* in the paper.

For many years prior to the issuance of the Joint Board's Reconvened Report, dated April 9, 1932, it was known that a wide difference of opinion existed between the Canadian and American Sections as to the relative merits of the two-stage and single-stage plans of development. It was also known that most members of the several American Sections of the Joint Board were strongly opposed to the two-stage plan and that many arguments advanced in support of such plan were not considered by those Sections to be of sufficient importance to justify the excess cost from a standpoint of sound engineering and economic reasoning rather than sentiment.

---

[33] "Great Lakes-St. Lawrence Deep Waterway Treaty," *Publication No. 347*, Dept. of State, 1932, p. 11.

[34] "Beauharnois Development of the St. Lawrence River," by W. S. Lee, M. Am. Soc. C. E., *Electrical Engineering*, June, 1933, p. 377.

[35] "Great Lakes-St. Lawrence Deep Waterway Treaty," *Publication No. 347*, Dept. of State, 1932, p. 10.

It seems evident that the two-stage plan was adopted for the simple and single reason that a one-stage plan could not be agreed upon under the Board's instructions to report on "a mutually satisfactory plan for the improvement of the International Rapids Section."[36] The author's analysis would indicate that it represents an unfortunate international compromise, apparently not the best and most economical engineering solution of the problem.

Suggested Procedure.—The great difference of opinion revealed by the author as to the merit of the two-stage *versus* the single-stage plans, raises considerable doubt as to the wisdom of the ratification of the Treaty as it now reads. It would seem that a speedy and satisfactory determination of the "best plan" will be possible only after a final, critical analysis is made of all available data pertinent to Plans *A, B,* and *C,* by an International Board, comprising all new members from both countries without preconceived or previously advocated or supported ideas to defend. Before such a board the members of previous boards should appear as witnesses, not as principals.

Unquestionably, either country has the right to prefer and to insist upon the adoption of a plan which is more expensive than the "best plan;" but in doing so, the right of the taxpayer and the ultimate consumer to be correctly informed as to the extra financial burdens he must carry, should be considered.

If a fair international compromise is to be reached, it would seem that the country which prefers the "best plan" should not be penalized by being forced to carry the extra costs imposed by a less economical plan. Therefore, if for any reason of sentiment or otherwise either country should prefer a more expensive plan, the extra capital cost and the extra operating expense should be determined and stated. In this way, both countries will understand in advance what extra cost is incurred because of the adoption of the more expensive plan. Such extra cost could be met by proper allocation of cost between the two countries or proper division of the power output.

The International Boundary should be adjusted, if necessary, so that the Canadian power house will be on the Canadian shore, regardless of the adopted plan. Such adjustment of boundary could also well equalize the loss of agricultural land by the two countries. Only the southern part of Canada is climatically adapted to intensive diversified agriculture and it is quite natural for Canadians to resent any disproportionate sacrifice of land in this region.

Under such procedure, the public mind will be assured of the superiority and fairness of the adopted plan, the opposition to this development will largely disappear, and the citizens of both countries will give to this great project the whole-hearted support it merits.

---

[36] See Rept. of Joint Board of Engineers (Reconvened), p. 3, paragraph 6.

ADOLPH J. ACKERMAN,[37] ASSOC. M. AM. SOC. C. E. (by letter).—The early history of the St. Lawrence Waterway project seems to be developing with surprising similarity to the early events in the planning of the Panama Canal. The general features of both projects quite obviously run along parallel lines: They are the two most important artificial navigation routes in the Western hemisphere; the estimated cost to complete the Canal when the United States took possession was about the same as the present estimated cost of the Waterway; engineering and construction problems are of similar magnitude and beyond ordinary conception; matters of policy in each project are of international importance; both are of vital concern to the same industry, the railroads, and where the Waterway at present has its chief controversy in the single-stage *versus* the two-stage plan, the Canal was debated in highest circles on the feature of the sea-level type *versus* the lock type. It is a matter of record that a majority of the Board created in 1905 to study the problem reported in favor of the sea-level canal. Subsequently, however, the Senate, giving heed to the Minority Report, passed a bill providing for the lock canal.

The present-day visitor to Panama, who heretofore has more or less taken the Canal "for granted," is at once impressed by the profound logic of its general plan. Such approval, in the end, is the supreme mark of engineering achievement and of unselfish administration of a public trust. It is, obviously, the basis on which Professor Mead has founded his analyses in calling attention to apparent deficiencies in the plans now being advocated in the Treaty negotiations for the Waterway.

At this time it seems likely that the parallelism of the St. Lawrence Waterway and the Panama Canal may be continued. It remains to be seen to what extent the "minority opinion" will receive adequate consideration or will influence future acts.

An unusual opportunity exists on the St. Lawrence Waterway project to use an engineering model to a greater extent than heretofore has ever been attempted. The importance of preliminary investigations by means of models has received general recognition in the United States only in the past few years. One of the greatest current examples is found in the Mississippi flood-control problem where engineering policies and traditions which have stood inviolate for fifty years or more, are boldly being replaced by a new policy of scientific planning on hydraulic models. It has been ably stated[38] that all these changes of policy have long had advocates. They have come to fruition now because of engineering direction that does not fear to experiment. Boldness of engineering initiative buttressed by experimental research has been the inspiration of the new planning. This spirit of research and of willingness to put its conclusions to actual trial deserves express recognition. It has prevailed in every rank of the Engineering Profession.

It is the responsibility of the Engineering Profession to earn this sort of recognition in planning the St. Lawrence Waterway. There are numerous problems of operating conditions and their effect on navigation, ice movements, erosion, river control, and construction procedure and hazards, which may be clearly understood by the few engineers who have devoted the greater part of their lives to a study of the St. Lawrence River, but it is important that their opinions and deductions be studied in the most scientific manner, and compared with any new findings, before becoming rigid policies.

---

[37] Constr. Plant Engr., Tennessee Val. Authority, Knoxville, Tenn.

[38] Editorial, *Engineering News-Record*, June 22, 1933, p. 819.

In the past decade engineers have adopted the science of models to a point where practically all important water-power projects are designed after observing the hydraulic performance of the principal elements on models. However, very often the general features had become established sufficiently to prevent the adoption of major improvements indicated by the model. It is safe to predict that hydraulic models of the St. Lawrence project will eventually be built. By building a comprehensive model as the first step, on which the various proposed plans may be studied in sufficient detail to demonstrate all conditions of operation, navigation, and construction procedure, the project is assured of the soundest basis of planning, and the best answer is given to those clamoring for immediate action.

Not only will disagreement among engineers be dispelled and individual definitions of the term, "hazard," give way to the most logical plan, but plans and sketches will be replaced by a physical picture which is at once understood by public officials, representatives, and the public at large. Such a model can serve as a valuable educational medium among the people directly concerned with the project, and, in place of inferences of political pressure or inadequate educational effort, its scientific operation will direct confidence toward the engineers and officials charged with the responsibility of creating the best and most economical St. Lawrence Waterway.

DANIEL W. MEAD,[39] HON. M. AM. SOC. C. E. (by letter).—The writer is pleased with Mr. Hogg's frank elucidation of the Canadian point of view in regard to the proposed St. Lawrence power development. He is in agreement with the views expressed far more than the discussion would seem to indicate. For example, he agrees with the first statement that "* * * the choice of a single-stage or a double-stage plan cannot be settled satisfactorily solely on engineering or economic grounds." This statement is verified by the official treaty lately before the Senate for consideration, which by no stretch of the imagination can be considered as the best engineering or economic solution.

The writer also agrees with Mr. Hogg that "* * * the fact that it [the St. Lawrence] is an international river cannot be ignored." While, in general, governmental activities must perhaps be based on "political" economy instead of on economics, the difficulties become greatly accentuated when a project becomes international and increase probably somewhat faster than the square of the number of Governments mutually interested.

These difficulties practically vanish, however, if between two nations the administration of one of them is so anxious for the project to materialize that it is not only ready to submit to dictation as to the plans for the development and its cost, but also to surrender, forever, sovereignty over non-international waters lying entirely within its own borders, and, finally, to limit arbitrarily the use of such waters by its own people.

---

[39] Prof. Emeritus, Hydr. and San. Eng., Univ. of Wisconsin; Cons. Engr., Madison, Wis.

Canada and the Province of Ontario are to be congratulated on their intelligent handling of this entire project. To reiterate Mr. Hogg's statement (under the heading, "Reasons for Not Accepting Author's Set-Up"), "* * * the Canadian organizations studying the problem have been living with the river for a number of years, and * * * practically the same personnel has been engaged in the work throughout." The Canadian and Provincial organizations worked independently, but conferred and discussed the problem fully. They found the single-stage development of greater economic value, but such a project involved the raising of the water of the St. Lawrence for about forty miles up the river above the projected dam site. The Canadian inhabitants along this stretch of river apparently became alarmed at the proposal to increase the height of the water, which involved (to them) unknown danger, real or imaginary. Therefore, they appealed to their Parliamentary representatives, and apparently succeeded in creating so strong a public opinion as to render this plan politically impossible.

With the Crysler Island Two-Stage Plan, only the upper twenty miles of the St. Lawrence is to be raised, and this to a less degree; so that while the people along this reach also objected, the ill effect was not considered so apparent and their influence was not sufficient to block the demand of the Ontario Hydro-Electric Commission for the maximum amount of power which could be developed "all things considered." Having fully decided what they could and would do, the Canadian members of the Joint Board were prepared to meet the members of the Joint Board from the United States.

The policy of the United States in regard to the study of this project has been quite different. It has been the continuing policy of the U. S. Government, as far as the Corps of Engineers is concerned, to place an engineering officer on a Federal job for a limited time only, and about the time that he becomes really useful to send him to some other and often quite different type of project. On the power project of the St. Lawrence International Section, for example, there seems to have been no continuing individual service of the American representation; each of the American Sections of the several Joint Boards that have considered this subject, has consisted in general of entirely different engineering officers and, hence, these Sections have been at a great disadvantage and more or less dependent on the Canadian Section and the information furnished by it.

The arbitrary position of the Canadian Section of the Joint Board, and the substantial agreement of the Power Authority of the State of New York and its engineers with the writer's conclusions, is best described by reference to the Second Annual Report of the Power Authority of the State of New York for the year ending December 31, 1932 (pp. 17–18).

Referring to the complications introduced in the negotiations between the U. S. Department of State and the Power Authority by the question of the engineering plans for the development of the International Rapids Section, the report states:

> "* * * the Power Authority early in the negotiations directed its engineers to make a thorough study of all the plans that had been proposed by the engineers of the United States and Canada.

"They reported that the plan prepared for the St. Lawrence Power Development Commission of New York by its Advisory Board of Engineers headed by the late Major General Edgar Jadwin was the most economical and efficient, from the standpoint of both power and navigation, that had been proposed.

"The Trustees therefore formally presented this plan to the State Department with a recommendation that it be given serious consideration by the Joint Board of Engineers which had been reconvened by the United States and Canada in connection with the treaty negotiations. The Power Authority was subsequently informed that the American members of the Joint Board strongly favored this single stage plan but that the Canadian members were insisting upon a two-stage plan with the upper dam at Crysler Island."

According to this report, the objections of the Power Authority to the Crysler Island Plan were laid before the State Department on January 6, 1932. Being strongly impressed, the representatives of the Federal Administration arranged for a joint conference with the representatives of Canada on January 16, 1932. At this conference the engineers of the Power Authority proposed a modified two-stage plan, with a main dam at Massena Point, and a control dam (at which no power could be developed) at Galop Island. It was hoped that this compromise might be acceptable because it was similar to a plan that had originally been preferred by the Canadian engineers and that was abandoned only because the United States Engineers objected to the relatively slight loss of power involved.

The Canadians rejected this plan, however, as well as all proposals for single-stage development and, to quote from the report:

"When it became clear that a treaty could not be negotiated that did not provide for a two-stage plan, the Power Authority adopted the position that, whatever plan might be agreed upon between the United States and Canada, the power development in which New York was primarily interested should not be required to pay more than the power project would cost if constructed in accordance with the most economical plan."

When the foregoing conditions are considered in the light of the American Section's final instructions from Washington (see paper, under the heading, "Introduction"), and the rejection by the Canadian Section of any plan other than the Crysler Island Two-Stage Plan, the findings of the Joint Board of Engineers (Reconvened) that the two-stage plan "is practicable and feasible from an engineering point of view," seems the only one possible under the circumstances.

In some matters the writer is obliged to differ with Mr. Hogg. His statement (under the heading, "General") that "he [the writer] also shows a marked preference" for the New York Massena Point plan, conveys an impression that the writer was in favor of the plan. The writer knew nothing about the proposed New York plan until, in February or March, 1932, when he began a study of the various reports, referred to in the paper. The writer has no preference with respect to the different plans other than that which resulted from a critical analysis of those reports. He does not doubt that Mr. Hogg believes that the estimates of the New York Commission's report are on an entirely different basis from the two Canadian estimates of the two-stage and the single-stage plans, *A* and *B*, and that the corrections which he suggests remove the Massena Point plan entirely from reasonable consideration. On the other hand he cannot believe that the late Maj-Gen. Edgar Jadwin, U. S. A., M. Am. Soc. C. E., the distinguished Chairman of the New York Commission (who, also, at one time served as Chairman of one of the American Sections of the Joint Board and who apparently was well informed on the subject) and the other distinguished civilian engineers who served with him on the New York Board, would furnish their client with an underestimate of more than $26 000 000.

As already explained, the writer is unable to answer specifically the questions raised by Mr. Hogg, and regrets that those civilian engineers who, being sufficiently well informed on this subject to have furnished an effective answer, preferred not to do so.

In the second paragraph under the heading, "General", Mr. Hogg explains what "accounts for what may appear to be lack of sufficient detail in the later reports." This lack is serious concerning not only the power development but the entire St. Lawrence project. Volumes have been written for and against the project, much of which has been in the nature of propaganda. There is—as far as the writer is aware—no place for the interested to turn to get an unquestioned fair and unbiased discussion or undisputed facts showing the desirability of the project, on which an intelligent opinion can be based.

Answering the comments of Mr. Ripley the writer would say that he was assigned the question of a comparison of the various plans of the proposed hydraulic power developments of the International Section of the St. Lawrence River and has not even attempted to discuss the economics of power transmission and use. Fortunately, this matter is covered at some length in the discussion of Mr. Bonner. Neither did the writer attempt to discuss the still greater and more complex question of the St. Lawrence Waterway in its broader significance. The latter question is so complicated that, apparently, little attempt has been made to justify the construction of this project which seems to have become largely a political matter. A fairly complete discussion of this subject appears in "The Great Lakes and the St. Lawrence Ship Channel," by R. S. MacElwee, Affiliate, Am. Soc. C. E., and A. H. Ritter, published in 1921. Based on an apparently impartial examination of the data available, and on a personal examination of the route by Mr. MacElwee, the authors of this volume conclude: (1) That both the waterway and the power development will be very profitable to the citizens of the United States and Canada; (2) that the saving on the shipping of grain will amount to from 8 to 10 cents per bushel; and (3) that great savings will be made on practically all that is produced within the area tributary to the Great Lakes. To quote from the book:

> "This saving will amount annually to approximately the entire cost of the improvement required to admit ocean vessels into the Lakes. * * * The water power developed will not only afford a revenue which will maintain the improvement and amortize the full cost within a reasonable period but it will be the direct means of creating an industrial development which in itself will provide a large traffic on the waterway. * * *"

On the other hand, the most thorough discussion of both the navigation and power questions with which the writer is familiar, is contained in the book entitled, "The St. Lawrence Navigation and Power Project," by Messrs. Moulton, Morgan, Lee, and others, published in 1929. This book is apparently disinterested and is based on the investigation of a number of people extending over several years. Their findings are:

First.—That the saving to the farmer will be 4 cents per bushel on the shipment of wheat and rye (which they estimate constitutes more than 50% of the probable total traffic) from Duluth, Minn., to Montreal, Que., Canada; that is, to reduce the costs from 9 cents per bushel (which was its 1929 price) to 5 cents per bushel over the St. Lawrence Waterway, will cost the taxpayer 11 cents per bushel, or involve a total cost directly and indirectly of 16 cents per bushel.

Second.—That while the power may be economical in connection with electro-chemical or electro-metallurgical industries situated on the river near the power plant, it will be uneconomical if transmitted to the New York Metropolitan, or to the New England, Districts.

Even if this opinion is correct, the project is apparently as sound as most of the Government navigation-power projects now under way. The economics of this problem are greatly involved and many opinions concerning them are diametrically opposed. In the writer's opinion this project ultimately will be carried to completion. If, in general, the internal navigation projects of the United States are at all warranted, this project which opens up a great territory of the United States and Canada to ocean navigation should ultimately be of great importance. It seems unfortunate that the nations involved have failed to investigate the economics of the problem to the fullest possible extent, but such investigations are so rare in Government undertakings that its absence in this case should not be surprising.

The writer appreciates the discussions of Messrs. Putnam, Smith, and Harza on the effects of these different power developments on navigation. This is a subject with which the writer is unfamiliar and the conclusions of these engineers indicate that the estimate, in the paper, of the greater value of the Massena Point Plant is not overdrawn.

The writer agrees with Mr. Ackerman that experimental models are a sound basis for determining the results which will be obtained from new hydraulic design and may well be utilized in some of the new problems in the proposed development of the St. Lawrence River. The difficulties involved in the question under consideration are not so much technical, however, as they are political. There is no question in the mind of the writer that the best plan can be made perfectly safe at an expense which, as compared with other plans, would fully warrant its adoption. The matter of convincing the electorate as to the questions of safety and advisability is entirely different. These are problems which quite possibly can not be demonstrated to the satisfaction of all concerned.

Canadian authorities recognize the fact that it is the part of wisdom to delay this project until the present depression is over. The following extract from an editorial in the *Canadian Engineer*[40] gives the point of view of at least one Canadian official:

> "Last week further statements were made to the public regarding the St. Lawrence project. Thus C. Alfred Maguire, one of the Commissioners of the Ontario Hydro-Electric Power Commission, speaking regarding the Hydro-Power situation at Oakville, is reported as saying: 'I think Providence was with the Commission and the people of Ontario when they were not able to get the St. Lawrence at the particular time, because had we been able to get the St. Lawrence scheme completed we should have had $8 000 000 deficit every year. Instead of that the Commission got the private interests to build plants and give us the power from Quebec. * * *' Such a view expressed by one who is in close touch with these matters and who thus draws special attention to what might have proved a great economic loss, emphasizes the need for fuller economic consideration especially under the rapid and pronounced changes that characterize national and international trade relationships."

The writer agrees with Mr. Lee and Mr. Rickey that this important subject is a pertinent and proper subject for the discussion of engineers of both Canada and the United States and is worthy of the most careful, fair, and honest consideration.

LOSS OF HEAD IN ACTIVATED SLUDGE AERATION CHANNELS

By Darwin Wadsworth Townsend, M. Am. Soc. C. E.[1]

With Discussion by Messrs. H. L. Thackwell, Henry R. King, M. H. Klegerman, and Darwin Wadsworth Townsend.

Synopsis

This paper involves the consideration of no new hydraulic theory or formulas. The problem implied in the title includes an analysis of flow conditions that differ from those encountered in the usual channel problems, because the introduction of diffused air tends to retard velocity.

The presentation is semi-hypothetical, and the various functional values expressed are, strictly speaking, relative only. As such they are susceptible to direct application and use on the basis of any value of n that may be selected. The assumption is made that a roughness coefficient of $n = 0.013$, in Kutter's formulas, is reasonably applicable for all practical purposes to channels constructed in a manner similar to that described herein, and for unaerated sewage.

The purpose of the studies was to determine the extent to which flow is retarded when diffused compressed air is introduced into a flowing mixture of sewage and activated sludge, the total suspended matters in the mixture varying inappreciably from a normal value of 3 000 ppm. Numerous previous experiments have led the writer to conclude that this solids content does not change the hydraulic properties of the mixture from those of water alone.

The tests indicate definitely that: (*a*) Resistance to flow increases because of diffused air; (*b*) as the velocity of flow decreases, the resistance increases; and (*c*) the use of higher values of n is necessary because of increased resis-

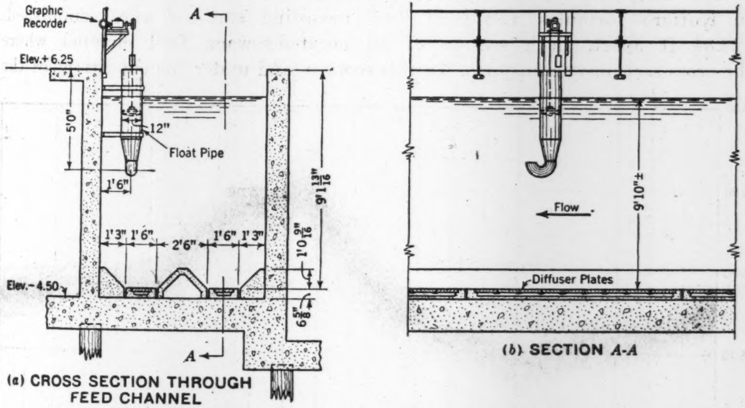
tance. The subject has been treated sufficiently herein to enable readers to comprehend the nature of the problem and the applicability of the results to problems of design.

Sanitary engineers are familiar with the fact that the activated sludge process of sewage treatment involves primarily the injection and diffusion of relatively large volumes of compressed air into the liquid sewage undergoing treatment, and that the countless ascending streams of tiny air bubbles injected at the tank or channel bottom offer resistance to the forward movement of the flowing sewage. This latter fact is obvious to one who has observed the surface appearance of an aeration tank or an aerated channel in which may be seen innumerable and continuously changing cross-currents, counter-currents, and swirls—all of which are indicative of resistance to the flowing stream.

It was because of this condition and the realization of its significance in hydraulic design, complicated by this flow-disturbance factor, that the writer undertook to determine the extent to which flow was retarded when diffused compressed air was introduced in the feed channels of the existing sewage treatment plant at Milwaukee, Wis. It is worthy of note that the selection of $n = 0.020$ in Kutter's formulas, was considered ultra-conservative in 1928 when the design of the present plant was begun, and that subsequent operation proved conclusively that this coefficient was inadequate.



(a) CROSS SECTION THROUGH FEED CHANNEL

(b) SECTION A-A

FIG. 1.—GRAPHIC RECORDER IN FEED CHANNEL.

The intent of this paper is not to formulate basic laws applicable to hydraulic properties of water or sewage, mechanically impregnated with diffused air. As a matter of interest, however, it may be assumed that: (1) Water impregnated or saturated with air has a specific gravity less than water alone; (2) because of this probable fact, it possesses hydraulic properties differing from those of plain water; and (3) if Assumptions (1) and (2) are correct, the hydraulic laws governing the flow of water would need to be modified somewhat, in order to classify this particular medium properly. However, in this paper, the subject must be treated from the viewpoint of an increased roughness coefficient, assuming the flowing medium to possess the hydraulic properties of water alone.

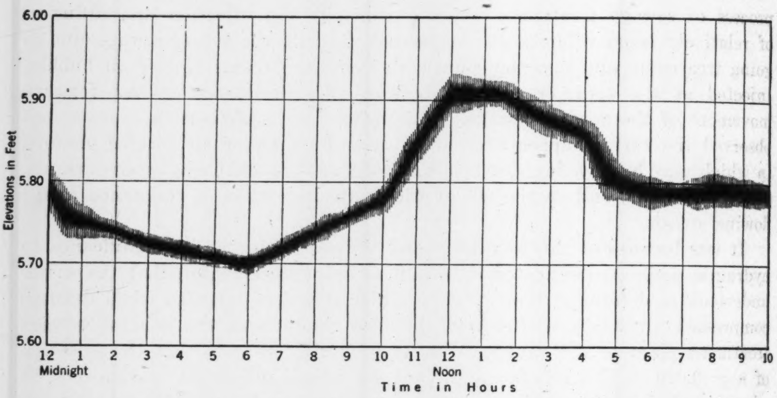


Fig. 2.—Head Level Chart in Feed Channel, Station No. 1, July 8, 1928.

For the purpose of determining the roughness coefficient applicable to use in Kutter's formulas, two head level recording stations were established, 123.34 ft apart, in a section of an aerated-sewage feed channel where the cross-section was uniform. In this section, and under the conditions of the

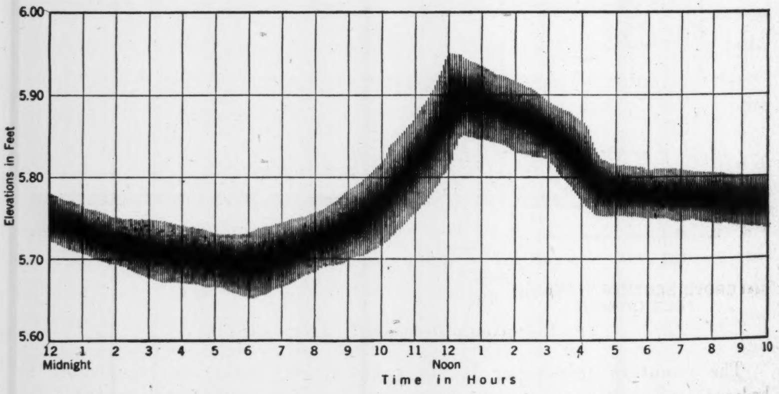

Fig. 3.—Head Level Chart in Feed Channel, Station No. 2, July 8, 1928.

test, the cross-section area was 75.39 sq ft, the wetted perimeter was 27.47 ft, and the mean hydraulic radius was 2.774 ft. The floats for operating the recording instruments were mounted in 12-in. pipes with upturned entrances, 6 in. in diameter, at the bottom, to exclude the ascending streams of air bubbles, as much as possible.

The type of float-chamber finally adopted (see Fig. 1) was one of several under consideration. The representative reproduction shown in Fig. 2, of one of the many graphic records taken at the up-stream recording station, demonstrates the degree of quiescence. It will be noted that the pulsations in the float compartment were practically continuous and that they varied in vertical movement between 0.02 ft and 0.05 ft. The records at the down-stream station, a graphic representation of which is shown in Fig. 3, indicated pulsations of greater magnitude than those at the up-stream station because of an obviously greater degree of diffused air disturbance at this point. The vertical movement of these continuous pulsations may be seen to vary between 0.06 ft and 0.09 ft.

The channel in which the stations were established contained a pair of practically continuous rows of diffuser plates (see Fig. 1), no two of which could be assumed to possess identical characteristics of porosity and air discharge.

The rate at which air bubbles blend, or coalesce, however, has a more important effect on pulsations. Presumably, the coalescence factor assumes greater prominence and greater irregularity as the velocity of flow increases. The velocities observed during the tests ranged between 0.9 ft per sec and 1.3 ft per sec, computed on the basis of the wet cross-section and Venturi meter readings of sewage flow.

From Figs. 2 and 3 one might conclude (with logical justification, perhaps) that the flow-disturbance factor inherent in the particular flows under discussion is not susceptible to precise analysis; the writer claims only that it is reasonably applicable as an approximation in practical design problems. It is concluded without hesitancy, however, that final results stated in the paper are sufficiently on the side of safety to warrant confidence in their subsequent use.

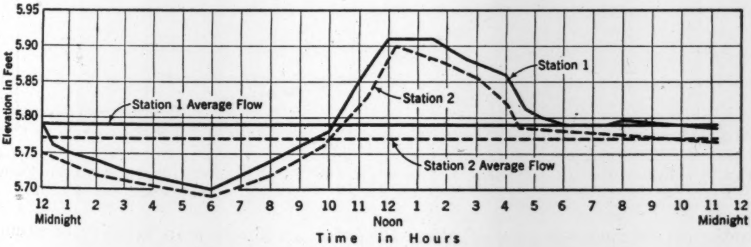

FIG. 4.—LIQUOR-LEVEL ELEVATIONS IN FEED CHANNEL, JULY 8, 1928.

A representative daily record of liquid levels taken at the two stations is presented in Fig. 4, the curves being values averaged from those shown in Figs. 2 and 3. It is significant and unusual, perhaps, that the total loss of frictional head between the two stations is much less (particularly when considering the record at the down-stream station) than the range in pulsations, the average being about 0.02 ft, and the pulsations ranging between 0.06 ft and 0.09 ft. The average curves in Fig. 4 compare favorably and consistently, however, with many similar records taken daily over a period of three weeks at the two stations. The average friction loss between these stations varied only slightly under comparable flows, generally about 0.02 ft to 0.03 ft.

A fact established quite definitely in connection with the loss of head determinations was that the coefficient of roughness (*n*-values) increased as the velocity of flow decreased. The approximate trend is indicated by the upper part of Curve 1, Fig. 5, which was constructed from liquid-level observations made in July, 1928, on the ridge-and-furrow aeration system. The value of *n* is 0.035 at 1.3 ft per sec and 0.0425 at 0.9 ft per sec, which indicates an increase in *n* of about 25% for a reduction in velocity of about 30%; and, *vice versa*, a decrease in *n* of 18% for an increase in velocity of 44%, considering only the two terminal points of the curve, as shown.

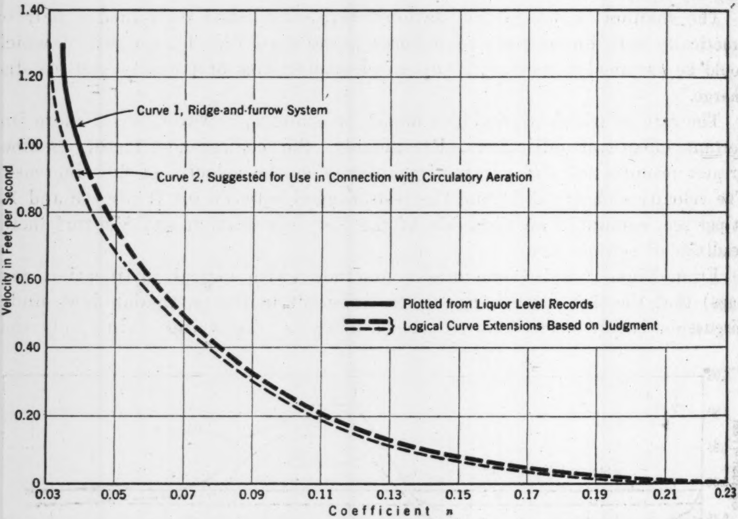

FIG. 5.—RELATIONSHIP BETWEEN VALUE OF *n* AND FLOW VELOCITIES IN AERATED FEED CHANNEL (WITH ESTIMATED EXTENSION BELOW VELOCITY OF 0.90 FOOT PER SECOND).

A hypothetical cause-and-effect theory may be ascribed to this varying roughness coefficient which, from the standpoint of practical merit and application, may possibly possess little to warrant any elaborate exploitation. Certain factors of influence appear to be sufficiently well defined, however, at least to warrant mention. Upon analysis, it becomes apparent that the hydraulic properties of a channel cross-section may be assumed to be changed artificially through the continuous presence in the flowing medium of the countless ascending streams of air bubbles, the degree of change depending primarily on the rate of diffused air injection. This statement is made with particular reference to an artificially and obviously decreased cross-section and the resultant increased wetted perimeter, ascribing to an air-bubble surface the same, or nearly the same, value of unit wetted perimeter as that which applies to the wetted surface of the channel structure itself. On the basis of this hypothesis, it is obvious that the "air"-wetted perimeter would be increased theoretically in proportion to the rate of diffused air injection, as previously noted, and, as a consequence, hydraulic radii would decrease in somewhat the same proportion, ignoring for the time being the extent of the fixed wetted surface of the channel structure and its definitely known influence upon the hydraulic properties of the channel.

Because of the tendency of the air bubbles to coalesce the degree and irregularity of which may vary with both the velocity of stream flow and rate of air injection, it may readily be seen how impractical of strictly theoretical application are certain factors which, apparently, are rather clearly defined and understood. For example, if there were no coalescence, and if the almost continuous streams of air bubbles could be assumed to rise in truly vertical streams substantially unchanged as to size and position, that part of the wetted perimeter herein ascribed to injected air could possibly be assumed to vary in direct proportion to the rate at which air was injected and to the total bubble surface exposed to the liquid in which the bubbles are contained. Furthermore, air bubbles are relatively small immediately after they are ejected from the pores of a diffuser plate (ordinarily $\frac{1}{16}$ in., or less, in diameter); frequent observations made in connection with the diffusion of air into glass cylinders containing clear water, indicate that for a distance of a foot or more immediately above the surface of the diffuser plate practically the entire space appears to be occupied by diffused air. This, in turn, indicates that a substantial part of the lower zone of the cross-section is appreciably restricted as to availability for water displacement, and, consequently, to the forward movement of the flowing medium. As the bubbles reach the upper zones they increase appreciably and become more irregular as to size, which is a direct result of air expansion caused by the decreased water pressure and, more particularly, by coalescence.

During the period in which liquid-level records were being obtained, air was forced into the flowing admixture of sewage and activated sludge at a constant rate of 1 cu ft of free air per diffuser plate per min, and upon a strictly assumed theoretical basis the air-bubble resistance to flow was constant. However, inasmuch as resistance to flow, or the roughness coefficient, has been shown to increase as the velocity of flow decreased, it follows that a decrease in roughness coefficient with a fixed rate of air injection, may be attributable to an increased degree of coalescence as a direct result of increased velocity.

Table 1 has been compiled in order to show more clearly the possible extent to which the hydraulic properties of a channel are subject to assumed modification due to the air-injection feature. The values are based on: (*a*) The velocities that obtained during the period in which records were taken (0.9 ft to 1.3 ft per sec); and (*b*) the friction head per linear foot of channel, using $n = 0.013$ as a basis (see Table 1, Columns (1) and (2)).

Values of n and C, shown in Columns (3) and (4), were computed. Column (5) contains relative velocity reductions as a result of increased n-values over and above $n = 0.013$; in other words, the velocity values shown in this column are those which. if used in connection with values in Column (3), would produce the same friction heads as those shown in Column (2), and are translations of values of Column (3) into terms of relative velocity.

Furthermore, translations on the foregoing basis for relative mean radii, *MR*, and wetted perimeters, are shown in Table 1, Columns (6) and (7), respectively. These data indicate the degree to which the two hydraulic functions may be assumed to be altered, on the hypothesis that the wetted perimeter may be increased and the hydraulic radius decreased, due to the presence of vertically rising streams of air bubbles which are assumed to offer flow resistance comparable to that of a surface with a fixed wetted perimeter. Column (8) and (9) (Table 1) indicate the same as Columns (6) and (7), but are expressed in terms of percentage decrease and percentage increase in the functional values noted.

In Column (10) (Table 1), is noted in percentage the extent to which the velocities would be accelerated if the resistance causing the increased n-values were removed, and $n = 0.013$ were substituted.

Much more of possible interest might be presented relative to: (1) The cause and effect of the air injection; (2) the resulting retarding current disturbance factor; and (3) its influence on hydraulic problems of design. Nevertheless, it is hoped that this discussion has been in sufficient detail to solicit appreciation of, and to direct attention toward, the significance attributable to the flow characteristics of sewage impregnated with air.

In the system of aeration using circulatory flow, relatively few diffuser plates are needed as compared with the so-called ridge-and-furrow system in use at the plant in Milwaukee. It is the writer's judgment that less retardation of flow might be anticipated in connection with that system. In Fig. 5, Curve 2 has been plotted arbitrarily and is suggested for use as noted in connection with circulatory aeration.

The reasons for anticipating lower *n*-values are as follows (and it is to be clearly understood that these reasons are formulated and offered in the absence of supporting data other than that of attempted logical analysis): In visualizing the movements of sewage admixed with activated sludge undergoing aeration where diffuser plates are numerous, as in the ridge-and-furrow system, there is in the general proximity of each diffuser plate a complete induced cycle of ascending and descending currents, the total length of ascent and descent traversed being approximately equivalent to twice the depth of the overlying liquid. Obviously, then, the more numerous the diffuser plates are the more numerous will be the current cycles, the greater will be the total distance traversed in a given time, and the greater will be the velocity of travel.

As a result of the higher and more frequent upward and downward current velocities, greater resistance to forward or horizontal flow might reasonably, and obviously, be expected. Otherwise stated, the angle of the resultant of the horizontal and vertical flow components referred to the horizontal might be expected to increase appreciably as the vertical velocities increase, the velocity of horizontal flow remaining constant.

In the strictly circulatory or spiral aeration system whether in a tank or sizable channel, fewer diffuser plates are used and, consequently, fewer ascending and descending flow-retarding currents are present. In this system in which the diffuser plates are located along one side of a tank or channel, a circulatory flow around the entire periphery is induced as a result of the injection of air. This creates a sufficient head at the liquid surface over the diffusers to set up the circulatory flow from which the system derives its name.

Little or no well-defined current other than a relatively slow forward movement is present in the "core" of the liquid, or in that part somewhat removed from the well-defined peripheral currents. Therefore, in the absence of currents in these zones (which, in area, comprise the major part of the total cross-section) there is little or no resistance to forward flow, the lateral restricting currents in the forward flow existing in the general proximity of the sides and bottom of the tank and at the liquid surface.

The range of channel velocity herein noted (0.9 ft to 1.3 ft per sec), is that in which activated sludge particles would ordinarily be precipitated to the bottom of a channel, in a liquid sewage medium. The diffusion of air into the mass obviously is made necessary when the range of flow is great and when there is insufficient head to produce higher and self-cleansing velocities.

Thus far, the paper has treated mostly upon flow conditions in supply channels, on the basis of the records mentioned. In aeration tanks where exceedingly low velocities occur (little in excess of 0.02 ft to 0.03 ft per sec) a curve showing n-values plotted against velocity would be expected to approach the horizontal closely as the velocity nears zero. To investigate this phase a base rate of curvature was established from readings between $v = 0.90$ and $v = 1.30$ ft per sec, and, from this, Curve 1 (Fig. 5) was extended toward values of low velocities. This projection showed as an asymptote to the horizontal zero axis; for example, a value of $n = 0.20$ was found to correspond with a velocity of only 0.02 ft per sec. This chance projection confirming logical expectations is of considerable interest.

The projection of this curve is of considerable interest, since besides showing working n-values at various velocities its horizontal tangential point, falling in the immediate vicinity of zero velocity as it does, lends additional confidence to the manner and accuracy with which the liquid-level records were taken and the subsequent computations made. A lower curve has also been constructed for use in connection with circulatory aeration flows.

In closing, the writer wishes to acknowledge with thanks the assistance of William Landsiedel, Assoc. M. Am. Soc. C. E., who, under the writer's direction, prepared and arranged the data in the various diagrams.

DISCUSSION

H. L. THACKWELL,[2] ASSOC. M. AM. SOC. C. E. (by letter).—It is important to select the correct coefficient of *n* in Kutter's formula, when solving for velocities in open-channel flow, with the conditions of the regimen varying from tabulated values, as registered and advocated by various experimenters and observers. This fact is emphasized in Mr. Townsend's paper.

Present field practice in hydraulics is stressing non-uniform and varied flow in open channels, rather than the rudimentary notions of uniform movement. Striking cases of turbulent flow occur in sewage disposal works. Every form of non-uniform movement may be observed in modern sewage disposal plants, namely, the hydraulic jump as used for mixing chemicals and for aerating purposes; spiral movements in certain types of aerating tanks; wave motion in distributing launders for filters; baffled flow in settling tanks; whirls and eddies obtained in various ways by agitating mechanisms; and diversion of flow directions in conduits, diversion boxes, and over-step aerators.

For some time the writer has felt that the hydraulics of sewage works has been neglected, and that more attention has been given to process treatment than to the mechanics and hydraulics of the subject. The Ganguillet and Kutter formula, for determining the value of *c* in the older Chezy formula, still has a common acceptance and specific meaning to the average engineer trained in America. With this formula, if the correct coefficient of roughness, *n,* is chosen for the channel, it is possible to obtain the coefficient, *c,* in Chezy's formula, and if the measurements of cross-section area, slope, and wetted perimeter are arrived at accurately, an average value of *v* may be obtained. It is doubtful whether slope determinations influence, or are necessary in obtaining, a correct value of *n* in the Kutter formula, which was primarily intended for uniform flow conditions.

The author has made observations on the velocities of an open channel having a very turbulent flow, due to the presence of rising air bubbles (resulting in a consequent swirling movement, both vertically and horizontally, and in a positive and negative direction), and he has computed a corresponding value of the coefficient, *n,* to fit such conditions. These observations range from 0.9 ft to 1.3 ft per sec. and, when such velocities are plotted with the coefficient, *n,* Mr. Townsend presents a curve which shows, within these limits, that the value of *n* apparently increases with lowering velocities.

Since the observed depths and varying cross-sectional areas are not given, it is presumed that the full wetted cross-section of the channel was used to obtain the mean velocity in each case, rather than the net cross-sectional area which might have been obtained by subtracting some bottom layer of air and water, where the jet action of the stream of air bubbles presents a definite barrier to forward horizontal flow. The trend of the curve thus plotted was ascertained and extended to zero-velocity limits, where the coefficient, *n,* was 0.23.

---

[2] Cons. and Const. Engr., Longview, Tex.

With the Chezy formula, as used in this case, the resistance to motion is proportional to the second power of the mean velocity, which is undoubtedly true for all velocities above the critical velocity. At this low critical point, however, the resistance may be proportional to the first power of the velocity.[3] The natural inference is that it would be fictitious accuracy to extend a trend curve beyond the limits of its governing equation. If the percentage of cross-sectional area, uninfluenced by jet action, had been used as a net cross-section, there is reason to believe that the coefficient, n, would not have increased with a decreasing velocity, but would have been nearly the same for all values of v. The difficulty would be to determine this net area uninfluenced by jet action, and yet supporting floating bubbles of air. An air-bubble surface (that is, freely floating and moving with the current of water), would not enter into the calculation of the wetted perimeter, any more than a log floating with a stream current would be considered in obtaining the wetted perimeter of a channel. If the bubble of air were fixed in position, the wetted circumference of such a bubble should be calculated and added to the wetted perimeter of the channel itself.

Before discussing the author's "cause and effect" theory in regard to the varying roughness coefficient, it will be necessary to obtain a better knowledge of the mechanics of the air bubble itself.

In June, 1932, the writer became interested in the subject of the mechanics of the air bubble and the laws governing it, and after searching literature on the subject, was surprised to find that very little experimental data had been published in the past on the subject of air induction into sewage or water. Mr. H. S. Allen made experiments on "The Motion of a Sphere in a Viscous Fluid," and published[4] his findings in 1900. That part of the subject-matter dealing with air bubbles was devoted to studying the velocity of very small bubbles rising in water. These bubbles were of such a small size (all less than $\frac{75}{100}$ mm), that the experiments and resulting data were not comparable to the larger air bubbles used for agitating water and sewage. Accordingly, the writer decided to make some simple experiments to obtain some definite first-hand information as to the velocity of the bubble rising in water, the size and shape of such bubbles, and their path of travel in ascending to the surface. The apparatus that was selected for the tests (see Figs. 6 and 7) consisted of a 5-ft glass cylinder with an inside diameter of 2 in., and having one end swaged and the other open. Both ends were fitted with rubber corks, the one at the swaged end had a single opening for a capillary tube insert, and the cylindrical end had two small tubes inserted in the stopper.

In one of these openings a small glass tube, 5 ft long, was inserted, having the submerged end fused down to a small J-shaped jet of very small bore. This tube was arranged so that it could be supported at any depth of submergence within the cylinder, thus acting as an air inductor into the sewage. The cylinder was supported vertically, by means of clamps, to the edge of a table. The other opening at the top of the stopper was connected by rubber tubing to a glass Y-tube, one arm of the Y-branch being connected by rubber hose to a mercury manometer, and the other to a vacuum suction pump. The lower end of the 2-in. cylinder was connected by tube and hose to another mercury manometer (see Fig. 6). The 2-in. cylinder was nearly filled with water. The J-inductor tube was next set in position, so that the jet opening was 4 ft below the surface of the water. The mercury gauges were set in position, and the lower gauge read 10.2 cm of mercury. The vacuum pump was turned on until the suction pressure occurring above the surface of the water was 10.2 cm of mercury; air was then drawn into the water immediately from the atmosphere, and liberated in the form of a stream of bubbles into the water column. Observations were made on the size of the bubbles, their shape and behavior of travel in rising to the surface, and the velocity of ascent.

[3] "Hydraulics and Its Applications," by A. H. Gibson, p. 295.

[4] *Philosophical Magazine*, September, 1900.

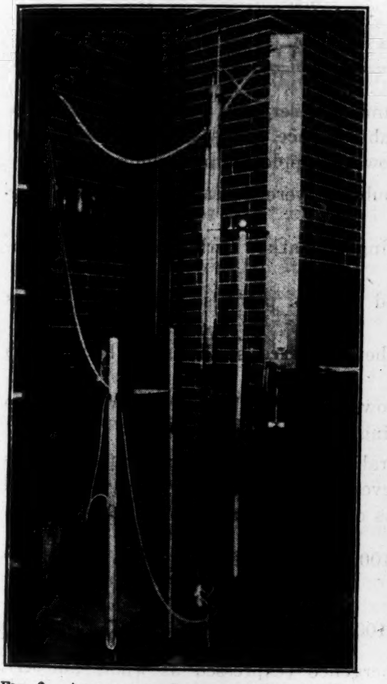

FIG. 6.—APPARATUS SHOWING RISING AIR BUBBLES.

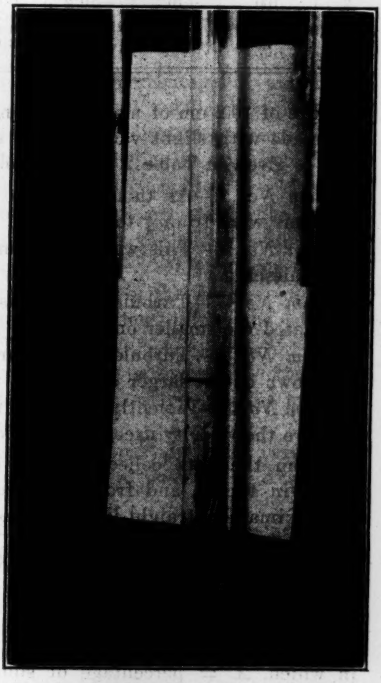

FIG. 7.—AIR-JET MOUTHPIECE SHOWING ACTION AGAINST WATER.

Observations were also made by forcing air in through the inductor pipe by direct compression, rather than by suction, as by the vacuum process. As soon as air bubbles filled the cylinder in a continuous stream, the surface of the still water rose to a new level; this higher elevation was due to the displacement of air volume, and slightly due to a velocity head, built up by the rising bubbles. Measurements were made of the depth of submergence, the rise in water level due to air volume, the velocity at fractional and whole distances of the bubble ascent, and the manometer readings. The total depth of unaerated water was 141 cm and the gauges were kept at a constant pressure of 10.2 cm of mercury. A number of series of identical observations was made with slight variations of submergence. One set of these observations is given in Table 2 with the following supplementary comments:

TABLE 2.—OBSERVATIONS ON BUBBLE PHENOMENA

Item No.	Depth of water, in centimeters (1)	Manometer on water supply, in centimeters of mercury (2)	Manometer on air supply, in centimeters of mercury (3)	Rise of water level due to air volume, in centimeters (4)	Percentage, volume of air in column (5)	Velocity of bubble ascent, in feet per second (6)	Percentage of submergence (7)	Power product, Column (5) by Column (7) (8)
1	119	+10.3	—10.2	7.5	5.92	0.78	84.5	5.00
2	100	+10.2	—10.2	9.0	8.25	1.09	71.0	5.86
3	85	+10.2	—10.2	9.7	10.25	1.31	60.2	6.16
4	70	+10.2	—10.2	9.2	11.6	1.45	49.8	5.79
5	55	+10.3	—10.3	8.0±	12.6	1.68	39.02	4.93

Item No. 1.—At this stage the bubbles were pulsating slightly. Their diameters were from $\frac{1}{4}$ to $\frac{1}{2}$ in.

Item No. 2.—This was the beginning of marked turbulent flow, with bubbles coalescing.

Item No. 3.—Turbulence increased at this point so that large bubbles dominated the smaller ones.

Item No. 4.—Turbulence still further increased, so that small bubbles were held down by the larger ones.

Item No. 5.—Violently turbulent flow, such that the operator was unable to measure the velocity except by extending the velocity curves.

From the data collected in several series, curves were constructed, as shown in Fig. 8, and from these curves the following formulas are derived (approximately straight-line variations on the various series of data):

$$Y = 0.15\ (100 - X) + 4 \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and,

$$V = 0.0192\ (100 - X) + 0.5 \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which, X = percentage of submergence (expressed as whole number); Y = percentage of air in a column of rising air; and V = vertical velocity, in feet per second, of rising bubbles.

By plotting the power product (Column (8), Table 2) against submergence (Column (7), Table 2) a maximum of aeration is indicated at 60% submergence (see Fig. 8, Curve C), with the provision that the air pressure is constant at the point of induction, this case being analogous to a constant

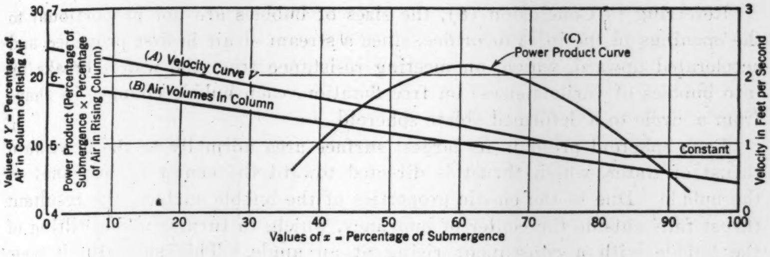

FIG. 8.

pressure blower connected to a variable-depth intake. From these data, and by observing the behavior of rising bubbles in the aerating cylinder, the following conclusions were drawn:

(1) Aeration by induction of compressed air into sewage or water may be steady, pulsating, or turbulent;

(2) With steady or pulsating conditions, the percentage of air in the cross-section is less than 7 by volume; and with all bubbles larger than a critical size (about 1 mm), the upward vertical velocity is constant and approximates 0.8 ft per sec (furthermore, this velocity is non-accelerating after the air has started to float freely as an individual bubble);

(3) With turbulent flow the upward velocity is non-accelerating, and varies in almost direct proportion to the percentage of air in the rising column (this velocity may vary from 0.8 ft per sec to 2 ft per sec, which upper limit is reached when the air volume of displacement is 16% of the water volume and at 22% submergence, provided the air pressure is constant at the point of induction);

(4) Bubbles have the same velocity in rising through water, whether they have been introduced by means of positive pressure, or by negative pressure (this deduction, of course, agrees with theory);

(5) The percentage of air injected is in direct proportion to the percentage of submergence, when the air is inducted at a constant pressure, and with the same type of injector orifice;

(6) The maximum inducted air remaining in the water at any one time, occurs when there is a submergence of 60%, and at this depth the aeration appears to be the most efficient (see Curve *A*, Fig. 8);

(7) The specific gravity of air mixed with water is in direct proportion to the volume of admixture; but when bubbles begin to appear and confined water is displaced upward, the specific gravity may be taken as that of water, provided no allowance has been made for the added depth of water column (temperature and atmospheric pressure not being considered);

(8) Air bubbles have a certain critical size in flotation, at which volume the shape changes from circular to lense or oblate spheroid; and,

(9) The heights of influence of jet action vary directly with the submergence, with the volume of air, and with the diffuser medium.

Referring to Conclusion (8), the sizes of bubbles are not proportional to the openings in the injector orifice, since a stream of air is first propelled and accelerated upward, which, on meeting resistance from the water, breaks up into bubbles of various sizes; on free flotation, each bubble changes in shape from a circle to a deformed oblate spheroid.

Each spheroid presents its largest surface area normally to the downward thrust of water, which thrust is directed toward the center of buoyancy of the bubble. Due to the elastic properties of the bubble surface, the resultant thrust falls outside the center of buoyancy, which, in turn, causes a tilting of the bubble with a consequent rising at an angle. This side slip is soon checked by resultant thrusts toward the opposite side of the center of buoyancy, and a corresponding shift occurs in bubble travel in the opposite direction. In this manner, the air floats upward with a zigzag movement and has a practically constant deviation from the vertical. Since the frictional resistances are proportional to the square of the velocity and directly to the exposed area the velocity soon becomes constant, and the volume remains nearly constant, due to the total compressive pressures acting against the surface area; these pressures are a summation of hydrostatic pressure and of velocity friction head. Apparently, these forces act automatically, and the size and velocity of the bubble remain practically the same throughout its travel range. Coalescence is the main cause of increased bubble size, but this factor will not cause increased velocities, or accelerating velocities, provided the proportion of entrapped air to water volume remains the same.

Referring to Conclusion (9), the minimum distance above the orifice, before the air bubble is freely floating and outside the influence of jet velocity, is about 6 in., and the maximum distance likely to occur in any ordinary orifice with various volumes and free flotation is 18 in.

The writer is aware of the fact that the foregoing observations are not conclusive, because the experiments were not sufficiently extensive and did not include the factors of temperature, humidity of air within the bubble of air itself, the atmospheric pressure, and the effect of interference within a cylinder of small caliber (2 in.). There was also a certain lack of precision and refinement in the measurements, the velocity being timed by stop-watch. However, the observations gave a fair idea of what was actually occurring and cleared up some points which, at first, seemed paradoxical; that is, that the bubbles do not have an accelerated velocity, and that the bubble does not increase in volume on rising through a lowered water pressure.

Returning now to the original discussion of the flow of sewage through an aerating launder, it is proper to conclude that the resistance to flow is caused by the following factors:

(*a*) The natural coefficient of friction of the sides and bottom of the channel itself;

(*b*) The resistance offered, mainly near the bottom of the channel, by the jet action or barrage of air particles which are traveling upward and floating horizontally with the current;

(*c*) The resistance due to cross-flow, or displacement flow under each rising bubble (this resistance will increase in direct proportion to the percentage of volume of air within the cross-section); and,

(*d*) The resistance due to vertical flow, upward and downward currents, which occur because unbalanced pressure columns have a higher or lower density caused by contained air. (The actual distance traveled by a particle of sewage is several times greater than the measured horizontal distance of flow).

Referring to Resistance (*c*), the path of the bubbles, traveling upward and floating sidewise, is measured by vector analysis. The higher the channel velocity, the more bubbles will remain in the sewage at any one time, on account of the longer travel distance before bursting at the surface. The lower the channel velocity, the greater is the resistance offered by the barrage at the bottom, since the air-jet has less deflection and such jet influence is continued for a longer time interval; however, there will be fewer air bubbles in the sewage on account of shorter travel in both time and distance.

A resultant of Resistances (*a*) to (*d*) will certainly slow down the velocity very appreciably. The fact remains, however, that the cross-section has been diminished far more by the influence of the bottom jet action in the case of low-velocity flow (having a constant volume of air per square foot of bottom area) than in the case of high-velocity flow. The agitation in the case of low flow should be greater than in the case of high flow, due to the increase of air to sewage ratio.

It would seem fairer to allow a deduction in area on account of jet action, rather than to show that a low velocity increases the coefficient of roughness, *n*, in Kutter's formula which, on the face of it, is contrary to theory.

In conclusion, the writer is grateful for this interesting paper by Mr. Townsend and for the light it has thrown on the subject of the hydraulics of aeration channels which, heretofore, has been much neglected.

It is to be regretted that the full data of the experiments were not published, such as the varying wetted cross-sections at different rates of measured flow. More experiments on this subject will be required before an accurate forecasting of the roughness coefficient, *n*, may be made on sewage aeration channels.

HENRY R. KING,[5] ESQ. (by letter).—This is the first publication of tests on the loss of head in aerated channels carrying activated sludge, that has come to the writer's attention. Such tests aid in the selection of economical channel sizes and are particularly helpful in the design of an aerated influent channel for a large battery of tanks, so that an equal division of the flow may be assured among the tank units with a minimum amount of regulation of the inlet gates.

The scarcity of data on the subject can be attributed to several reasons. The activated sludge process is relatively new; large plants are few; and, consequently, there is a lack of data on many special problems of design. The head losses occasioned by aeration constitute only a small part of those occurring in a plant as a whole. Of major importance are the losses at tank inlets and exits, through meters and bends, in passing over weirs, and in the conduits between the several stages involved in the complete treatment of the sewage.

---

[5] Asst. Civ. Engr., The Sanitary Dist. of Chicago, Chicago, Ill.

The designer may be 100% in error in estimating the additional friction of flow due to aeration, but the hydraulic capacity of the plant will be approximately as originally intended. Consequently, the need of experiment may not have been fully appreciated. If, however, it was, the fact remains that the aeration channels in an activated sludge plant are not as a rule very suitable for experiments. The velocities are low, the distances are short through which uniform flow obtains, and, consequently, the head losses are so slight as to make precise measurement difficult, inasmuch as measurements are required where the flow is disturbed by numerous rising air bubbles and where the variation in the porosity of the diffuser plates may result in a greater disturbance near one gauge than at another. However, the writer believes that tests can be made to secure worth while results.

It would have been of interest if Mr. Townsend had given a description of the procedure followed in making the tests at Milwaukee. Perhaps the floats would have been less disturbed by pulsations if the upturned entrances of the pipe connections to the float-tubes had been lower down in the channel than shown in Fig. 1. The weight of the liquid on the bottom of the channel remains constant regardless of the volume of entrained air. At an elevation some distance above the bottom, as the volume of air in the mixture increases, a greater proportion of the weight of the liquid is lifted above this elevation and, as a consequence, the pressure here increases. Therefore, one would presume that the nearer the entrances of the piezometer piping to the bottom of the channel the less the magnitude of the pulsations in the float-tubes, due to variations in the volume of air in the mixture.

The following procedure is suggested for making tests that involve relatively small losses, such as Mr. Townsend had at Milwaukee (0.02 to 0.03 ft). Care should first be taken to determine the inherent errors in the gauges and, before each test, they should be checked with the channel standing quiescent at the normal depth of flow. Then, the air should be turned on at the rate to be used during the test and the effect of aeration at zero velocity noted at the gauges. The flow should then be started and maintained at a constant rate for some time while the losses are recorded first with the air on and then with the air off. The difference in head loss for these two conditions of flow of course, would be that due to aeration.

In 1931, at the North Side Sewage Treatment Works, of The Sanitary District of Chicago, head-loss tests were made on a return sludge aeration channel, 4 ft wide, with vertical walls. On the bottom, on the center line, was one longitudinal row of diffuser plates (12 by 12 in.), in boxes, 18 in. wide, from which the bottom sloped upward at 45° to meet the channel walls. The return sludge flowed at depths between 4 and 5 ft above the plates. The hydraulic radius was approximately 1.4 ft and the rate of aeration, 1.4 cu ft of free air per min per lin ft of channel. The test was made over a length of 410 ft, in which the flow increased by five equal increments, each introduced from two pipes at right angles to the longitudinal axis of the channel about 6 in. above the surface and at intervals of about 70 ft. For 20 000 000 gal per day the velocity varied from 0 to 2.25 ft per sec, and the surface drop for the entire distance was 0.42 ft. Making allowances for head losses due to the falls of incoming sludge, in accordance with the method devised by Julian Hinds, M. Am. Soc. C. E., for side channel spillways,[6] the value of *n* in the Kutter formula was computed at 0.034, or more than twice the value for the same sludge in a closed conduit. This friction coefficient seemed high. To determine whether this was due to the use of air, another test was made for a total quantity of 20 000 000 gal per day. Stable flow was maintained while measurements were repeated several times, with the air alternately on and off.

The results showed an average surface drop of 0.42 ft with aeration and 0.41 ft without it. This test indicated that aeration had but slight effect on head loss in this particular case. Hence, the high loss must have been caused by the obstructions presented within the channel itself through the presence of the air pipes and the disturbances caused by the downward discharge of the pairs of incoming sludge pipes. Although the channel was far from ideal for the purpose of determining accurately the effect of aeration on head loss, the writer is inclined to believe, from the results obtained, that the effect may be relatively small when compared to the losses that occur without the presence of aeration.

M. H. KLEGERMAN,[7] ASSOC. M. AM. SOC. C. E. (by letter).—Further evidence that engineers engaged in the design and operation of hydraulic works are seeking and finding information concerning hydraulic coefficients, either to re-assure themselves of the work of the early investigators, or to find applications for new conditions, is presented by the tests performed at Milwaukee, Wis., and described in this paper.

Many of the empirical data upon which design to-day is based, had their beginning, as is generally known, in the middle of the Eighteenth Century (Brahms, 1753; Brahms and Chezy, author of the well-known formula, $V = c\sqrt{RS}$, in 1775), and many of the coefficients often accepted by engineers at the present time, without much concern as to their limitations or applicability to modern materials, were developed by Ganguillet and Kutter and others, in the latter part of the Nineteenth Century. In the course of the translations of the work of Ganguillet and Kutter, additional important contributions were made to the hydraulic literature on the subject of frictional coefficients by the various translators. Probably an outstanding contribution since the beginning of the Twentieth Century, can be found in the work of Williams and Hazen, in the development of their formula, now so well known, for the determination of flow in pipes, together with the publication of their hydraulic tables presenting frictional coefficients and head losses.

In the water-works field particularly, the comparatively recent introduction of new material (bituminous and cement coatings for steel and cast-iron pipes, used both for protection against corrosion and for increasing the carrying capacity by providing a smoother interior surface; the greater use of concrete pipe; and the recent introduction in the United States of such new pipe-manufacturing methods and materials as centrifugally spun cast-iron pipes, modern steel and concrete pipe, and pipe of a cement and asbestos compound) has created keen interest among engineers as to the question of coefficients of flow and their interpretation as to capacity.

---

[6] "Side Channel Spillways," by Julian Hinds, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 881.

[7] Asst. Engr., Alexander Potter, New York, N. Y.

The technical literature of other countries, particularly Great Britain, also discloses that the relatively recent departure in pipe lining from the original practice of merely dipping cast-iron or steel pipes in a coal-tar and linseed-oil preparation, is directing considerable interest among European engineers to the necessity of obtaining a formula for the discharge of these new types of pipe. It is the opinion that without such a formula it is not feasible with certainty to watch the rate at which discharge is diminishing, since no common datum is available on which to base later results.

More information, too, is now sought not only on carrying capacities of conduits of these materials when new, but also on the relative ability to maintain initial carrying capacities and their rates of reduction, under various conditions of usage.

While engineers who have the facilities and opportunities at hand for making these tests are engaged upon such work, it would seem highly desirable to extend it into an examination of conditions of flow in which not only water is concerned, but in which water is in an intimate physical combination with other substances, such as air, in the case of aeration channels, or sludge, in the case of sludge force mains. Furthermore, conditions about sewage treatment plants present many cases of varied or unsteady flow, even where sewage alone is concerned. Instances of test data for head losses under such conditions, are not many, and an organized attempt to obtain and correlate mass data of this kind would prove of value to designing engineers.

The tests described by Mr. Townsend indicate that head losses occur to an extent probably not before fully realized, and must be considered in the design of channels of the type described. It is unfortunate that the tests had to be made on a comparatively short length of channel (the length being limited only to 123.34 ft), because, as stated in the paper, the range in pulsation of the recorders was from three to four and one-half times the loss in head over the section. In view of this condition, it is difficult, immediately, to accept the conclusion that the "final results stated in the paper are sufficiently on the side of safety to warrant confidence in their subsequent use." The likelihood of finding aeration channels of considerable length for testing purposes, is probably very limited, however.

It is noted that the value of the slope used for computations in Kutter's formula, was that of the water surface as determined from the depth recorders established at each station. In an open channel of the type described, it is likely that disturbances introduced by the injection of compressed air, atmospheric disturbances, irregularities of the channel and of the diffuser plates, etc., may have resulted in different depths of flow and, consequently, in different velocities at each of the observation stations. In that event the slope of the energy gradient, instead of the water surface, would result, of course, in more accurate determinations. The actual effect upon the value of n as so determined, however, can not be known without the information required to compute the energy gradients at each station.

If other tests of this nature should be undertaken, it would be of value to know what the temperature conditions and atmospheric pressures are during the time of test, as these conditions may influence air-bubble coalescence which, as the author described, has an important bearing on the resistance to flow. In open channels of the type used in the Milwaukee test, some resistance to flow must certainly be created by wind resistance at the water surface exposed to the atmosphere. In tests performed upon large sewers flowing partly full, the writer has found that values of n are somewhat higher (due, it is believed, to "air resistance" at the surface) than when flowing full or nearly full. Observations on the direction and intensity of wind during tests, therefore, might be of some value in comparisons of test data.

"Before-and after" tests—that is, determinations of head loss with and without aeration—are important in order that the effect of the latter may be fully evaluated. The author has apparently obtained such information, as he gives the value of $n = 0.013$ for the channel with non-aerated sewage, although it is not clear whether this value has been determined from tests with diffuser plates in position, or whether it is an assumed condition.

Information as to surface and bottom velocities, as well as on mean velocities and their inter-relation, would perhaps help determine to what extent the flow varied from "free-water" flow, and, also, in what sections of depth the greatest disturbances occur.

The varying value of n with varying velocities, as reported by the author (that is, $n = 0.03$ at a velocity of 1.3 ft per sec, with $n = 0.23$ as velocity approaches zero), indicates, of course, that the condition of resistance to flow as denoted by n, is "internal" in Nature; that is, it more nearly represents a state of the contained liquid under varying conditions, than a condition of the channel itself, with which Kutter's n is usually associated. While the author brings out the fact that for the purpose of his paper, the subject is treated from the viewpoint of an increased roughness coefficient, assuming the flowing medium to possess the hydraulic properties of water alone, it would appear of interest and along the methods often adopted in estimating transition losses, etc., to learn whether or not head losses for a flow of an air and sewage mixture could not be more practically expressed in terms of "percentage of loss of head for clear water." Expressed in these terms, there may be the further advantage of eliminating the use of a varying coefficient.

There is another explanation, however, that might be made in connection with the author's conclusion that the coefficient of roughness, n, increases as the velocity decreases.

By reference to Fig. 1, it will be observed that the channel in which the tests were performed is composed of two different materials, namely, the sides of concrete and the bottom of a combination of concrete and diffuser plates.

In other words, the bottom and sides of the channel are of different degrees of roughness; the roughness coefficients for the channel bottom and sides have different values.

Robert E. Horton, M. Am. Soc. C. E., refers[8] to this condition as "composite" roughness. According to Mr. Horton,

> "The value of Kutter's or Manning's n applicable to the sides of such a channel may be designated as n_s and that applicable to the bottom as n_b. The value of n derived from experiments on such a channel may be designated the 'equivalent' roughness. If a channel had a degree of roughness corresponding to n throughout its entire cross-section, it would give the same discharge and velocity as the actual or experimental channel at the same depth and slope."

Mr. Horton further established the fact that a value of equivalent roughness (assuming, of course, constant "internal" characteristics of the flowing liquid) derived from experiments on a given channel is really applicable to a single depth. In other words, if the roughness of the bottom is not the same as that of the channel sides, the equivalent value of n varies with the depth.

A formula suggested by Mr. Horton for determining the value of n applicable to channels with two degrees of roughness, is as follows:

$$n = \left(\frac{n_b^{\frac{3}{2}} + 2\,z\,n_s^{\frac{3}{2}}}{1 + 2\,z} \right)^{\frac{2}{3}} \qquad \text{(3)}$$

in which, z = ratio of depth of flow in channel to bottom width.

As is evident from the foregoing, the composite n will vary with z, so that if $z = 0$, $n = n_b$, and n approaches n_s as z approaches infinity.

In the absence of more specific observational test data, it is not possible to state whether the results obtained by Mr. Townsend would agree fully with Equation (3). The original observations may contain sufficient data so as to make possible the computation of n_b from this equation (assuming n_s to be equal to 0.013.) Having computed n_b for a given value of z and n, it would then be a simple matter to substitute in Equation (3) the value of n_b thus obtained, and with a different observed value of z, compute the value of the composite n. Comparison of the value of n thus computed with that reported for a specific velocity, might establish whether or not the relation implied by the Horton formula holds in the case of aeration channels.

The author is to be commended for his work and method of presenting results. Of particular interest is the presentation of the "cause and effect" theories. His efforts will undoubtedly result in directing attention to this phase of sewage flow and should encourage others to investigate and publish their results for the benefit of all engaged in the design of sewage works.

DARWIN WADSWORTH TOWNSEND,[9] M. AM. SOC. C. E. (by letter).—Contributions to the subject-matter of his paper by Messrs. Thackwell, King, and Klegerman are gratefully acknowledged by the writer. Commenting generally upon these discussions, attention might well be directed again to the velocity-retarding effect attributable to air-bubble induction and the subsequent coalescence encountered in practice, as differentiated from the assumed hypothesis based upon laboratory observations made in connection with air bubbles rising through clear and quiescent water contained in glass cylinders.

---

[8] *Engineering News-Record,* November 30, 1933.

[9] Cons. Engr. (Consoer, Townsend, Older and Quinlan, Inc.) Milwaukee, Wis.

That reduced cross-sectional area obtains due to the continuous presence of diffused air throughout the liquid medium, there can be little doubt. There also can be little doubt that the continuous and irregular swirling of an aerated mass results in cross-currents, up-and-down currents, and diametrically opposed currents, which would vary, continuously, the degree and character of the flow in a cross-section. For this obvious reason the writer elected not to attempt to state increased frictional resistance in terms based upon reduced cross-section and consequent increased velocity. In the writer's judgment a roughness or retarding factor, most prominent in character, is present in the flowing liquid mass.

The air bubbles contained in the aerated mass do not merely float along in the stream current in an undisturbed state as a log of wood might be expected to float along on the surface of a stream; they are decidedly and irregularly active in their continuous ascent, through expansion and coalescence, and the combination of both. If small logs instead of air bubbles were liberated in a continuous stream from a channel bottom, the flow-retarding effect would be quite dissimilar to that which might be expected from the same logs floating horizontally in the current.

It is true that the friction loss per unit of aerated channel length may be relatively small under conditions of low velocity. These losses on the other hand may be relatively large under conditions of high velocities. Furthermore, the accumulation of many relatively small friction loss increments may, and do, represent a substantial percentage of the total friction head in the design of a sizable activated sludge plant.

The conditions that obtain in a flowing aerated stream do not lend themselves ideally to head-recording accuracy. This fact the writer attempted to make clear in his discussion relative to pulsations; the results he obtained, and those encountered in practice, are sufficiently accurate to warrant their subsequent use with safety in problems of design.

It is obvious why the *n*-value increases as flow velocity decreases. If the upward or vertical velocity of the air-bubble stream, for instance, were greater than that of the horizontal liquid flow velocity, a curve indicating the degree of resistance would more nearly approach the vertical than would be the case if the velocities were applied in the reverse order. In other words, the same general theory of head loss and velocity resultant which applies to two horizontally flowing streams uniting with each other at an angle, applies in a somewhat modified degree in the case of the problem under discussion. In both cases it becomes necessary to build up sufficient head to overcome the resistance encountered. The trend curve (Fig. 5), which was based somewhat upon chance projection is the best illustration of the relationship between *n*-values and velocities.

WILLIOT EQUATIONS FOR STATICALLY INDETERMINATE STRUCTURES

IN COMBINATION WITH MOMENT EQUATIONS IN TERMS OF ANGULAR DISPLACEMENTS

By Charles A. Ellis,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Ralph A. Tudor, Leon S. Moisseiff, A. A. Eremin, and Charles A. Ellis

Synopsis

If the Williot diagram served only as the graphic solution for the deflections of a truss, it would still hold a prominent place among the analytic methods used by the designing engineer; but its usefulness is by no means so circumscribed. When combined with Maxwell's theorem of reciprocal displacements it is the quickest solution for statically indeterminate reactions in continuous spans, two-hinged arches, and similar structures. It also serves in determining the angular displacements of members in secondary stress analysis.

Another inherent quality in the Williot diagram recently discovered should be of considerable assistance in stress analysis. So far as known, it is a new idea in the theory of structures. Like many other inventions, necessity was the mother of this one. In studying a large and unusual structure, the writer encountered a problem in stress distribution that would not yield to an exact or even to a satisfactory solution because of the lack of sufficient equations, until he discovered them in the geometric properties of the Williot diagram.

This paper recites the circumstances leading up to this dilemma, describes the development of the Williot strain equations (Equations (13) to (21), inclusive, and Equations (29), (30), (36), and (37)), and shows how they were combined with moment equations expressed in terms of angular displacements to meet the situation.

Note.—Published in January, 1934, *Proceedings*.

[1] Prof. of Structural Eng., Purdue Univ., Lafayette, Ind.

Certain abnormal structures, such as some types of towers for suspension bridges, do not lend themselves readily to solution for statically indeterminate stresses. Special methods are found necessary. This paper describes the expedient of expressing moments in terms of angular displacements as the vehicle by which such problems may be carried to a solution. The expressions for moments at the ends of the member, *IK* (Fig. 1), for example, are usually written in the form:

$$\left.\begin{aligned} M_{ik} &= \frac{2\,EI}{l_{ik}}\,(2\,\phi_i + \phi_k - 3\,\psi_{ik}) \\ M_{ki} &= \frac{2\,EI}{l_{ik}}\,(2\,\phi_k + \phi_i - 3\,\psi_{ik}) \end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots(1)$$

in which, E is the modulus of elasticity, and I represents the constant moment of inertia. When I is not constant throughout but has the magnitude, I_{ik}, for the upper half and I_{ki} for the lower half, and if $I_{ki} = nI_{ik}$, the expressions may be written, as follows:

$$\left.\begin{aligned} M_{ik} &= \frac{8\,n\,EI_{ik}}{l_{ik}\,(n^2 + 14\,n + 1)}\,[(n + 7)\,\phi_i + (2\,n + 2)\,\phi_k - (3\,n + 9)\,\psi_{ik}] \\ M_{ki} &= \frac{8\,n\,EI_{ik}}{l_{ik}\,(n^2 + 14\,n + 1)}\,[(7\,n + 1)\,\phi_k + (2\,n + 2)\phi_i - (9\,n + 3)\,\psi_{ik}] \end{aligned}\right\} \ldots(2)$$

Whatever the variations in I, the moments may still be expressed as functions of the angles, ϕ and ψ. Thus,

$$\left.\begin{aligned} M_{ik} &= a\,\phi_i + b\,\phi_k - c\,\psi_{ik} \\ M_{ki} &= d\,\phi_k + e\,\phi_i - f\,\psi_{ik} \end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

the coefficients, a to f, being expressed numerically when the variations in I are known.

Since the writing of these equations requires known moments of inertia, the application of this method postulates a designed structure. If the structure is statically indeterminate, in order to compute the approximate stresses required for designing, it is necessary to formulate a tentative design by making certain assumptions as to the probable behavior of the structure, which will render it statically determinate. This tentative design will contain all the errors made in the assumptions. It is desirable, therefore, that the assumptions closely approximate the actual conditions. This is not a difficult matter for the experienced engineer when dealing with normal structures.

Other structures, however, may be so novel or peculiar in type or so extraordinary in size, or both, that they do not come in this category. The writer found this to be true when designing the towers for a suspension bridge, given to him in the form shown in Figs. 2 and 3. This pattern of wind bracing makes the structure many times statically indeterminate. It may not be a good example of economic or efficient bracing, but it illustrates the discovery made while designing it.

FIG. 3.

The axial wind stresses and moments in the post members above the floor may be rendered statically determinate by assuming a point of contraflexure at the middle of each post member; or, in other words, by assuming that the moments at the two ends of each member are equal. The sum of these two moments for given loads is constant, or very nearly so, whatever the design and, furthermore, in the interest of economy, they should be nearly equal; but designing the horizontal struts to accomplish this end is not so simple a problem.

Again, if this were an ordinary structure, the wind stresses in the diagonals below the floor could be rendered statically determinate without appreciable error, by assuming that the horizontal shear was resisted entirely and equally by the two web systems. It is not an ordinary structure, however; the wind shear above the floor must be resisted entirely by shears and bending moments in the posts. The post members above the floor, therefore, must be very stiff; and those below the floor must be similar in size for practical purposes. Because of this extra stiffness, the posts participate with the bracing in resisting the shear to such an extent that the assumption of of all shear being resisted by the diagonals becomes a gross error. This paper will show how, in the first approximation, this assumption, for lack of a better one, was made for a tentative design, and how by a new process it was eliminated in the third approximation.

The design began and proceeded in a series of four approximations followed finally by a review. Each approximation included a computation of stresses based on certain assumptions, followed by a tentative design. As one approximation followed another the assumptions were either corrected or eliminated so that each tentative design approached more closely to the final design. This process was continued until all assumptions except one were eliminated. Since the external forces acting on each post were the same, their elastic curves were assumed to be identical. This assumption postulates equal bending moments and shears, equal and opposite axial wind stresses in the two posts, and equal values of ϕ and ψ for corresponding joints and members.

FIRST APPROXIMATION

The towers were tentatively outlined as shown in Fig. 2. A reasonable share of the allowed unit stress was reserved for axial wind stress and bending stresses of all kinds, and the remainder was allocated to axial dead and live load stresses. Cross-sectional areas were tentatively determined and the cellular tower sections (Fig. 4) were laid out, giving due regard to slenderness ratios. The tower wind loads were computed and the additional wind loads from the cables and suspended structures were included at the top and at the floor level, *KL*, respectively. These loads, as shown in Figs. 2 and 3, are for one post only; they are the same for both posts.

The wind stresses in the diagonals were computed on the assumption that the two web systems resisted all the horizontal wind shear equally divided. After the erection and riveting of the two lower panels, the diagonals must participate with the posts in supporting whatever vertical dead and live loads are added to the posts thereafter.

Let p = the dead and live load unit stress in the post; p', the participation unit stress in the diagonal; and θ, the angle, OKW (Fig. 2). Then, $p' = p \cos^2 \theta$. This dead and live load participation stress was estimated, thus determining the allowable unit wind stress, and the diagonals were designed accordingly. The member, KL, was designed to meet the requirements of a floor-beam, and the two lower horizontal members were designed as nominal members free from primary stress. Except for the horizontal struts above the floor the first tentative design was complete.

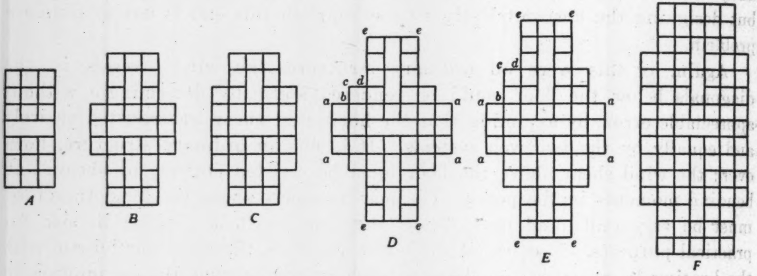

FIG. 4.—TYPICAL CROSS-SECTIONS OF TOWER (SEE FIG. 3 FOR LOCATIONS).

SECOND APPROXIMATION

In the next computation, the transverse wind stresses and moments in the posts were rendered statically determinate by assuming a point of contraflexure at the mid-height of each panel. Analysis of the cables and suspended structure showed that the tower must submit to a longitudinal deflection at the top equivalent to 17 in. in either direction. The longitudinal moment of inertia of each post member was computed. The section of the post changed at each panel point. A parabola tangent to the center line at the base of the post and having an abscissa of 17 in. at the top, was assumed for the elastic curve. The moment of the eccentric dead, live, and wind loads was computed at each panel point and combined with the moment of a horizontal force, H, acting at the top. An expression for the deflection at the top was developed by the area-moment method and equated to 17 in. With this equation solved for H, the total longitudinal moment was computed for each panel point.

The axial dead, live, and wind stresses and the transverse and longitudinal moments were now approximately known. The resulting unit stresses at cross-sections above and below each panel point were computed for critical points in each cross-section, and the first tentative design was thus revised.

In this revision further attention was given to the number and arrangement of cells in the various cross-sections, and to the area and kind of metal to be used in each. These studies resulted in the use of six typical cross-sections, as shown in Fig. 4, the locations of which are given in Fig. 3. The saddle casting governed the size of Section *A*, and the minimum allowed radius of gyration for the lower half of the post determined the size and shape of Sections *E* to E_5, which are alike, except for the thickness of metal in the faces, *aa* and *ee* (Fig. 4). A minimum allowed thickness of metal fixed the minimum area of metal in any given section, and this fact greatly influenced the grade of steel used. The intermediate Sections *B, C,* and *D,* were finally chosen so that silicon steel was required only in Sections *A, B,* and *C*. In the remaining sections carbon steel with minimum thickness of plates ($\frac{7}{8}$ in.) and angles ($\frac{5}{8}$ in.) was used throughout, except in the extreme faces, *aa* and *ee*. By limiting the variations to these extreme faces, the transverse moments of inertia could be varied considerably by a relatively small change in area, and caused little change in the longitudinal moment of inertia, and *vice versa*. Later developments in the design proved that the sections were economic and well chosen.

THIRD APPROXIMATION

For the purpose of investigating the transverse elastic curve the structure was divided into two parts at a point just above the member, *KL*. The wind strains were computed from stresses as previously determined in the members of the lower part and a Williot diagram was drawn, assuming *Q* and *S* (Fig. 2) as fixed in position. Transverse moments of inertia were computed and the moments at the ends of each member expressed in the form of Equations (1) to (3), except that ψ for each member was given the numerical value determined from the Williot diagram. The wind forces on the structure are shown acting from right to left. The moments of these forces above and about any section are counter-clockwise and in this paper are called positive, hence the counter-clockwise couples, *M*, and the counter clockwise rotations, ϕ and ψ, are positive.

The equations, $\Sigma M = 0$, were written for Joints *K, W, O, X,* and *Q*. Since ϕ has the same value for corresponding joints; that is, $\phi_l = \phi_k$, etc., only the two diagonal members on the left of the center line of the tower need be considered in the equations, $\Sigma M = 0$, for Joints *W* and *X*. In the equation for Joint *K*, M_{ki} was not expressed in terms of ϕ_i and ϕ_k, but was equated to the known quantity found at the beginning of the second approximation, for by so doing ϕ_i was eliminated from the equation. The five equations were solved and the angles, ϕ, determined.

In the treatment of the upper portion, M_{ik} and M_{ki} were expressed in terms of ϕ_i, ϕ_k, and ψ_{ik}, and each was equated to its approximate value as determined in the second approximation. The known quantity obtained in the analysis of the lower portion was substituted for ϕ_k and the two equations were solved for ϕ_i and ψ_{ik}. The remaining members of the post were similarly treated, and the quantities, ϕ, for each joint and, ψ, for each member determined. From the known values of ψ the transverse moments of the eccentric dead and live loads were computed, and the sum, M_{ak}, of these moments from *A* to *K* was determined. Since the wind stresses were tensile in one post and compressive in the other, their eccentric moments balanced each other and, therefore, were not included.

Heretofore all computations had been based on the outline sketch of Fig. 2. A drawing to scale was now made of the transverse view. The horizontal struts above the floor were assigned vertical dimensions, giving a proper architectural balance to the structure, as outlined in Fig. 3. When the bracing below the floor was added, it was evident that, for good detailing, the diagonals should intersect the horizontals at the inside faces of the posts rather than on their center lines. These eccentric connections had also a theoretical advantage, since the resulting eccentric moments reduced the lateral deflection of the tower, The member, QS, was raised to a proper distance from the base and a new post member, QT, entered the problem.

The computations for this second tentative design had been made on the assumption that the shear in each panel below the floor was resisted entirely by the web system. The process by which this assumption was eliminated, namely, by analyzing the wind shear distribution between the posts and bracing, will now be explained. Throughout the analysis the following symbols with identification subscripts will be used. All dimensions are expressed in inches; all loads and stresses, in pounds; and all moments, in inch-pounds:

b = distance center to center of posts.
W = dead and live load stress in any post member.
H = horizontal shear in any post member, or the horizontal component of stress in any diagonal below the floor.
V = vertical component of stress in any diagonal below the floor, or the vertical shear in any strut above the floor.
P = axial wind stress in any member.
l = length of any member.
$\Delta = \frac{Pl}{AE}$ = the wind strain in any member.
S = one-half the total wind shear in any panel.
M_{ak} = sum of the transverse eccentric moments in one post from A to K.
M_W = moments of wind forces on one post above and about W.
M_X = moments of wind forces on one post above and about X.
M_T = moments of wind forces on one post about the center line of the tower at the base.

From Fig. 5,

$$H_{ko} + H_{kw} = S_{ko} \qquad (4)$$

also,

$$M_{ko} + M_{ok} + l_{ko}\,\psi_{ko}\,W_{ko} + l_{ko}\,H_{ko} = 0 \qquad (5)$$

or,

$$M_{ko} + M_{ok} + l_{ko}\,\psi_{ko}\,W_{ko} = l_{ko}\,(H_{kw} - S_{ko}) \qquad (6)$$

The quantities, M_{ko} and M_{ok}, may be expressed in terms of ϕ_k, ϕ_o, and ψ_{ko}, while l_{ko}, W_{ko}, and S_{ko} are known; hence, H_{kw} may be expressed in terms of ϕ_k, ϕ_o, and ψ_{ko}. As H_{kw} is the horizontal component of the stress in KW and KWR, the strains in these members, Δ_{kw} and Δ_{kwr}, may be expressed in terms of ϕ_k, ϕ_o, and ψ_{ko}. Likewise, Δ_{ox} and Δ_{oxs} may be expressed in terms of ϕ_o, ϕ_q, and ψ_{oq}.

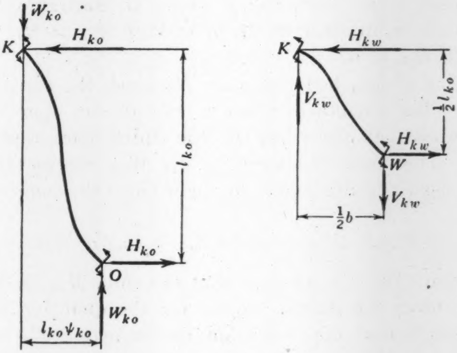

FIG. 5.

The stress in KO may be found by balancing the moments about W and observing that the moment at the middle of the member, KO, is $\frac{M_{ok} - M_{ko}}{2}$, whence,

$$\frac{b}{2} P_{ko} = M_W + M_{ak} + \frac{l_{ko}}{2} \psi_{ko} W_{ok} + \frac{M_{ok} - M_{ko}}{2} \quad \ldots\ldots\ldots\ldots (7)$$

from which, Δ_{ko} may be expressed in terms of ϕ_k, ϕ_o, and ψ_{ko}. Also,

$$\frac{b}{2} P_{oq} = M_X + M_{ak} + l_{ko} \psi_{ko} W_{ko} + \frac{l_{oq}}{2} \psi_{oq} W_{oq} + \frac{M_{qo} - M_{oq}}{2} \quad \ldots\ldots (8)$$

from which, Δ_{oq} may be expressed in terms of ϕ_o, ϕ_q, ψ_{ko}, and ψ_{oq}. Likewise,

$$\frac{b}{2} P_{qt} = M_T + M_{ak} + l_{ko} \psi_{ko} W_{ko} + l_{oq} \psi_{oq} W_{oq} + l_{qt} \psi_{qt} W_{qt} + M_{tq} \quad \ldots\ldots (9)$$

from which, Δ_{qt} may be expressed in terms of ϕ_q, ψ_{ko}, ψ_{oq}, and ψ_{qt}.

The equations, $\Sigma M = 0$, were written for Joints K, W, O, X, and Q; also, the equation,

$$M_{tq} + M_{qt} + l_{qt} \psi_{qt} W_{qt} + l_{qt} S_{qt} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

a total of six equations.

A moment term, M_k, to account for the eccentric diagonal connection was included in the equation, $\Sigma M = 0$, for Joint K, as follows: Let a equal one-half the width of the post at K, then $M_k = aV_{kw}$. From Fig. 5:

$$M_{kw} + M_{wk} + \frac{1}{2} l_{ko} H_{kw} = \frac{1}{2} b \; V_{kw} \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

whence M_k may be expressed in terms of ϕ_k, ϕ_w, and ψ_{kw}. The eccentric moments at O and Q are treated in a similar manner.

In the equation for Joint K a correction is made in the value of M_{ki}, which was previously determined as indicated in the first paragraph of the second approximation by assuming a point of contraflexure at the mid-height of the panel, or, in other words, by making $M_{ik} = M_{ki}$ in the equation, $M_{ik} + M_{ki} + l_{ik}\,S_{ik} = 0$.

After the value of M_{ki} had thus been obtained, the panel height, l_{ik}, was changed by assigning a depth to Strut 4; and also an approximate value for ψ_{ik} was determined, as described in the third paragraph of this third approximation. Therefore, the term, $l_{ik}\,\psi_{ik}\,W_{ik}$, representing the moment of the eccentric dead and live loads, may now enter the computations. Hence, from Fig. 1,

$$M_{ik} + M_{ki} = -\,l_{ik}\,S_{ik} - l_{ik}\,\psi_{ik}\,W_{ik} \ldots\ldots\ldots\ldots\ldots (12)$$

From Equation (12) it is obvious that the sum, $M_{ik} + M_{ki}$, is statically determinate whatever the design, except for the quantity, ψ_{ik}, which is so comparatively small that any variation in its magnitude will have slight effect on the sum. For example, the magnitude of ψ_{ik} was found to be approximately 0.0017; hence,

$$\begin{aligned} -\,l_{ik}\,S_{ik} &= -\quad 1\,476 \times 1\,715\,000 = -\;2\,531\,000\,000 \text{ in-lb} \\ -\,l_{ik}\,\psi_{ik}\,W_{ik} &= -\,1\,476 \times 0.0017 \times 74\,000\,000 = -\;186\,000\,000 \text{ in-lb} \\ \hline M_{ik} + M_{ki} &= -\;2\,717\,000\,000 \text{ in-lb} \end{aligned}$$

Instead of dividing this sum equally it was decided to divide it proportionately to the section moduli of the post at I and K, so that the resulting unit stresses would be equal, with the following result;

$$\begin{aligned} M_{ik} &= -\;1\,291\,000\,000 \text{ in-lb} \\ M_{ki} &= -\;1\,426\,000\,000 \text{ in-lb} \\ \hline M_{ik} + M_{ki} &= -\;2\,717\,000\,000 \text{ in-lb} \end{aligned}$$

The magnitude of M_{ki} was thus arbitrarily fixed at $-1\,426\,000\,000$ in-lb, the design was made to conform thereto, and any variation in the sum of the two moments on account of later changes in ψ_{ik} was absorbed, therefore, in M_{ik}. The term, M_{ki}, is expressed numerically in the equation, $\Sigma M = 0$, for Joint K; therefore, the quantities, ϕ_i and ψ_{ik}, do not appear in the equation.

The post is assumed to be completely restrained at T; that is, $\phi_t = 0$. Hence, the unknowns appearing in the six equations are a ϕ for each of five joints and a ψ for each of ten members, making fifteen unknowns. Nine additional equations are necessary therefore, for a solution. These nine equations may be obtained from the geometrical properties of Fig. 6. This is a Williot diagram as ordinarily understood with certain basic variations. Usually such a diagram can be made only when the strains corresponding to Δ_{qx} and the other heavy lines on Fig. 6 are known. Actually, the lengths of these lines are unknown; but their directions are known. Hence, the Williot diagram can be sketched and from its geometrical properties relations can be set up between the various strains in the form of equations.

Letting θ (Fig. 6) indicate the angle that the diagonal makes with the vertical, the nine required equations will then be as follows:

$$l_{qx}\,\psi_{qx} = \Delta_{qt} \operatorname{cosec} \theta + \Delta_{qx} \cot \theta \qquad (13)$$

$$l_{ox}\,\psi_{ox} = (\Delta_{qt} + \Delta_{oq}) \operatorname{cosec} \theta + \Delta_{ox} \cot \theta \qquad (14)$$

$$l_{ow}\,\psi_{ow} = (\Delta_{qt} + \Delta_{oq}) \operatorname{cosec} \theta + \Delta_{ow} \cot \theta \qquad (15)$$

$$l_{kw}\,\psi_{kw} = (\Delta_{qt} + \Delta_{oq} + \Delta_{ko}) \operatorname{cosec} \theta + \Delta_{kw} \cot \theta \qquad (16)$$

$$l_{oq}\,\psi_{oq} = (2\,\Delta_{qt} + \Delta_{oq}) \cot \theta + \Delta_{oxs} \operatorname{cosec} \theta \qquad (17)$$

$$l_{ko}\,\psi_{ko} = (2\,\Delta_{qt} + 2\,\Delta_{oq} + \Delta_{ko}) \cot \theta + \Delta_{kwr} \operatorname{cosec} \theta \qquad (18)$$

$$b\,\psi_{qs} = 2\,\Delta_{qt} \qquad (19)$$

$$b\,\psi_{or} = 2\,(\Delta_{qt} + \Delta_{oq}) \qquad (20)$$

$$b\,\psi_{kl} = 2\,(\Delta_{qt} + \Delta_{oq} + \Delta_{ko}) \qquad (21)$$

The expression previously derived for each Δ, in terms of ϕ and ψ, may now be substituted in these nine equations, and the fifteen equations solved for the fifteen unknown quantities, ϕ and ψ.

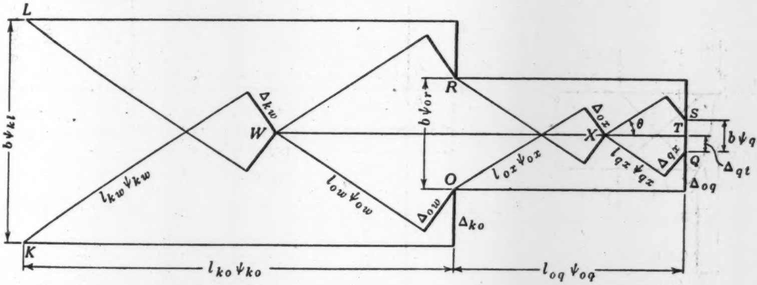

FIG. 6.

In this particular design, the diagonals in the two panels had equal areas since the wind shear differed but slightly in the two panels, one-half the shear being 2 767 000 lb in the upper panel and 2 979 000 lb in the lower panel. When the equations had been solved and the stresses, moments, and shears computed, it was found that the diagonal, *KWR*, was carrying a shear of 3 162 000 lb and resisting not only the wind shear but also the 395 000-lb shear in the post, *KO*, as well; while the diagonal, *OXS*, was carrying a shear of only 1 363 000 lb, the remaining 1 616 000 lb being resisted by the post, *OQ*. The moment, M_{ko}, was nearly double the moment, M_{ok}, while the moment, M_{oq}, was only about one-tenth the moment, M_{qo}, and a point of contraflexure still remained in this member. The stress in *KWR* was considerably more than double the stress in *OXS*.

These results were rather astonishing at first sight, but a numerical check showed that the moments, shears, and stresses balanced for each joint and section. The computations clearly indicated that a better balance in shear distribution should be sought and that strain rather than strength should be the governing factor in the design of the web system. Shifting from one system of bracing to another in the middle of a structure is not unlike changing commanders in the midst of a battle or swapping horses in the middle of a stream. Radical changes in the diagonals and minor changes in the posts were necessary before a satisfactory balance in shear distribution was secured, each set of changes being followed by corresponding revisions in the fifteen equations which were then solved for the fifteen quantities, ϕ and ψ.

In the treatment of the upper portion, M_{ki} was expressed in terms of ϕ_k, ϕ_i, and ψ_{ik}, and equated to its fixed magnitude. In Equation (12) the known magnitude of M_{ki} was substituted and M_{ik} expressed in terms of ϕ_k, ϕ_i, and ψ_{ik}. The quantity, ϕ_k, was known, having been determined from the computations made for the lower portion after the last revision mentioned in the preceding paragraph. The two equations were solved for ϕ_i and ψ_{ik} and the moment, M_{ik}, was computed. The sum, $M_{jg} + M_{gj}$, was then determined from an equation similar to Equation (12), the sum divided proportionately to the transverse section moduli of the post at J and G, and a definite magnitude fixed for M_{jg}.

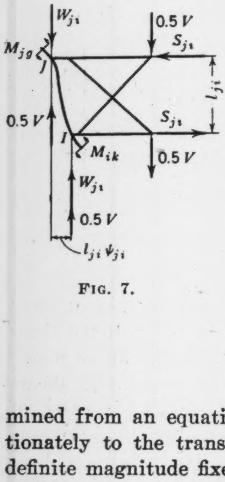

FIG. 7.

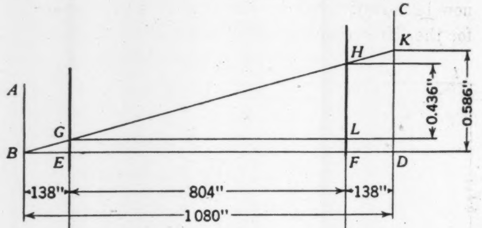

Fig. 8

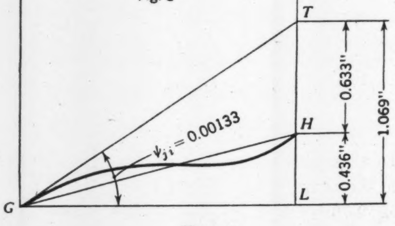

FIG. 9.

If a point of contraflexure is assumed at the middle of Strut 4 then, from Fig. 7, if V is the vertical shear in the strut,

$$M_{ik} + M_{jg} + l_{ji}\,\psi_{ji}\,W_{ji} + l_{ji}\,S_{ji} = \frac{1}{2}\,bV \,\ldots\ldots\ldots\ldots (22)$$

All quantities in the first member of Equation (22) are known except ψ_{ji}, which in the first approximation of the strut may be assumed equal to ϕ_i and the shear, V, determined.

An interesting problem arises at this point. The following quantities are known: $V = 5\,138\,000$ lb; $\psi_{ji} = \phi_i = 0.00133$; $\Delta_{it} = \Delta_{ik} + \Delta_{ko} + \Delta_{oq} + \Delta_{qt} = 0.293$ in.; and $P_{ik} = 13\,269\,000$ lb. The strut must be designed so that, when rotated through the angle, ψ_{ji}, and then distorted by the shear, V, the elevations of the ends of the bottom chord will be consistent with the strains, Δ_{it}, in the posts below. In Fig. 8, let AB and CD represent the center lines of the posts; GE and HF, their inside faces; and EF the center line of the bottom chord of the strut—all in their unstrained positions. The strain in each post is $\Delta_{it} = 0.293$ in., shortening one post and lengthening the other so that the difference in elevations of B and D after distortion is $0.293 \times 2 = 0.586$ in. If this difference is represented by KD, then the difference in elevations of the two ends of the bottom chord is,

$$HL = \frac{804}{1080} \times 0.586 = 0.436 \qquad (23)$$

In Fig. 9, GT is the tangent to the elastic curve of the bottom chord making the angle, ψ_{ji}, with the horizontal, GL, hence,

$$TL = 804\,\psi_{ji} = 1.069 \qquad (24)$$

whence,

$$TH = 1.069 - 0.436 = 0.633 \qquad (25)$$

The distance, TH, is the vertical deflection of the bottom chord to be accounted for by strains in the members of the strut. The problem, therefore, is to find the areas of the members which will cause this deflection when the members are stressed by a shear, $V = 5\,138\,000$ lb. The stresses, S, in terms of V, divided equally between the two web systems are given in Fig. 10.

FIG. 11.

Let A = the area of all the members, then,

$$TH = \sum \frac{S\,u\,l}{A\,E} = \frac{0.000\,059\,V}{A} = \frac{303}{A} = 0.633 \qquad (26)$$

whence, $A = 478$ sq in.

This area gives low unit stresses—about 6 000 lb for the chords and 8 000 lb for the webs—which indicates that small strains or stiffness rather than strength governs the design. Since stiffness is required, the members themselves as well as the strut as a whole should be designed with this end in view, by concentrating as much metal in the extreme fibers or flanges as is consistent with good design.

The distribution of the shear between the two web systems, *I*-1-4 and *J*-2-3 (Fig. 11) will now be investigated. Let P represent the vertical component of stress in *I*-1, and $5\,138\,000 - P$, the vertical component in *J*-2. The stresses, S, and the strains, Δ, multiplied by E, are given in Table 1.

TABLE 1.—WIND STRESSES AND STRAINS MULTIPLIED BY E IN STRUT 4, THIRD APPROXIMATION

Member		A	$\frac{l}{A}$	S	$E\,\Delta = \frac{Sl}{A}$

2-3.......	540	478	1.13	$7\,702\,000 - 1.1499\,P$	$8\,701\,000 - 1.693\,P$
J-*I*.......	360	7 220	0.0498	$13\,269\,000 - P$	$662\,000 - 0.0498\,P$
3-4.......	360	7 220	0.0498	$13\,269\,000 - P$	$662\,000 - 0.0498\,P$

The post members, *J*-*I* and 3-4, have an area of 7 220 sq in. The areas of all strut members are 478 sq in., except the diagonals, *I*-1 and 1-4, which are assigned an unknown area, A, and an unknown value of $\frac{l}{A} = a$.

In Fig. 9, let $T\,H = d =$ the vertical deflection of Joint 4, due to strains in the members, then,

$$d = 804\,\psi_{ji} - 0.436 \quad\quad (27)$$

or,

$$E\,d = 29\,000\,000\,(804\,\psi_{ji} - 0.436) = 23\,316\,000\,000\,\psi_{ji} - 12\,655\,000 \quad\quad (28)$$

Two general expressions for d in terms of the strains may be obtained from the Williot diagram, Fig. 12. Joint *I* is fixed in position; Member *J*-*I*, fixed in a vertical direction; and the vertical deflection of Joint 4 is *I*-4. If $\theta =$ the angle, 1-*I*-2, then,

$$E\,d = E\,(\Delta_{j2} + \Delta_{23})\,\operatorname{cosec}\theta + E\,(\Delta_{i2} + \Delta_{24})\cot\theta + E\,(\Delta_{ji} + \Delta_{34}) \quad\quad (29)$$

also,

$$E\,d = E\,(\Delta_{i1} + \Delta_{14})\,\operatorname{cosec}\theta + E\,(\Delta_{j1} + \Delta_{13})\cot\theta \quad\quad (30)$$

Equating the two expressions for $E\,d$ in Equations (28) and (29), substituting the expressions for the strains, Δ, from Table 1, and solving,

$$P = -\,3\,205\,000\,000\,\psi_{ji} + 6\,989\,000 \quad\quad (31)$$

A Williot diagram, Fig. 13, may be drawn to determine an approximate value of ψ for each strut member. The stresses are computed on the assumption that the shear of 5 138 000 lb is resisted equally by the two web systems. The strains are determined therefrom by assuming 478 sq in. as the area of all members. Joint I is fixed in position and Member J-I is rotated through the angle, $\psi_{ji} = 0.00133$; whence the horizontal distance between I and J is $360\ \psi_{ji} = 0.479$ in. Then the vertical distance, 4-I, which corresponds to $H\,L$ in Fig. 9, scales approximately 0.436 in. In scaling the quantities, $l\psi$, they are found to be approximately symmetrical about the center line of the strut and the values of ψ are thus assumed. Exact instead of approximate values of ψ for the strut members could have been included in the computations by simply sketching Fig. 13 and developing therefrom the expression for each ψ in terms of ψ_{ji} and the strains, Δ, as given in Table 1. The expedient used, however, saved considerable labor at a small sacrifice in accuracy.

FIG. 13.

The moment at the end of each member in the left half of the strut is expressed in terms of ϕ and ψ and the known value of ψ is substituted. The equations, $\Sigma M = 0$, are written for Joints I, 1, 2, and 5. At Joints 1 and 2, ΣM includes only the two members on the left of the center line. In the equation for Joint I there will be a term, M_i, to account for the eccentric connection of the diagonal, thus,

$$M_i = 138\,P = 138\,(-\,3\,205\,000\,000\,\psi_{ji} + 6\,989\,000) \ldots\ldots (32)$$

A fifth equation is written,

$$M_{ji} + M_{ij} + l_{ji}\, S_{ji} + l_{ji}\, \psi_{ji}\, W_{ji} - 402V = 0 \ldots\ldots (33)$$

Since ϕ_i is known, the five equations may be solved for ϕ_j, ϕ_1, ϕ_2, ϕ_5, and ψ_{ji}. Then the first four terms in the equation,

$$M_{ji} + M_{j5} + M_j + M_{j1} + M_{jg} = 0 \ldots\ldots\ldots\ldots\ldots (34)$$

may be computed and M_{jg} determined.

The magnitude of M_{jg} thus found differed considerably with the desired value previously assigned, since in approximating the shear, V, from Equation (22), ψ_{ji} was assumed equal to ϕ_i and no account was taken of the moments at the ends of the strut members at J and I. The value of ψ_{ji} was corrected in Equations (22), (24), and (25); the end moments of the four strut members were included in Equation (22); and a revised value of the shear, V, was obtained. When the computations had been revised a satisfactory agreement existed between the derived and assigned magnitudes of M_{jg} and no further revision was necessary.

The value of P, determined from Equation (31), was substituted in the expressions for $E\Delta$ in Table 1 and $a = \dfrac{l}{A}$ was determined from Equation (30), from which the required area of the diagonals, I-1 and 1-4, was found. The remaining struts were treated in a similar manner.

FOURTH APPROXIMATION

In the analysis of Strut 1 no variation in the shear, V, could be made, since $V = P_{cd}$. When the analysis had been completed the moment, M_{ba}, did not check with the moment of the known forces above B. This was accounted for by the fact that in Equations (7), (8), and (9) the eccentric moments, M_{ak}, were taken from a rough approximation to the elastic curve and no account was made of the moments at the ends of the sixteen strut members. The equations were corrected accordingly and the computations revised throughout.

The corrections for the lower portion were quite simple and, because no changes in design were necessary, were confined to the numerical terms in the equations affected. Revisions in design were necessary only in Struts 1 and 2. The value of M_{ba} was then in close agreement with the known value.

The expedient of assigning definite magnitudes to the moments M_{ki}, M_{jg}, M_{fe}, and M_{dc}, and making the design conform thereto greatly reduced the amount of work. Any set of computations and revisions was then confined to a relatively small part of the structure.

Further attention was now given to the longitudinal moments. In the second approximation a parabola was assumed for the elastic curve, tangent at the base with a deflection of 17 in. at the top. In the fourth approximation, x_1 and x_2 were taken as the deflections at K and F, and the deflections at all other points where there was a change in section were expressed as functions of the unknowns, x_1 and x_2. Expressions in terms of x_1, x_2, and H were developed by the area-moment method for the deflections at K, F, and the top, and were equated to x_1, x_2 and 17 in., respectively. The equations were solved, the remaining deflections determined, and the longitudinal moments computed. In the second approximation the deflections at F and K were 7.922 and 1.313 in., respectively, as computed from the parabola. In the analysis just described the deflections were found to be 7.631 and 1.175 in., respectively.

REVIEW OF THE DESIGN

Since the design had been made by fixing arbitrarily the magnitude of the moments, M_{ki}, M_{jg}, M_{fe}, and M_{dc}, and designing the structure accordingly, it was decided to make an independent set of computations, beginning in this case at the top. The following outline gives the gist of the method in greatly condensed form. The brief details should help other designers to a direct, time-saving solution.

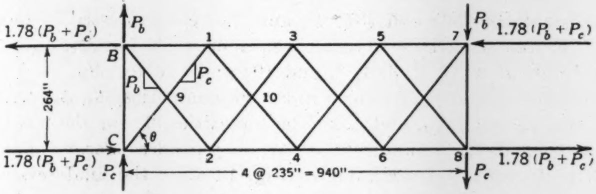

FIG. 14.

7–8........	264	3 895	0.068	P_b	$0.068\ P_b$

Let P_b and P_c represent the vertical components of the stress in the diagonals of Strut 1, as shown in Fig. 14. The computations of stresses and strains were made as in Table 2. Let d = the vertical deflection of Joint 8 due to strains, and Δ_{ct} = strain in the post from C to T. Then,

$$d = 940\,\psi_{bc} - \left(2\,\Delta_{ct} \times \frac{940}{1080}\right)$$

or,

$$E\,d = 27\,260\,000\,000\,\psi_{bc} - 50\,481\,000\,\Delta_{ct} \ldots\ldots\ldots\ldots (35)$$

The following equations were derived from the geometry of a Williot diagram drawn similar to Fig. 12:

$$E\,d = 4\,E\,\Delta_{b2}\,\text{cosec}\,\theta + E\,(4\Delta_{c2} + 2\,\Delta_{b1} + 2\,\Delta_{12})\cot\theta$$
$$+ E\,(\Delta_{bc} + \Delta_{78}) \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

$$E\,d = 4\,E\,\Delta_{c1}\,\text{cosec}\,\theta + E\,(4\,\Delta_{b1} + 2\,\Delta_{c2} + 2\,\Delta_{34})\cot\theta \ldots (37)$$

From Equations (36) and (37) P_b and P_c were expressed in terms of ψ_{bc} and Δ_{ct}. Eleven equations were written—one each for M_{ab} and M_{ba}; one each for Joints B, C, 1, 2, 3, 4, 9, and 10; and one for $M_{bc} + M_{cb}$. These eleven equations contained fourteen unknown quantities, ϕ_a, ϕ_b, ϕ_c, ϕ_d, ϕ_1, ϕ_2, ϕ_3, ϕ_4, ϕ_9, ϕ_{10}, ψ_{ab}, ψ_{bc}, ψ_{cd}, and Δ_{ct}. The quantities, ψ, for the strut members were not treated as unknowns; their magnitudes were obtained from the Williot diagram drawn similar to Fig. 13 after the final revision in the design had been made. Five of these fourteen unknowns, ϕ_c, ϕ_d, ψ_{bc}, ψ_{de}, and Δ_{ct}, appear in later equations. The remaining nine were eliminated from the eleven equations, leaving two equations containing the five unknowns, ϕ_c, ϕ_d, ψ_{bc}, ψ_{de}, and Δ_{ct}.

A similar treatment was given to Strut 2 which is 888 in. long. Then, as before,

$$d = 888\,\psi_{de} - \left(2\,\Delta_{et} \times \frac{888}{1080}\right)$$

Two equations were developed from the geometry of a Williot diagram and a third equation was written as follows: $\Delta_{et} = \Delta_{ct} - \Delta_{cd} - \Delta_{de}$. From these three equations the vertical components in the diagonals, P_d, and P_e, were expressed in terms of ψ_{bc}, ψ_{de}, and Δ_{ct}. Eight equations, $\Sigma M = 0$, were written for the eight joints, one for $M_{cd} + M_{dc}$ and one for $M_{de} + M_{ed}$. These equations, with the two brought down from Strut 1, gave twelve equations from which nine unknowns were eliminated, leaving three equations having the six unknowns, ϕ_e, ϕ_f, ψ_{bc}, ψ_{de}, ψ_{ef}, and Δ_{ct}.

Strut 3 was similarly treated, resulting in four equations having seven unknowns, ϕ_g, ϕ_j, ψ_{bc}, ψ_{de}, ψ_{fg}, and Δ_{ct}. The analysis of Strut 4 gave five equations with eight unknowns, ϕ_i, ϕ_k, ψ_{bc}, ψ_{de}, ψ_{fg}, ψ_{ji}, ψ_{ik}, and Δ_{ct}.

An equation was now developed by equating two independent expressions for Δ_{kt} as follows:

$$\Delta_{kt} = \Delta_{ct} - (\Delta_{cd} + \Delta_{de} + \Delta_{ef} + \Delta_{fg} + \Delta_{gj} + \Delta_{ji} + \Delta_{ik})$$
$$= \Delta_{ko} + \Delta_{oq} + \Delta_{qt}$$

From these six equations, ψ_{bc}, ψ_{de}, ψ_{fg}, ψ_{ji}, and Δ_{ct}, were eliminated, leaving one equation having the following unknowns: ϕ_i, ϕ_k, ϕ_o, ϕ_q, ψ_{ik}, ψ_{ko}, ψ_{oq}, and ψ_{qt}. An equation in terms of ϕ_i, ϕ_k, and ψ_{ik}, was written from $M_{ik} + M_{ki}$. The lower portion was treated in the same way as in the fourth approximation, except that M_{ki} was expressed in terms of ϕ_i, ϕ_k, and ψ_{ik} instead of as a known quantity. This introduced two additional unknowns, ϕ_i and ψ_{ik}, into the equations for the lower portion, but the upper portion, in turn, supplied the two additional equations necessary for the solution.

All assumptions made in the approximate solutions have been eliminated except that of identical elastic curves for the two posts. Two possible exceptions to this statement may be claimed. One exception is the assumption of numerical terms in Equations (7), (8), and (9) for the sum of the moments, M_s, in the sixteen strut members and for the sum of the eccentric moments, M_{ak}. The error involved is the difference between the magnitudes appearing in the equations and the magnitudes derived therefrom.

For example, in the final review of the problem, the magnitudes used in the equations were $M_{ak} = +$ 665 000 000 in-lb and $M_s = -$ 239 000 000 in-lb, as determined from the fourth approximation. When the review was completed the magnitudes were found to be $M_{ak} = +$ 663 000 000 in-lb and $M_s = -$ 235 000 000 in-lb. In any given set of computations, M_{ak} and M_s, are, respectively, the same in all three Equations (7), (8), and (9); and when these are combined with either $M_W = +$ 9 707 000 000 in-lb in Equation (7), or with $M_X = +$ 12 930 000 000 in-lb in Equation (8), or with $M_Y = +$ 14 874 000 000 in-lb in Equation (9), the errors are too small for consideration.

The other exception is the assumption that the post bases are in complete restraint against rotation, or $\phi_t = 0$. In order to ascertain the total possible range of moments, shears, and stresses, a review was also made on the assumption that the base was free to rotate by making $M_{tq} = 0$ and treating ϕ_t as an unknown quantity. The chief differences in the results of these two assumptions were confined to the part below the floor. For the fixed base, the moments in the posts and the stress in the upper diagonals were larger, and the stress in the lower diagonals smaller, than for the free base. The transverse deflection at the top was 11.14 in. for the fixed assumption and 11.31 in. for the free assumption.

CONCLUSION

It seems unnecessary to make extended comments or to draw specific conclusions from this expository rather than argumentative monograph, further than to emphasize the simplicity of the process by which the Williot equations are developed. The facility of their application, however, will vary according to the nature and degree of complexity of the problem in hand. There is, of course, an analogy between the Williot deflection equations and the energy or elastic equations derived from equating external to internal work. When confronted with the analysis of any statistically indeterminate structure, the analyst will solve the problem by the method with which he is the most familiar, whether it is the elastic, the deflection, or any other method, provided the particular method adopted ends in fruition. All methods, however, are not equally efficient. In the present case the completed analysis of the towers may be checked by equating internal and external work after the problem has been solved and the deflections are known; but the problem cannot be solved by this method except possibly by an almost endless procession of "cut and try" guesses as to the displacements of all joints in the structure; whereas by the method of expressing moments in terms of angular displacements, the displacements may be treated as unknowns and a solution obtained with the help of the Williot strain equations.

It may be that this method is known to others, but during his years of academic and professional experience the writer has never encountered a presentation of it, and probably never would have discovered the method had not necessity given it birth.

DISCUSSION

Ralph A. Tudor,[2] Assoc. M. Am. Soc. C. E. (by letter).—The complete and accurate analysis of a large suspension bridge tower is an unusual problem and one much more difficult than at first might appear. It is essentially a tall slender column braced in one direction only and subject to enormous vertical loads at its top, which are more often than not acting eccentrically. In addition, horizontal wind loads must be considered and only by comparison with the great vertical loads do they seem small.

The analysis of the tower legs for supporting the vertical loads and for the necessary bending longitudinal with the bridge has been more or less standardized, as described in Mr. Ellis' paper. However, the effect of the participation of the bracing with the legs in supporting the vertical loads, the effect of the transverse wind loads on all parts of the tower, and the magnitude of secondary stresses have not often been considered in detail. The method presented by Mr. Ellis, and his use of the geometry of a Williot diagram covers this phase of the problem and should give results very near the truth. Of great importance is the fact that the method considers, simultaneously, primary

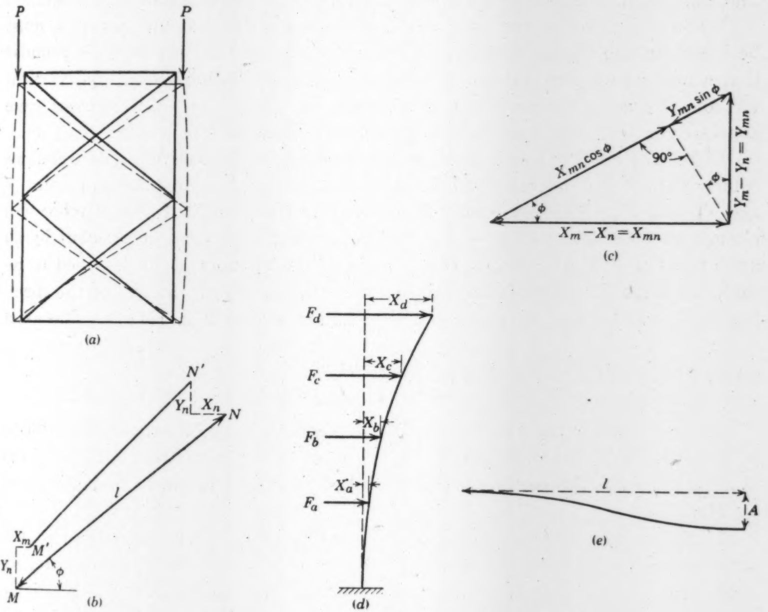

FIG. 15.

---

[2] Senior Designing Engr., Bridges, Div. of Highways, State Dept. of Public Works, San Francisco, Calif.

(including participation) and secondary stresses. In this manner, allowance is made for the full effect of one on the other without subsequent corrections.

It is unusually interesting that, while Mr. Ellis was finding necessity "the mother of invention," the analysis of another suspension bridge tower was proceeding elsewhere. The same vexing problems were recognized, and a solution was effected which is fundamentally very similar to that already presented. The tower differs in architectural detail in that it is braced throughout its entire length, except through the roadway portal, by a system of double diagonals.

Referring to Fig. 15(*a*), it can be seen that a portion of the tower fabricated as shown by the solid lines will be deformed into some such shape as that shown by the dotted lines when the loads, *P*, are applied. The elastic shortening of the legs under load will decrease the vertical length of the panels and will require a reduction in the length of the diagonals. This action will place stress in the diagonals and the horizontal component of this stress will be resisted by bending in the tower legs or stress in any horizontal that may exist. Any external horizontal load will create a new stress balance.

When the problem was first encountered it seemed that any solution must be based on the elastic features of the structure, and it was on this premise that a method was developed. The unknowns were the horizontal and vertical (X and Y) components of the movements of the joints. All stresses were expressed in terms of these unknowns and equations of stress balance set up.

Refer to Fig. 15(*b*) and consider any member, such as MN. The unknown components of the movement of Joint M are X_m and Y_m, and those of Joint N are X_n and Y_n. The horizontal component of the length of the member will change by an amount $(X_m - X_n) = X_{mn}$, and the vertical component by an amount $(Y_m - Y_n) = Y_{mn}$. If the slope of the member, ϕ, is assumed to remain unchanged (which is essentially true), the change in length of the member, MN, will be, $\delta_{mn} = X_{mn} \cos \phi + Y_{mn} \sin \phi$ (see Fig. 15(*c*)). The axial stress in the member will then be $\left(\frac{A\,E\,\delta}{l}\right)_{mn}$.

In this manner the axial stress in all members may be expressed in terms of the unknown joint movements. Since joint movements are a feature of the Williot diagram, the method being described is quite similar to that developed by Mr. Ellis.

If all joints were pin-connected and bending of members did not exist, the structure could be solved by equating the sum of the horizontal forces entering each joint to zero ($\Sigma H = 0$), and treating the vertical forces similarly ($\Sigma V = 0$). This would give two equations for each joint, which would equal the number of unknowns and permit a solution.

However, in examining the structure it can be seen that bending in the legs will materially influence the joint displacements and must be fully provided for in the analysis. On the other hand, for the particular tower considered, the web members are comparatively flexible, and their bending will not appreciably effect the distortion of the structure as a whole. Bearing this in mind, equations for $\Sigma V = 0$ may be stated for all joints and for $\Sigma H = 0$ for those joints not along the tower legs.

In stating the remaining equations, the tower legs are considered to be vertical cantilevers fixed at the base. At each joint along the leg a horizontal force of unknown magnitude is applied. This force is simply the algebraic sum of the horizontal components of the axial stresses carried by the members entering the joint, plus any externally applied load. Thus, in Fig. 15(*d*), the leg is acted upon by the forces, F_a, F_b, F_c, and F_d, and the joints are deflected by the amounts, X_a, X_b, X_c, and X_d. Then,

$$\begin{aligned} X_a &= M_{aa} F_a + M_{ab} F_b + M_{ac} F_c + M_{ad} F_d \\ X_b &= M_{ba} F_a + M_{bb} F_b + M_{bc} F_c + M_{bd} F_d \\ X_c &= M_{ca} F_a + M_{cb} F_b + M_{cc} F_c + M_{cd} F_d \\ X_d &= M_{da} F_a + M_{db} F_b + M_{dc} F_c + M_{dd} F_d \end{aligned}$$

The M-values are functions of the tower dimensions. By this means the remaining equations are provided, and their solution is only a matter of careful perseverance.

With the magnitude of the joint movements determined for a given condition of external loads, the axial stresses are computed by $\frac{A\,E\,\delta}{l}$. Bending stresses are determined by distributing the fixed end moments in accordance with the Cross method. The fixed end moments (see Fig. 15(*c*)), are equal to, $M = \frac{6\,E\,I\,\Delta}{l^2}$.

This method has been used to solve other frames in which bending of the members is an important item.

Leon S. Moisseiff,[8] M. Am. Soc. C. E. (by letter).—This paper is a contribution of the first order to the methods available to engineers for determining the strains and stresses in elastic frames subjected to considerable deformation and departure from their original geometric form. The author has extended the utilization of the device known as the Williot diagram to the rotation of the members of a stiff frame at any joint. He has opened thereby an approach for the investigator which in many instances will facilitate his labors and in others will afford the only possible path to a closely accurate determination of the behavior of a stiff frame under loads.

Mr. Ellis relates how, encountering the problem of a high tower subjected to large vertical and horizontal forces and designed as a stiff frame, he developed the presented solution. The writer believes that it is pertinent to fix here the co-ordinates of this case in time and space. The Golden Gate Bridge, now under construction (1934), crosses the entrance of San Francisco Bay by a suspended structure with a main span of 4 200 ft and side spans of 1 125 ft. This enormous span, the longest of any bridge, as a matter of design and clearance, requires high towers. They were made about 700 ft in height above the masonry pier and 746 ft above mean high water. The width of the bridge centers of towers, trusses, and cables is 90 ft, and the magnitude of the towers is such that about 21 000 tons of steel are required for one tower.

---

[8] Cons. Engr., New York, N. Y.

The location of the bridge over the Golden Gate, the entrance to the largest harbor on the Pacific Coast, in a landscape of rare scenic beauty, demanded a structure of chaste and majestic appearance. It was thought that by avoiding a multiplicity of diagonals for the bracing of the towers and leaving the cross-sectional view of the towers as free from obstructions as possible, a satisfactory solution would be attained. This led to the adoption of a stiff frame design with diagonals below the roadway and horizontal braces above it. The appearance of the northern tower more than realizes the anticipation of the designers.

This is the "flesh-and-blood" story of the skeleton tower which the author encountered and to which he refers. The method and procedure that he developed during his work on the design of the towers are the subject of his paper. It should properly be added that the final proportioning of the towers differs somewhat in cross-sectional areas from those given in the paper. In general, the procedure and method described were followed in the final design of the Golden Gate Bridge towers, on which the author has done excellent work.

The procedure in the final computations was as follows: For transverse wind loads all stresses in the tower were computed simultaneously; the final unknowns were expressed as the rotation angles of the joints and the rotations of the members.

The only simplification introduced in the analysis was in the treatment of the four horizontal struts above the roadway as units. It was made by neglecting the effect of the secondary stresses in the members of the struts on the bending moments in the tower shafts. The shear transmitted through the struts was expressed as a function of the unkown rotation angles of the joints and the end member (tower shaft). It was thus made possible to reduce the number of the final simultaneous equations to thirty, the bottom horizontal member being designed to carry no stress. One tower shaft has eleven joints; the diagonal bracing below the floor has two more; and, there are eleven members in the shaft and six in the diagonal bracing. As each of these represents an unknown, a total of thirty unknowns result. To include the omitted effect of the secondary stresses in the members of the struts in the procedure would have rendered the simultaneous solution nearly impossible. The two upper top struts alone would have added thirty-four additional final equations.

The secondary stresses in the members of the struts were computed subsequently from the primary stresses, and it was found that the resulting rotation angles at the ends were close to those derived from the solution of the thirty simultaneous equations. It may be added here that the top strut was analyzed subsequently by the same procedure as the tower. This was done in the computations for the tower model mentioned later, as an additional check of the original assumptions.

After the solution of the thirty simultaneous equations, the rotation angles of all joints and members of the shaft were known, as well as the rotation of the end members and end joints of the struts. These values, belonging to the top strut, were then introduced as known quantities, and it was thus possible to compute all stresses in the strut simultaneously by establishing and solving seventeen equations. The results proved that the transferred shear assumed in the original equations was closely correct and that the resulting stresses in the struts were also in agreement with the original computations.

The computations of the stresses and the design of the Golden Gate Bridge which, of course, included that of the towers, have been checked in the writer's office.

Considering the importance and size of the towers and the fact that novel methods of analysis had to be developed for more accurate computations of their stresses, it was decided to verify the design and computations by tests of a model which should simulate, as nearly as possible, the structure and assure elastic behavior within the limits of test loads and observations.

A model of stainless steel was fabricated which was almost an exact replica of the actual tower to the ratio of 1 to 56 in linear scale. The height of the model was 12.5 ft. The vertical load on top of the model was 38 000 lb, corresponding to the vertical load on top of the actual tower of about 120 000 000 lb.

The model was fabricated under the direction of George E. Beggs, M. Am. Soc. C. E., and the tests were conducted under his charge at Princeton University. The model tower was simultaneously loaded both vertically and laterally in proportion to the wind load on the actual tower. A most complete set of observations was made by strain-gauges. The results obtained from the observations on the model were in full agreement with the results of the theory used in the design of the tower.

It will be of interest to know that when the first design of the towers was made, practically for purposes of estimate, it was necessary to determine the lateral deflection of the tower tops. This was computed both by the work method and the slope method. It happened that, by each of these methods, a lateral displacement of about 6 in. was found. Upon closer examination of the problem it became apparent that the deflection found by the work method is due to the axial deformation of the tower shafts only and that the deflection found by the slope method is due to the flexure of the shafts only. Therefore, the two results, the one by the work method and the other by the slope method, should be added in order to obtain the approximate result of displacement. To this again should be added the effect of the eccentricity of the tower loads while so displaced and which will cause additional displacement. The total sum of the lateral displacement thus arrived at was about 17 in. It was then realized that a correct solution could only be obtained by developing a simultaneous integral theory. This has been done by the author. It should be stated here that the lateral deflection of the tower tops is 12.6 in. for the tower as built.

The discussion leads to a comparison of the stiff frame, braced horizontally, with the common diagonally braced frame. It is usually assumed in every-day practice that a diagonally braced frame is statically determinate and that its stresses are therefore definite and computed with little effort. Any one who has given some thought to the problem will admit, of course, that this is not so. In order to have a statically determinate structure, all joints must be hinged and frictionless. Structures are not built in this manner. The frame structures as built are many times statically indeterminate and the correct determination of their stresses is highly complicated.

The assumption of frictionless joints, however, is so prevalent because it is the basis of elementary class-room teaching. This is a necessary result of the evolution of engineering science. Humanity, in its desire to understand the action of natural forces and to forge tools to determine the quantitative character of their action, had to resort to simplifying assumptions. It was an enormous step forward when the conception of the hinged, frictionless frame of rigid members was evolved. To this simplified theory is due the great advance in the design of structures and bridges. For the smaller structures subjected to moderate loads the theory is sufficient. The larger bridges built with higher strength steels and subjected to greater forces and deformations demand a deeper analysis which should correspond more closely to the actual behavior of the structures.

From the point of view of a simultaneous solution a frame with diagonal bracing is more complicated and more laborious to compute than one with horizontal struts. Thus, the Golden Gate Bridge tower, as designed, required thirty equations and, if braced with diagonals, would have required thirty-five equations. The towers of the San Francisco-Oakland Bay Bridge did, in fact, require thirty-five equations.

In connection with the simultaneous analysis of frames and trusses it is well to point out that the separation of strains and stresses caused by external forces, into primary and secondary, is artificial and incorrect. Unless the frame is treated in its entirety erroneous results are frequently obtained. In some cases, even the direction of the stress is in error. There is an evident interaction of the members of a frame and only a simultaneous solution can approach their actual behavior.

A. A. Eremin,[4] Assoc. M. Am. Soc. C. E. (by letter).—An original method of computing the stresses in a suspension bridge tower is developed in this paper, including consideration of rigid connections at the joints.

A number of analytical and semi-graphical methods for designing frames have been proposed, the relative merits of which depend upon the error introduced, the simplicity of the operations, and the time saved. Mr. Ellis has developed equations for a direct relation between the angular displacements at the joints and the external forces. However, these equations are complicated and numerous. To compute the angular displacements in the simple symmetrical frame (Fig. 2) below Joints *K* and *L*, fifteen simultaneous equations must be solved. This is a difficult task even with a computing machine.

---

[4] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

Furthermore, in the Williot strain diagram, a geometrical relation between small deformations and long normal lines is sometimes difficult to express. Especially is this true in the case of a diagram for an arch frame. Stresses in a frame with rigid joints are generally computed in two operations: The primary stresses are determined under the assumption that the members of the frame are hinged at the joints; and the secondary stresses are computed to express an effect of the rigidities at the joints and eccentricities of the connections on the primary stresses.

Computation of the secondary stresses is based on the convenient formula for a change in the angle due to changes of lengths in all three members in any triangle, thus:

$$E\ \delta\alpha = (S_3 - S_2) \cot \beta + (S_3 - S_1) \cot \gamma \ldots\ldots\ldots (38)$$

and for checking

$$\delta\alpha + \delta\gamma + \delta\beta = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

The simultaneous equations for computation of the angular displacements developed by Equation (38) may be arranged so that the arithmetical error in solving these equations will not be accumulating. Furthermore, any part of a frame may be analyzed separately.

However, Mr. Ellis has stated correctly that the facility of application of the Williot equations will vary according to the nature and degree of complexity of the problem in hand. The author is to be complimented for this interesting contribution to the theory of design of statically indeterminate structures.

CHARLES A. ELLIS,[6] M. AM. SOC. C. E. (by letter).—Thanks are due to those who have discussed this paper, for their kindly and constructive comments.

Mr. Eremin mentions that the equations are complicated and numerous. It is a fact that all mathematical expressions appear more or less complicated on first sight. The equations certainly are numerous; but the extraordinary structure rather than the method of analysis is responsible for the number.

Mr. Moisseiff has stated, in effect, that this new method provides the only possible path to a closely accurate determination of the behavior of a stiff frame under loads, especially when the frame is subjected to considerable deformation and departure from its original geometric shape. He has commented on the artificiality and incorrectness of solving for primary and secondary stresses separately. Mr. Tudor has also pointed out the great importance of "the fact that the method considers, simultaneously, primary

---

[6] Prof. of Structural Eng., Purdue Univ., Lafayette, Ind.

(including participation) and secondary stresses." These points were not sufficiently emphasized in the paper and a further word may be clarifying.

The diagonal members below the floor (Fig. 3) were originally designed (see "First Approximation") on the commonly accepted assumption that they would resist the total horizontal wind shear in each panel. The degree to which this assumption proved to be in error (more than 100%), because of extraordinary stiffness in the vertical posts and their consequent capacity to resist shear, is indicated in the "Third Approximation" below Fig. 6.

The discovery and first application of the Williot equations came about, as follows: The transverse elastic curve was investigated as described in the first three paragraphs of the "Third Approximation." An ordinary Williot diagram for the lower portion was drawn after strains had been computed from approximate stresses and the quantities, ψ, were determined therefrom. Equations $\Sigma M = 0$, were written and solved; and the moments, M, at the ends of each member were computed. With M_{ko} and M_{ok} approximately known, it was possible to compute the shear, H_{ko}, in the member, KO, from Equation (5). It was obvious at once that this shear was a very considerable quantity, much too large to be neglected in assuming that the diagonals resisted the total horizontal wind shear. Repeated attempts by trial and error were made to estimate the shear distribution between the posts and diagonals. Each attempt included a revised set of stresses and strains, and a revised Williot diagram, etc. These attempts seemed to be getting nowhere, either because the writer's guesses went wide of the mark or because of the numerous factors in the problem.

After repeated drawings of the Williot diagram from revised guesses as to shear distribution, it became obvious that each ψ could be expressed algebraically in terms of the strains in the members, as shown in Equations (13) to (21); so, instead of determining the quantities, ψ, from a Williot diagram drawn from assumed strains, the question arose "Why not express each ψ in terms of unknown strains?" It was clear that the value of ψ_{oq} and ψ_{ko} had much greater influence on shear distribution than values of ψ for any or all other members. Hence, in the first application of the Williot equations, ψ_{oq} and ψ_{ko} were expressed as in Equations (17) and (18), and approximate numerical values derived from the preceding Williot diagram were assigned to the remaining ψ's. Equations (4) to (9) show how the expressions for stresses, P, and resulting strains, Δ, were developed. The result of this solution, since it contained Equation (4), determined the shear distribution, and revealed the glaring error originally made in assuming that the diagonals resisted all the external shear. It was then decided to "go the whole route" and use all equations—(13) to (21)—thereby eliminating all assumptions possible. This procedure was taken after major revisions had been made in the design of the diagonals and minor changes in the posts. The great value of the Williot equations was at once apparent, and they were used later to good effect in the analysis of the upper part of the structure.

Mr. Moisseiff's discussion of the labor involved in the solution of a structure with diagonal bracing compared with one having horizontal struts, should be qualified somewhat. If the two diagonals in any panel are removed and one horizontal strut is substituted, the number of members is reduced; and if the horizontal member is of the plate girder type and if no consideration is given to its depth, except its moment of inertia, then Mr. Moisseiff's statement, that a structure with diagonal bracing is more complicated and more laborious to compute, is correct.

On the other hand, when the horizontal member is a truss 30 ft deep having very large chord and web members, a thorough analysis becomes much more complicated because, although two diagonals have been omitted in each panel, two post members have been added, together with a truss composed of numerous members. When the magnitude and novelty of the structure, and the consequent uncharted field of structural analysis with little or no precedent to follow, were considered, it was deemed wise to apply as thorough an analysis as possible. It was for these reasons that the Williot equations were applied also to the part above the floor.

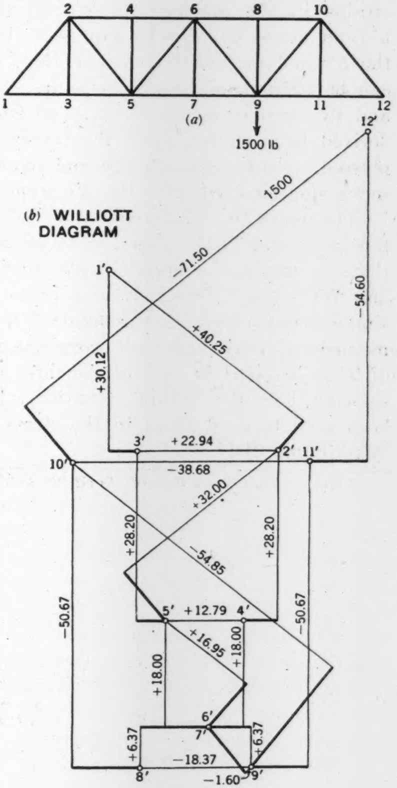

FIG. 16.—MOHR'S SEMI-GRAPHICAL METHOD OF ANALYZING SECONDARY STRESSES.

Of course, the usual assumption that the diagonals resist the total shear in a panel would not result in such gross error in an ordinary truss ; but it is pertinent to emphasize that any method (Manderla's included) of computing secondary stresses in a truss, which fails to take account of the influence of secondary stress upon primary stress, can no longer be considered as "most exact."

The valuable and scholarly paper entitled "Secondary Stresses in Bridges,"[6] by C. B. von Abo, Assoc. M. Am. Soc. C. E., describes nearly all methods of secondary stress analysis known at that time, and gives solutions by the various methods, using the truss and load as shown in Fig. 16(*a*). The vertical shear in Panel 3–5 (Fig. 16(*a*)), for example, is 500 lb. The analysis shows that deformation imposes moments at the ends of the Members 2–4 and 3–5; consequently, these members are resisting transverse shear. These shears should be considered with the vertical component of the stress (primary and secondary) in Member 2–5, when balancing the total external shear of 500 lb in the panel. The true vertical component of the stress in this diagonal is not 500 lb, and any computation of secondary stress made on this assumption will be in error. The same conclusion applies to all members. The error here is small and of academic significance only, but Manderla's method can no longer stand as the model for accuracy. The analysis by the simultaneous solution is a closer approach to accuracy and will take on practical value as the chord members become relatively stiffer and relieve the diagonals in transferring shear from one end of the panel to the other.

---

[6] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 69.

The primary and secondary stresses in the truss analyzed by Mr. von Abo may be solved simultaneously by using the Williot equations with Mohr's semi-graphical method as follows: In the Williot diagram (Fig. 16(b)) let the strains in the members be represented by Δ_{12}, Δ_{23}, etc. The quantities, ρ (and hence ψ), can be expressed, by the Williot equations, in terms of the Δ's and the thirty-three equations written. Twelve equations, $\Sigma M = 0$, can be written, one for each joint. They will contain twelve unknowns, ϕ, and twenty-one unknowns, Δ. The twenty-one additional equations may be derived from statics, since the transverse shear in any member may be expressed as a function of the end moments of that member. A solution of these equations will give the Δ's from which the stresses can be determined.

The use of the Williot equations is by no means limited to structures of the type presented in the paper, or to solutions in connection with moment equations in terms of angular displacements. The writer has shown elsewhere[7] how Williot equations may be used to advantage in solving the stresses in a simple truss having four redundant members. Solutions by the well-known methods of work and least work are included to show the relative amount of labor involved in each of the three methods. An illustration is also given, showing how the Williot equations, had they been available, might have been used to good effect in the stress analysis of the towers of the George Washington Bridge.

RAINFALL STUDIES FOR NEW YORK, N. Y.

By S. D. Bleich,[1] Esq.

With Discussion by Messrs. H. Alden Foster, J. J. Slade, Jr., Charles W. Sherman, Merrill M. Bernard, Clifford Seaver, Jose Garcia Montes, Jr., Rhodes E. Rule, and S. D. Bleich.

Synopsis

The object of this paper is to collect rainfall data, arrange them in order of intensities, and then derive formulas and graphs which may be used for purposes of sewer design and investigations. Statistics of the heavier rainfalls have been culled from the records of the Central Park gauge in New York, N. Y., covering the period from 1869 to 1930, inclusive. The intensities for various durations are then listed in order of their magnitudes and several types of precipitation formulas are investigated. By comparison of the results the modified exponential type proves most nearly to accord with the observed data. With suggested constants this is recommended for use in New York City and, when properly adjusted as to values of coefficients, to other localities as well.

For the proper design of storm sewers it is essential to know fairly definitely the frequency at which the severe rainfall intensities occur for different intervals of time. The rate of rainfall is one of the factors used in estimating run-off in the determination of sewer capacities and the choice of its value will be governed by the frequency. The most severe intensities of rain are not generally used in obtaining the capacities of sewers, as the cost of such sewer sizes would be excessive and, in fact, unwarranted because of the rarity of these storms.

Severe rainfalls are listed in terms of the frequency of their occurrence. Further, it is necessary to classify them by their duration, by their rate or intensity corresponding to the duration, and by the frequency that such rates or intensities have been equalled or exceeded.

Note.—Published in February, 1934, *Proceedings*.

[1] Asst. Div. Engr., Board of Transportation, New York, N. Y.

Rainfalls are designated by referring to the frequencies at which certain intensities occur for various periods. For instance, a "2-year" storm is one in which the relation between rate of rainfall and corresponding duration has been equalled or exceeded on an average of once in two years for the entire recorded period.

RAINFALL DATA AND THEIR USES

It is apparent that the first task is to collect the basic data. This, in many respects, is the most difficult part of the work as the records for any one rain-gauge are enormous. Those from the Government Observatory in Central Park, New York City, which extend over 62 years, from 1869 to 1930, inclusive, and form the subject of this paper, required a great deal of patience and painstaking labor in tabulating the data as correctly as possible.[2] The earlier records do not give as complete details for short-time intensities as the more recent ones, and this must be borne in mind in interpreting them.

A summary in Table 1 shows the limitations found or assumed in collecting the data, while the storm records themselves are listed in Table 2. It is evident that there is no regularity in the recurrence of severe intensities for any period. In order, therefore, to obtain working rules, it is desirable to arrange all intensities in a regular sequence starting with the heaviest and proceeding to the lowest. This has been done in Table 3.

TABLE 1.—SCOPE OF RAINFALL TABULATION FOR CENTRAL PARK GAUGE. NEW YORK CITY, 1869 TO 1930, INCLUSIVE

Period, in minutes	Maximum observed intensity, in inches per hour	Minimum intensity considered, in inches per hour *
5	9.12	3.00
10	9.06	1.92
15	8.44	1.92
30	5.50	0.91
60	3.31	0.90
120	1.85	0.90

* Except years in which the maximum is less than the minimum given.

Since the record covers 62 years, the frequency (second column), corresponding to the first number, is $\frac{1}{62}$, or 0.016 times per year. A "5-year" storm lies between Serial Nos. 12 and 13, as one-fifth of 62 is 12.4.

Summarized from Table 3, the character of the various kinds of storms are as given in Table 4. Where the serial number is a fraction the rainfall intensities have been interpolated.

As the data in Table 3 are limited, and known as "random samples," any one sample may not conform to the general trend of the aggregate samples. This is readily indicated by the irregular lines when the data are plotted on cross-section paper.

The human mind strives to secure order in the relations of physical measurements and considers that the apparent irregularity is due to errors

---

[2] Data collected by Mr. O. Hufeland, *Engineering News*, August 31 and September 7, 1916, covering the period, 1869 to 1913, inclusive, supplemented by published records of the U. S. Weather Bureau. Gaps in these data indicate that such maximum rainfall intensities were not available.

in the measurements, to the incompleteness of the observations, or to both. To overcome such apparent deficiencies resort is made to various methods. A smooth curve may be drawn which would average the plotted data, or an equation may be developed by methods used in statistics or biometrics. In this study the graphical and algebraic methods have been used.

The data in Table 3 may be treated in three ways:

1.—A relation may be obtained for the data taken along the horizontal lines showing a relation for each frequency between duration and rainfall intensity.

2.—A relation may be obtained for the data listed in vertical columns under each given duration. This will show a relation for each duration between the rainfall intensity and the frequency.

3.—A single relation may be obtained between the three factors of duration, rainfall intensity, and frequency, using all the data both horizontally and vertically in a single comprehensive calculation.

TABLE 4.—CONDENSED STORM DATA, CENTRAL PARK GAUGE, NEW YORK CITY, 1869 TO 1930, INCLUSIVE

Duration, in minutes	Serial No.......... 62 Times per year..... 1 Storm designation.. 1 yr	31 0.5 2 yr	12.4 0.2 5 yr	6.2 0.1 10 yr	2.48 0.04 25 yr	1.24 0.02 50 yr
5..........	4.08	5.04	6.36	6.98	8.31	9.09
10..........	3.06	3.66	5.06	5.28	7.59	8.86
15..........	2.56	3.12	4.09	4.78	7.23	8.33
30..........	1.72	2.14	2.74	3.22	5.23	5.44
60..........	1.10	1.33	1.70	2.12	2.90	3.24
120..........	....	....	1.06	1.29	1.62	1.81

It is more convenient for general use to obtain the first form of relationship between the duration and the rainfall intensity for the "1-year" and other storms. In the Borough of Manhattan at least the "10-year" storm would be used for sewer design, whereas for certain parts of the Borough of Queens, the formula or curve for a "2-year" storm would be satisfactory.

The second form of relationship between frequency and rainfall intensity will give for each duration an entire gamut of storms, including 1-year, 2-year, and others. The third form, combining into one formula a relation between the three variable factors of intensity, duration, and frequency, would graduate the data on a surface, whereas the previous forms graduate the factors on a series of lines without showing any regularity among the different lines. All three forms of relationship are exemplified in this paper.

RECIPROCAL FORMULA

In Greater New York there is a partiality for a reciprocal formula of the type:

$$R = \frac{A}{t + b} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(1)}$$

giving the relation between t, the duration of the storm, in minutes, and R, the corresponding rainfall intensity, in inches per hour, equalled or exceeded once in a certain number, n, of years. Hence, Equation (1) would be the formula for a theoretical "n-year" storm. For a 1-year storm ($n = 1$) and, similarly, for other storms, A and b would have one set of fixed values, which must be obtained for that storm. If done by trial this would be a laborious hit-and-miss method; but by the method of least squares the data given in Table 3 are sufficient. Calculations of A and b may be simplified by the following consideration: If the logarithms of Equation (1) are taken, it becomes,

$$\log R = \log A - \log (t + b) \qquad \text{.....................(2)}$$

This equation is linear between $\log R$ and $\log (t + b)$. If logarithmic ruled paper is used the R and t data will plot as an irregular line or curve for each character of storm. If, however, to each value of t a certain fixed value for b is added, the effect is to straighten the curve. That value of b is used which will make the transformed line most nearly straight and, at the same time, plot to an angle of 45° with the axes. The graphs for Equation (1) are shown on Fig. 1, using the data from Table 3. The transformed lines are not indicated.

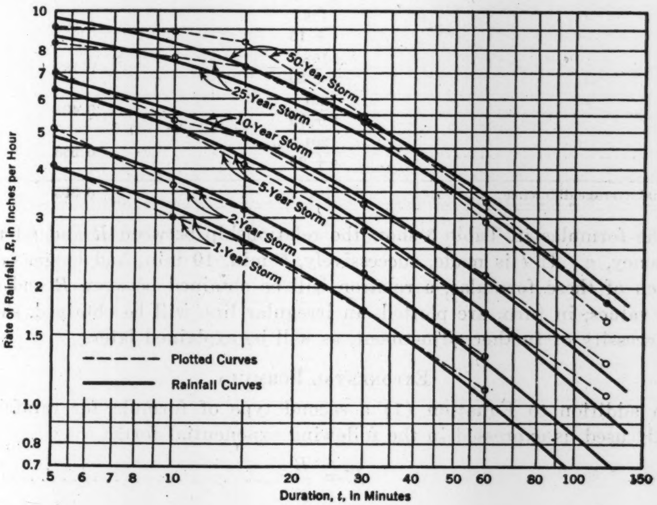

Fig. 1.—Rainfall Curves in Form, $R = \frac{A}{t + b}$. Data from Central Park Gauge, New York, N. Y., 1869 to 1930. Formulas for Various Storms Given in Table 5.

Now that b is known, A is computed from Equation (2) by the method of least squares as illustrated for a more complicated case in the Appendix.

Formulas of the type given in Equation (1) for the various storms are plotted in Fig. 1 and listed in Table 5. Comparisons are then made between the observed results and the results obtained from the formulas. The average difference between the observed intensity and the result from Equation (1) equals 0.182 in. per hr for the 10-year storm. Similar average differences for the various characters of storms have been computed as shown in Table 5.

The final average difference computed as described in the Appendix, is 0.303 which may be taken as a measure of the closeness with which formulas of the type of Equation (1), as illustrated in Fig. 1, fit the observations. This diagram shows that expressions similar to Equation (1) cannot be made to fit the data as accurately as is desired.

TABLE 5.—VARIATION OF RAINFALL CURVES BY RECIPROCAL FORMULA FROM OBSERVED DATA

Storms	Values for Rate R, Equation (1)	Average difference from observed data, in inches per hour
1-year	$\frac{76.4}{t+14}$	0.075
2-year	$\frac{96.3}{t+15}$	0.140
5-year	$\frac{128}{t+15}$	0.099
10-year	$\frac{168}{t+20}$	0.182
25-year	$\frac{261}{t+25}$	0.404
50-year	$\frac{291}{t+25}$	0.563
Final average difference	......	0.303

The formulas in Table 5 show the relationship between R and t for each frequency, n. If t is made, successively, 5 min, 10 min, and longer periods, in each of these formulas, a relation will be obtained between R and n. If these values, in turn, are plotted, an irregular line will be obtained, showing the necessity of further adjustment, as will be explained later.

EXPONENTAL FORMULA

In addition to Equation (1) a second type of formula for rainfall frequently used, is expressed in the following exponential form:

$$R = \frac{B}{t^c} \qquad (3)$$

in which, B and c are constants, having one set of values for a 1-year storm and a different set for a 2-year and other storms. Taking the log of Equation (3),

$$\log R = \log B - c \log t \qquad (4)$$

which is a straight line between log R and log t. This line may be obtained directly, whereas in Equation (1) a constant value had to be added to t to yield an approximate straight line. The tangent of the slope of the transformed lines represented by Equation (1) is the same for all storms, when their graphs are plotted with similar scales in both directions on logarithmic paper for the 1-year and other storms, all making an angle of 45° to the "log t" line. In Equation (4) the tangent of the slope is c, which differs for various storms. Therefore, the lines representing such storms on logarithmic paper, Fig. 2, will not be parallel. In this diagram, also, values of B and c have been determined by the method of least squares as given in the Appendix. The resulting forms of Equation (3) and the average deviations for the different storms are given in Table 6.

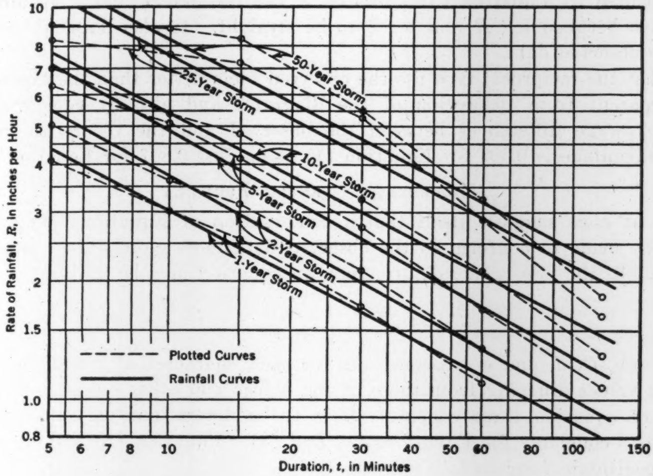

FIG. 2.—RAINFALL CURVES IN FORM, $R = \frac{B}{t^c}$. DATA FROM CENTRAL PARK GAUGE, 1869 TO 1930. FORMULAS FOR VARIOUS STORMS GIVEN IN TABLE 6.

TABLE 6.—VARIATION OF RAINFALL CURVES BY EXPONENTIAL FORMULA FROM OBSERVED DATA

Storm	Values for Rate R, Equation (3)	Average difference from observed data, in inches per hour
1-year...........................	$\frac{10.11}{t^{0.529}}$	0.128
2-year...........................	$\frac{12.38}{t^{0.53}}$	0.144
5-year...........................	$\frac{18.1}{t^{0.576}}$	0.376
10-year...........................	$\frac{18.1}{t^{0.53}}$	0.370
25-year...........................	$\frac{24.8}{t^{0.526}}$	1.27
50-year...........................	$\frac{28}{t^{0.53}}$	1.41
Final average difference..........	....	0.807

The first form of rainfall formula, the reciprocal type illustrated by Equation (1), has the defect that it requires the straight line between log R and log $(t + b)$ to be at a definite inclination of 45° downward to the right for all characters of storm, and, therefore, may not be made to conform to the observed data as closely as desired. This was actually found to be the case, as may be seen in Fig. 1. The second, or exponential, type, as represented by Equation (3) and Fig. 2, has the defect that it requires the relation between log R and log t to be straight. It also does not conform to the observed data.

That the reciprocal type fits the observed facts better than the exponential is apparent from inspection of the diagrams and also by comparing the final average differences between the observed and the theoretical results. The advantage is 0.303 for Equation (1) as against 0.807 for Equation (3).

Modified Exponential Formula

It at once suggests itself that a combination of Equations (1) and (3) may be made to conform to the observed data more closely than either one alone. In the most general form such an equation may be written:

$$R = \frac{C}{(t + d)^e} \quad \ldots\ldots,\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which, C, d, and e are constants for each character of storm, the 1-year storm values differing from those of the 2-year and other storms. With this type of equation three constants have to be determined as compared with only two constants for Equations (1) and (3). Equation (5) may be written in logarithmic form as follows:

$$\log R = \log C - e \log (t + d) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

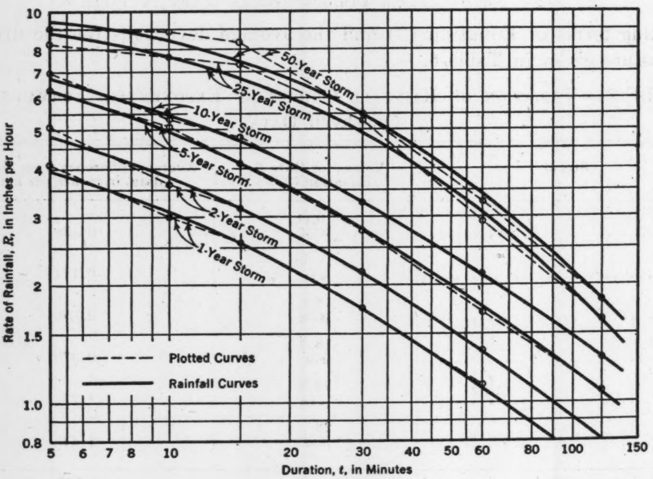

FIG. 3.—RAINFALL CURVES IN FORM, $R = \frac{C}{(t + d)^e}$. DATA FROM CENTRAL PARK GAUGE, 1869 TO 1930. FORMULAS FOR VARIOUS STORMS GIVEN IN TABLE 7.

This is not linear between log R and log t, but is linear between log R and log $(t + d)$. Therefore, if the various observed values are plotted on logarithmic paper (Fig. 3), the lines connecting them will be irregularly bent the same as in Fig. 1. When this bent line is transformed by adding a constant value, d, to each value of t, keeping the corresponding R the same, a differently bent line will be obtained. If the bending is increased, smaller values for d should be tried, and conversely until almost a straight line is obtained. This process is the same as was described in developing Fig. 1. The proper values of d which will make the transformed line almost straight can then be readily interpolated and checked by plotting.

After d has been obtained in this manner, e and C are computed by the method of least squares, as shown in detail for this case in the Appendix. The appropriate formulas for the various storm classifications and the resultant deviation of the plotted data from the curves for R (Fig. 3), are given in Table 7.

TABLE 7.—VARIATION OF RAINFALL CURVES BY MODIFIED EXPONENTIAL FORMULA FROM OBSERVED DATA

Storm	Values for Rate R, Equation (5)	Average difference from observed data, in inches
1-year	$\frac{38.85}{(t+10)^{0.842}}$	0.057
2-year	$\frac{41.62}{(t+9)^{0.813}}$	0.096
5-year	$\frac{60.53}{(t+10)^{0.835}}$	0.061
10-year	$\frac{63.75}{(t+12)^{0.796}}$	0.155
25-year	$\frac{1\ 468}{(t+40)^{1.342}}$	0.329
50-year	$\frac{4\ 201}{(t+50)^{1.513}}$	0.428
Final average difference	....	0.235

About 1921 the Bureau of Sewers of the City of New York developed various formulas by a trial-and-error method from the rainfall data, which formulas were plotted on ordinary cross-section paper. These formulas were

TABLE 8.—COMPARISON OF VARIOUS FORMULAS FOR RAINFALL, WITH OBSERVED DATA

Types of formulas	TWO-YEAR STORM		TEN-YEAR STORM	
	Formulas	Average difference from observed data, in inches per hour	Formulas	Average difference from observed data, in inches per hour
Old formulas	$\frac{120}{t+20}$	0.285	$\frac{150}{t+15}$	0.387
Reciprocal formulas (Fig. 1)	$\frac{96.3}{t+15}$	0.140	$\frac{168}{t+20}$	0.182
Exponential formulas (Fig. 2)	$\frac{12.38}{t^{0.53}}$	0.144	$\frac{18.1}{t^{0.53}}$	0.370
Modified exponential formulas (Fig. 3)	$\frac{41.62}{(t+9)^{0.813}}$	0.096	$\frac{63.75}{(t+12)^{0.796}}$	0.155

of the type given in Equation (1). It is interesting to give comparative results between these "old formulas" and the various formulas presented in this paper, as shown in Table 8. The average differences from the observed data are smallest for the formulas in Table 7, plotted in Fig. 3, and largest for the old formulas.

RELATION BETWEEN RAINFALL INTENSITY AND FREQUENCY

If the observed data in Table 3 are plotted for each duration given in the vertical columns, irregular lines will be obtained, showing the relation between the rainfall intensity, R, and the frequency, n, for the duration given. It is evident that there is as much justification for seeking order in the relation between R and n for each duration, t, as between R and t for each frequency, n, or character of storm that has been obtained in Figs. 1, 2, and 3. Studies have been made to obtain such relationship from Table 3.

The equation connecting R, rainfall intensity, and n, average number of times per year which it occurs or is exceeded, is:

$$R\,n^h = k \qquad \text{(7)}$$

in which, h and k are constants for each duration, t. The various values of h and k are given in Fig. 4 with the curves and the observed data.

These formulas in Fig. 4 have been computed from the observed data by the method of least squares. The results will agree, in general, only approximately with those obtained from the formulas in Fig. 3.

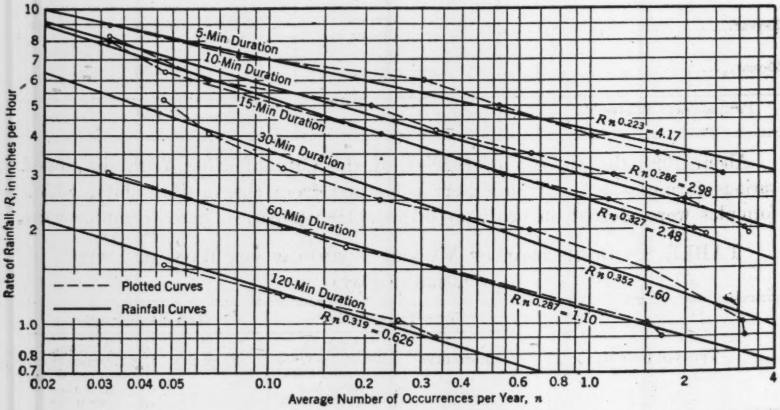

FIG. 4.—HEAVY RAINFALL FREQUENCIES IN FORM, $R\,n^h = k$. DATA FROM CENTRAL PARK GAUGE, NEW YORK, N. Y., FROM 1869 TO 1930.

It is desirable to harmonize all the data given in Table 3 showing a relation between R, t, and n. An approximate relation between the three factors has been obtained, as follows:

$$R\,n^{0.3} = \frac{42.5}{(t + 12)^{0.85}} \qquad \text{(8)}$$

The logical refinement leading to the development of Equation (8) may be unnecessary in practice. It would probably be expedient to use the set of formulas which best fit the observations even if they do not harmonize with one another. Accordingly, it is recommended that the formulas in Table 7, and Fig. 3 be used in sewer investigations and design.

PROBABILITY METHOD

Rainfall records note certain facts which have already occurred. Like history they teach by example. If the conditions continue with little alteration, it is assumed that the past records may be used to anticipate what may occur in the future. Any regularity which may be perceived in past events may be assumed to recur in the future.

Various expressions have been given in this paper which tend to show such regularity by a method known as "curve fitting." Other methods can also be used in interpreting those records for future guidance. The best known are those used in biometrics and vital statistics, as developed by Karl Pearson and his school. They are offshoots of the theory of probability.

The duration curve is sometimes called the integral curve and gives the relative frequency that a certain magnitude has been equalled or exceeded. The magnitude may refer to average monthly or annual stream flow, total annual rainfall, or rainfall intensity for a 15-min duration. The frequency curve gives only the frequency of occurrence of a definite magnitude, showing, for instance, how many times an annual rainfall of 40 to 45 in. may be expected to occur in 100 years. The integral or duration formula is obtained from the frequency formula. Its expression is generally very complicated.

Various types of frequency curves or equations have been suggested. "Types I and III" appear to fit engineering data best. Type I applies to a range of records which are skewed and have both a finite minimum and a finite maximum value. Type III is used for records having a finite value in one direction only. From the manner in which the variations of the magnitude from the average occur in the recorded data the probable skew value is obtained by certain mathematical processes.

This probability method, applied to the data in Tables 2 and 3, shows that the Type III curve fits the data best. The coefficient of skew appears to vary from 1.56 to 3.02, with an average value of 2.22. The curves in Fig. 5 have been prepared for durations of 5, 10, 15, 30, 60 and 120 min, based on the Type III curve with a uniform coefficient of skew, $C\,S = 2.22$. From Fig. 5 it appears that once in 50 years a rainfall intensity of 7.40 in. per hr and more may occur for a 10-min duration; 4.55 in. per hr and more for 30 min; and 2.80 in. per hr and more for 60 min.

A comparison between the results obtained from Figs. 3 and 5 is given in Table 9. An inspection of Table 9 indicates that the modified exponential method gives results more in accord with the actual data than the probability method.

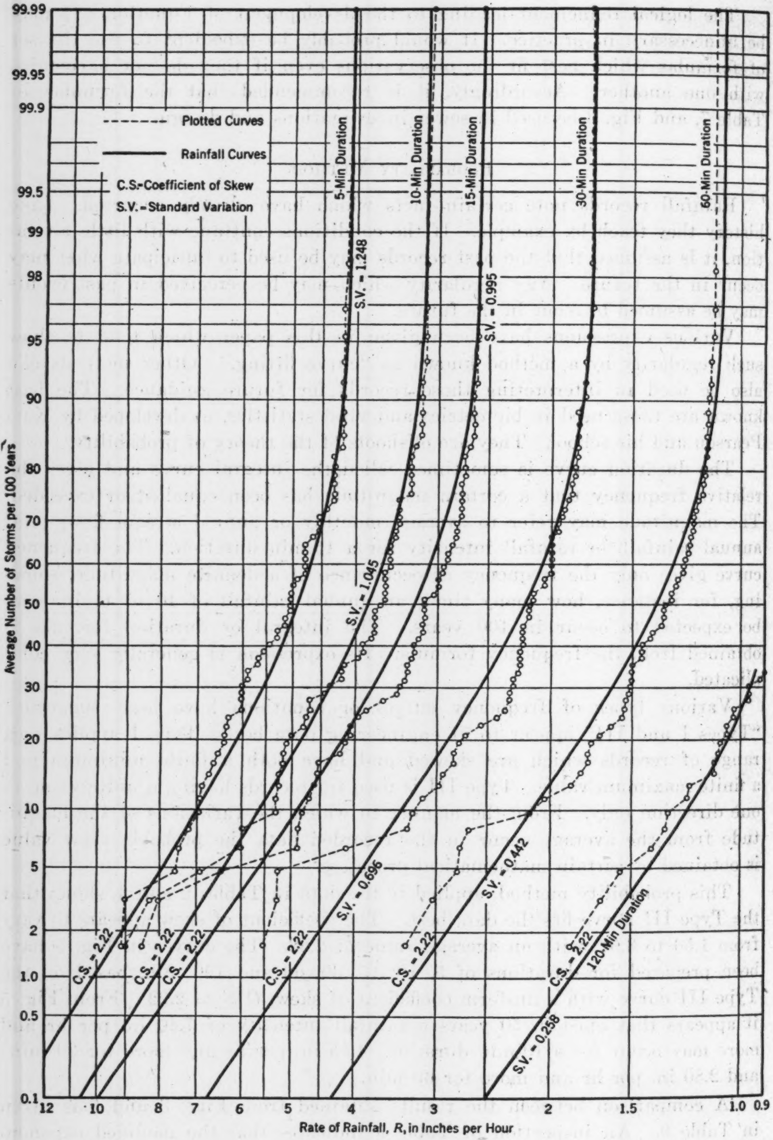

FIG. 5.—HEAVY RAINFALL FREQUENCIES. DATA FROM CENTRAL PARK GAUGE, NEW YORK, N. Y., 1869 TO 1930. CURVES BY PROBABILITY METHOD.

TABLE 9.—RAINFALL INTENSITIES BY MODIFIED EXPONENTIAL AND PROBABILITY METHODS COMPARED WITH ACTUAL INTENSITIES

Duration, in minutes	Frequency, in years	n	Modified exponential method, Fig. 3, in inches per hour	Probability method, Fig. 5, in inches per hour	Actual intensities, in inches per hour
10	Once in 50.	0.02	8.20	7.40	8.86
30	Once in 50.	0.02	5.50	4.55	5.44

10	Once in 2.	0.50	3.79	3.81	3.66
30	Once in 2.	0.50	2.12	2.20	2.14
60	Once in 2.	0.50	1.33	1.38	1.33

CONCLUSION

Various types of formulas have been developed showing the relations between the rainfall intensities, durations, and frequencies of occurrence. The results, however, do not equally fit the recorded storms, and the single unified formula, Equation (8), does not appear to be sufficiently close to the observations to warrant its use for all kinds of storms. The six formulas given in Table 7 and plotted in Fig. 3 answer most accurately the requirements of the engineer, either for computing storm sewers or for making investigations of the flooding of buildings or of underground subways in New York City. It is also believed that this paper gives in ample detail the procedure to be used in obtaining similar formulas for locations other than New York City.

ACKNOWLEDGMENT

The paper was prepared in the course of work in the Sewer and Drainage Sub-Division of the Designing Office of the Board of Transportation, New York City. The collection of the data and the laborious calculations were made by William A. O'Leary, Assoc. M. Am. Soc. C. E. Acknowledgment is made to C. E. Conover, Division Engineer of the Designs Division, A. I. Raisman, Chief Designing Engineer, Members, Am. Soc. C. E., and Robert Ridgway, Past-President and Hon. M., Am. Soc. C. E., Consulting Engineer, of the Board of Transportation, all of whom made the work of preparing this paper possible.

APPENDIX

DERIVATION OF FORMULA FOR 10-YEAR STORM IN THE FORM, $R = \dfrac{C}{(t + d)^s}$

This Appendix explains the calculation of the modified exponential formula, Equation (5), for a 10-year storm; the calculations of the reciprocal formula, Equation (1), and the exponential formula, Equation (2), are similar. The data from Table 3 for a 10-year storm are plotted on logarithmic ruled paper shown as a broken line. By adding, however, a constant, 12, to t the graph will become very nearly straight. With Equation (5), the slope of the line is not restricted to 45° as required by Equation (1). The equation of this line may be found by the method of least squares. In this case: $R = \dfrac{C}{(t + 12)^e}$. Taking logarithms of both sides,

$$\log R = \log C - e \log (t + 12)$$

and using observed values of R and t,

$$\log R - \log C + e \log (t + 12) = D$$

in which, D is a small number. Then,

$$\Sigma\,[\log R - \log C + e \log (t + 12)]^2 = \Sigma\, D^2 = M$$

For M to be a minimum,

$$\frac{\partial M}{\partial \log C} = 0$$

$$\frac{\partial M}{\partial e} = 0$$

and,

$$\frac{\partial M}{\partial \log C} = -2\,\Sigma\,[\log R - \log C + e \log (t + 12)] = 0$$

that is,

$$\Sigma \log R = n \log C - e\, \Sigma \log (t + 12) \ldots \text{(1st Normal Equation)}$$

in which, n is the number of observations, which is equal to 6 in Table 10. Also,

$$\frac{\partial M}{\partial e} = 2\,\Sigma\,\left\{[\log R - \log C + e \log (t + 12)] \times \log (t + 12)\right\} = 0$$

or,

$$\Sigma\,[\log R \times \log (t + 12)] = \log C\, \Sigma\, (t + 12)$$
$$- e\, \Sigma\, [\log (t + 12)]^2 \ldots\ldots\ldots \text{(2d Normal Equation)}$$

TABLE 10.—CALCULATION OF FACTORS IN NORMAL EQUATIONS.

t (1)	$t + 12$ (2)	$\log (t + 12)$ (3)	$[\log (t + 12)]^2$ (4)	Observed R (5)	$\log R$ (6)	$\log R \times \log (t + 12)$ (7)	Computed R (8)	Difference (9)	Difference^2 (10)
5	17	1.2304	1.5139	6.98	0.8439	1.0383	6.69	−0.29	0.0841
10	22	1.3424	1.8020	5.28	0.7226	0.9700	5.46	+0.18	0.0324
15	27	1.4314	2.0489	4.78	0.6794	0.9725	4.62	−0.16	0.0256
30	42	1.6232	2.6348	3.22	0.5079	0.8244	3.26	+0.04	0.0016
60	72	1.8573	3.4495	2.12	0.3263	0.6060	2.13	+0.01	0.0001
120	132	2.1206	4.4969	1.29	0.1106	0.2345	1.32	+0.03	0.0009
Sums	....	9.6053	15.9460	......	3.1907	4.6457	......	......	0.1447
Average difference	....	....	....	......	......	....	......	......	0.155

The data and computations from the observed values of t are listed most conveniently in the form given in Table 10. From this is found:

$$\text{Average difference} = \sqrt{\frac{0.1447}{6}} = 0.155$$

Completing the normal equations for the summations in Table 10,

$$3.1907 = 6 \log C - e \times 9.6053$$

and,

$$4.6457 = 9.6053 \log C - e \times 15.9460$$

Solving, $e = 0.795$ and $C = 63.75$. Therefore,

$$R = \frac{63.75}{(t + 12)^{0.795}}$$

in which, R = rate of rainfall, in inches per hour, and t = duration, in minutes.

DISCUSSION

H. ALDEN FOSTER,[3] M. AM. SOC. C. E. (by letter).—The author has analyzed the rainfall data by probability methods, based on the frequency curves of Karl Pearson. As no details of this analysis are presented, it may be helpful to engineers who are unfamiliar with these methods to state that the subject was treated, in 1924, by the writer[4] and, in 1927, by R. D. Goodrich, M. Am. Soc. C. E.[5]

In applying the frequency curve method, the author states that "the coefficient of skew appears to vary from 1.56 to 3.02, with an average value of 2.22." Fig. 5 was plotted, using the average coefficient of skew, 2.22, for all the curves. It is apparent from an inspection of Fig. 5 that this average value is not suitable for all the curves. It is not surprising, therefore, that the probability method used by Mr. Bleich gives results that differ from the actual data more than those obtained by means of the exponential method (Fig. 3, or Equation (5)).

The author states that "it is desirable to harmonize all the data given in Table 3 showing a relation between *R, t,* and *n,*" and submits Equation (8) as a summary of these data. In his "Conclusion" he states that "Equation (8) does not appear to be sufficiently close to the observations to warrant its use for all kinds of storms." A generalized empirical formula is a dangerous tool to use in any case, unless its limitations are well understood. It would seem unwise, therefore, to publish a new rainfall formula that is admittedly unreliable even when applied to its basic data.

The rainfall records given in Tables 2 and 3 are well prepared, and should be of value to the profession. The formulas in Table 7 should also be useful as a guide for engineers studying problems of storm run-off in this part of the United States.

J. J. SLADE,[6] JR., ESQ. (by letter).—An interesting and important correlation between the duration and intensities of New York storms is developed in this paper. The author has spared no labor in comparing the results obtained by the use of various methods of analysis, and he finds that his formula gives a better representation of the observed data than others that he considers.

One question is left open, however, which merits consideration: What are the values that any formula is expected to give? The observed data represent a set of events that have occurred in the past and that almost certainly will never occur again in the form once observed. The fact that an empirical formula gives, closely, the values of an observed set of events does not mean that it will fit closely a future set. It is not surprising that the author finds that the values obtained from his modified exponential formula agree more closely with observed values than do those obtained by the probability method, since he has determined the constants in his formula by the method of least squares to give just such an agreement.

[5] A graphical method for analyzing similar data is given in "Straight Line Plotting of Skew Frequency Data," by R. D. Goodrich, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 1.

[6] Asst. Prof. of Eng. Mechanics, Rutgers Univ., New Brunswick, N. J.

Mr. Bleich regards the probability method as an alternate in the solution of this problem. The method is not alternative, however, but rather complementary to any method used. The correlation required in this particular problem is between members of a small set culled from a large group of events. Such a local set cannot be treated independently; it belongs to the whole group, and it is only as a part of the whole group that one may make assertions about it.

The probability method gives information about the entire group of events. For instance, it involves all the available information regarding the 30-min duration intensities, and then it indicates how, in the long run, these intensities will be distributed. It does not fit the record locally; it fits it as a whole. The past 62-yr record deviates from the probability curve, and so will the future record; but the probability curve furnishes a norm about which any record of the phenomenon in question will fluctuate.

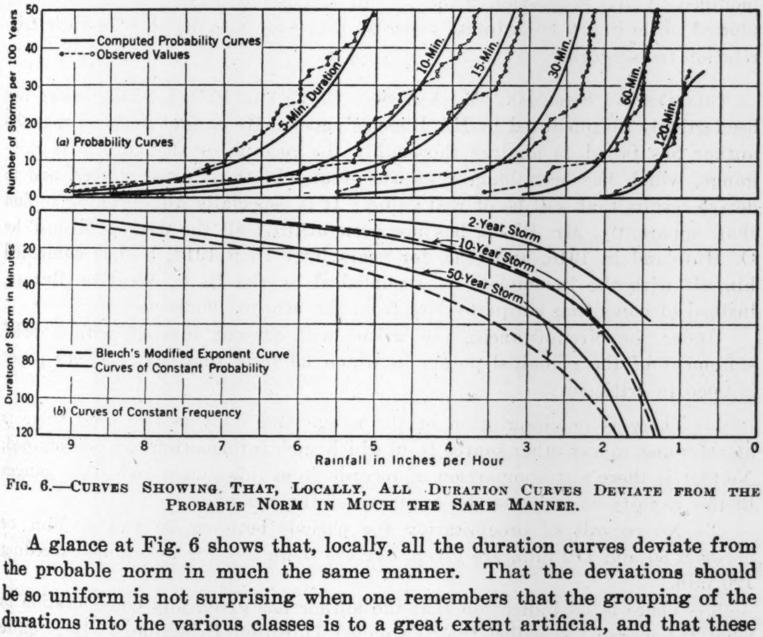

FIG. 6.—CURVES SHOWING THAT, LOCALLY, ALL DURATION CURVES DEVIATE FROM THE PROBABLE NORM IN MUCH THE SAME MANNER.

A glance at Fig. 6 shows that, locally, all the duration curves deviate from the probable norm in much the same manner. That the deviations should be so uniform is not surprising when one remembers that the grouping of the durations into the various classes is to a great extent artificial, and that these various classes really blend into each other. On the other hand, this uniform deviation may be taken to mean that the actual distribution of intensities is not the one given by the probable norm, but rather by some other curve which should fit the observed data more closely—only the observations of the next few hundred years will give an answer to this question. However, it is likely that this deviation is characteristic of the current meteorological period more than of the long-term distribution of intensities.

If these contentions are correct, the constants of the modified exponential formula should be computed, not from the observed data, but from the modified values given by the probability method, because the determination of the constants directly from the data makes use of only a few isolated observations. It does not in any way take into account the distribution of other intensities, whereas the values as adjusted by the probability method result from taking into account the entire observed set.

Fig. 6(*a*) gives the probability curves for the various durations carried out to a frequency of 50 storms in 100 yr. These curves are the same as those in Fig 5. The slight modifications result from the fact that the writer has used the true coefficient of skew for each curve instead of the author's constant value of 2.22. Fig 6(*b*) gives three curves of constant frequency as obtained from the curves of Fig 6(*a*), together with two of Mr. Bleich's modified exponential curves. It is seen that the 50-yr storm curve would be greatly modified by the suggestion made in this discussion. The curves have been plotted on ordinary co-ordinate paper so that they may be seen in their true relation to each other.

CHARLES W. SHERMAN,[7] M. AM. SOC. C. E. (by letter).—The writer has been greatly disappointed in Mr. Bleich's paper. He cannot but feel that the author has failed to analyze thoroughly the records of the automatic rain-gauge, which has been longest in use of any in the United States, and to derive results that will be of real value. It is especially discouraging to find that, apparently, Mr. Bleich has not even utilized all the data published[8] by O. Hufeland in 1916, and that, for years later than 1913, he has contented himself with the incomplete data published by the U. S. Weather Bureau, instead of compiling adequate data from the original chart records.

Under the circumstances, the writer will content himself with a brief statement of the principal points in which he feels that Mr. Bleich's paper is open to criticism:

1.—There is no description of the gauge and its exposure, and there is no reference to any other source from which such information can be obtained. Neither is there any comparison of records from this gauge and other gauges in the vicinity to indicate the accuracy of the record.

2.—No records of precipitation for periods between 30 and 60 min, or between 60 and 120 min, are given, nor are there any for durations exceeding 120 min.

3.—There is no indication that the author has given any consideration to what the writer has called the "Extended Duration Principle."[9] It is quite possible that a considerably larger number of records of storms of comparative long duration than the author has utilized, would have been obtained by the application of this principle.

[7] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

[8] *Engineering News*, 1916, pp. 76, and 594.

[9] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 953.

4.—It does not appear logical that the constant, C, in Equation (5), should vary from 38.85 for storms of 1-yr frequency, to 4 201 for storms of 50-yr frequency; nor that the exponent, e, in the same formula should vary between 0.795 and 1.513.

In his own studies of rainfall intensity and frequency at Boston, Mass., the writer found[10] that C varied according to a mathematical law from 16.0 for 1-yr frequency to 45.9 for 50-yr frequency; and that d and e were constant. Similar results, although with other values of the constants, were found[11] for Detroit, Mich., by Milton F. Wagnitz, M. Am. Soc. C. E., and Lewis C. Wilcoxen, Assoc. M. Am. Soc. C. E.

Equation (8) is similar in form to that used by the writer and by Messrs. Wagnitz and Wilcoxen. Apparently, Mr. Bleich has not much confidence in it; but the writer suspects that if the analysis of the records had been more detailed, as suggested in the preceding Comments (2) and (3), considerable justification for Equation (8), or one similar to it, would have been found.

A comparison of this formlula with those devised for Detroit, and for Boston, is as follows:

Place	Formula	Derived by:
New York, N. Y.	$Rn^{0.3} = \dfrac{42.5}{(t + 12)^{0.85}}$	Bleich
Detroit, Mich.	$Rn^{0.263} = \dfrac{37.6}{(t + 8)^{0.855}}$	Wagnitz and Wilcoxen
Boston, Mass.	$Rn^{0.27} = \dfrac{16.0}{(t + 7)^{0.7}}$	Sherman

5.—Mr. Bleich has made no mention of previous papers on rainfall intensity as indicated by the Central Park gauge, except that of Mr. Hufeland.[8] The data and discussions in the reports of the Committee on Rainfall and Run-Off of the Municipal Engineers of the City of New York, published in 1913 and 1922, are worthy of consideration and comment, as are also comments[12] by the late Kenneth Allen, M. Am. Soc. C. E., in 1921, and again in 1922.[13] Mr. Allen's formulas are of the same general form as those of Mr. Bleich, as given in Table 7; but the constants given by Mr. Allen differ from those presented by Mr. Bleich much more than would be expected as the result of including ten years of additional records. It would seem that some statement regarding the earlier studies and explanation for the different results obtained would be in order.

MERRILL M. BERNARD,[14] M. AM. SOC. C. E. (by letter).—This paper is to be commended as a presentation of an excellent procedure in the treatment of rainfall intensity data. Mr. Bleich has accomplished the task of fitting curves, accurately, to plotted points and developing the mathematical expression for the curves; but can the formulas for the 25-year storm and the 50-year storm be accepted as the permanent relationship of rainfall rate and duration? Will the next 63 years of record reproduce the same curve group? When the station has reached 80 years of record, will not several of the present maximum values remain unexceeded? Furthermore, is it not probable that the next 40 years of the record will contribute a number of values which will fall within the unusual interval between the author's 10-year and 25-year storm, thereby affecting the position of the higher frequency curves? What is the climatological cycle, in years, necessary to be spanned by a single station record, in order to make that record a dependable basis for the upper frequency values? How accurately does the composite record fulfill the purpose of the single station record?

The writer believes that the formula types, reciprocal and exponential, serve two distinct purposes, the former more accurately representing the comparatively short periods of continuous downpour and the latter the average of intermittent rainfall for the longer durations. His opinion has been that, because of a paucity in single-station records of adequate length, covering duration periods of less than 1 hr or 2 hr, the Meyer curve group,[15] properly interpolated geographically, could be accepted as the best available expression of rainfall intensity for such duration periods. That New York City could have adopted them without material error is shown subsequently.

The rainfall intensity formula for New York City, taken from the writer's charts,[16] and designed for durations of from 120 min to 4 days, is,

$$R_a = \frac{28\ F^{0.22}}{t^{0.75}} \qquad (9)$$

in which, F is the frequency, in years, and t, the duration of rainfall exceeding 1 hr, in minutes. To conform with Mr. Bleich's notation the writer's i is given as R_a, the average rainfall intensity, in inches per hour.

It should be noted that Equation (9) is developed through researches which have utilized the theory that a composite record of several stations within a limited area may be taken as a single-station record having a length equal to the sum of their station-years.

If the formula is modified by the inclusion of an additive factor in its denominator, it can be brought into a general form that expresses rainfall rate in terms of any duration, from 5 min to several days, and for any frequency. This factor seems to be a function of frequency, and expressing it thus, the formula for New York City becomes,

$$R_a = \frac{28\,F^{0.22}}{\left(t + \dfrac{9}{F^{0.20}}\right)^{0.75}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Fig. 7 is a comparison of the resulting curve-group and the plotted curves of Mr. Bleich's study.

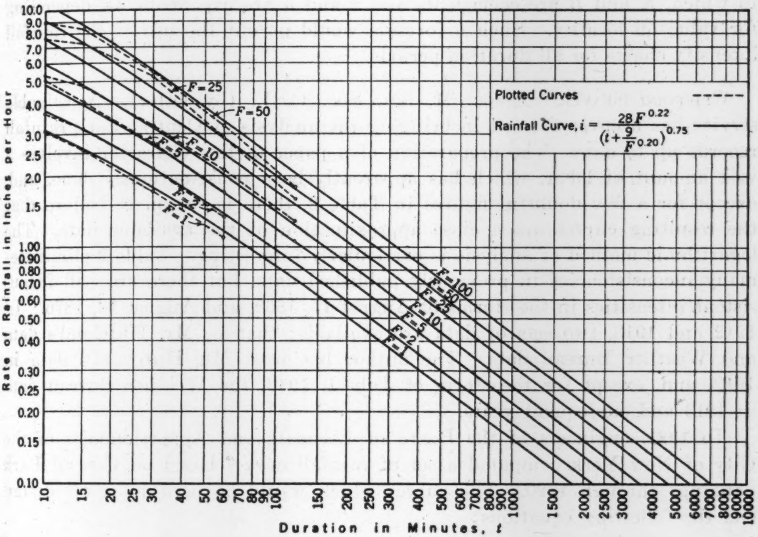

FIG. 7.

Table 11 gives the average deviation, in percentage, of the computed values from the observed values for the 1-year, 2-year, 5-year, and 10-year storms, and for durations of 5 to 120 min, for Mr. Bleich's modified exponential formulas, the writer's formula for New York City, and the Meyer formulas, in which the factors are given the average of the Group 2 and Group 3 values.[17]

TABLE 11.—COMPARISON OF AVERAGE DEVIATION FROM OBSERVED VALUES FOR THREE TYPES OF RAINFALL INTENSITY FORMULAS

Storm	AVERAGE DEVIATION FROM OBSERVED VALUES, PERCENTAGE		
	Author's modified exponential formulas	Equation (10)	Meyer's reciprocal formulas
1-year	1.50	3.39	7.26
2-year	2.27	2.21	7.03
5-year	1.49	1.51	4.07
10-year	2.29	5.79	3.40

---

[17] "Elements of Hydrology," Second Edition, p. 166.

The writer has sacrificed little in curve and point agreement to maintain the general form of his equation. A more general form suggesting itself is,

$$R_a = \frac{K\ F^x}{\left(t + \frac{B}{F^x}\right)^n} \quad \text{(11)}$$

in which, K and B are coefficients and x and n are exponents, all depending for value on locality. Such a formula would permit the use of the rainfall intensity charts for all duration periods.

CLIFFORD SEAVER,[18] ASSOC. M. AM. SOC. C. E. (by letter).—A valuable service has been performed in bringing the analysis of Central Park rainfall records up to date. The preparation of a paper of this character involves a vast amount of labor, which has apparently been conscientiously done, and, except for a few doubtful figures in Table 2, there is reason to believe that the resulting curves are a close approximation of the available data. The logarithmic method of analysis is particularly interesting. Table 2 eliminates many inconsistencies in previously published data, but there are still inconsistent intensities in the storms of August 15, 1869, and August 16, 1876. In 1912 and 1913, two sets of data are available; that is, Mr. Hufeland's data and Weather Bureau data. The author has used Mr. Hufeland's data in 1912, and, except for the storm of July 1, 1913, the Weather Bureau data in 1913 and subsequent years.

In 1921, engineers of the Board of Estimate and Apportionment of the City of New York computed a set of rainfall curves based on Central Park gaugings through 1920. The curves which would be used in sewer design had the following equations:

15-Year Storm:

$$R = \frac{47}{(t + 8)^{0.75}} \quad \text{(12)}$$

10-Year Storm:

$$R = \frac{43}{(t + 8)^{0.75}} \quad \text{(13)}$$

5-Year Storm:

$$R = \frac{25}{(t + 4)^{0.67}} \quad \text{(14)}$$

It was the intention to use the equation for the 15-year storm for the most highly developed areas, and those for the 10-year and 5-year storms for partly developed territory. The writer had no part in preparing these curves and does not know how much mathematical refinement was used in fitting them to the data, but it is interesting to note that Equations (12), (13), and (14) are of the "modified exponential type" (Equation (5)) found by the author to fit his data best.

---

[18] Asst. Engr., Board of Estimate and Apportionment, City of New York, New York, N. Y.

For a given frequency, the curves developed by the Board of Estimate and Apportionment are somewhat lighter than those proposed by the author, the Board's 10-year storm being approximately equal to the author's 5-year storm. This is due, primarily, to a different conception of frequency, rather than to any marked change in the data since 1920. The Board's engineers defined a 5-year storm as one which, over a 50-year period, would not be equalled during 40, or exceeded during 41, of those years. They placed no limits on the number or intensity of the cloudbursts that might be expected during the remaining nine years.

With this conception of frequency, it is a little difficult to define a 1-year storm, and, for this reason, the writer is inclined to favor the author's definition as being of more general application.

The use of a set of rainfall curves, each curve applicable to a different degree of development, never found much favor with the engineers of the Borough Sewer Bureaus. At the present time (1934), each Borough of the City of New York has its own rainfall curve, selected by its own engineers, and applicable to all parts of that Borough.

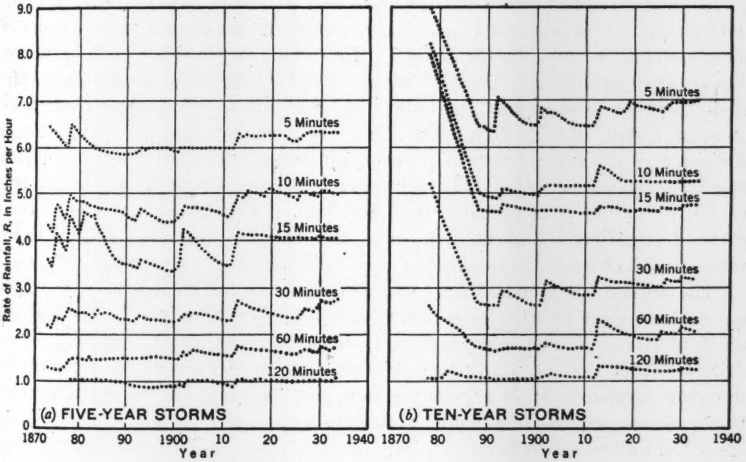

FIG. 8.—RAINFALL CURVES SHOWING YEARLY CHANGES IN DATA.

A fact sometimes forgotten by those using rainfall curves is that they are of a temporary nature and must be revised from time to time, if they are to remain reasonably accurate in view of all existing data. To illustrate this point, the writer has prepared two diagrams, which might be described as "life histories" of the author's 5 and 10-year rainfall curves. Fig. 8(*a*) shows yearly changes in the data for the author's 5-year storm, assuming them to be computed at the end of each calendar year, and Fig. 8(*b*) is the corresponding diagram for the 10-year storm; the curve labels are the durations.

During early years, the curves are affected by the shortness of the record and the unusually severe storm of 1878. Most of the curves reached their low point in the decade, 1890-1900, and, since then, have shown an irregular upward trend which may still be in progress, although the curves have been reasonably stable since 1913. If extended each year, a set of curves of this kind can be kept up to date with little labor, and will give prompt notice of any great changes in the data, which would require a revision of the rainfall curve.

In 1910, one would have said that a reliable 5-year rainfall curve could be obtained from a 42-year record; yet, if such a curve had been computed in that year, it would have been badly in need of revision by 1913, as changes in the data were nearly as great as the difference between the author's 5-year and 10-year curves. Fig. 8 shows that the author's curves, computed from the 1930 data, are still essentially correct, as changes in the data during the last three years have been small.

In his "Synopsis," the author recommends the modified exponential type of equation "for use in New York City, and, when properly adjusted as to values of coefficients, to other localities as well." If $e = 1$, in Equation (5), a "reciprocal" equation is obtained, and, if $d = 0$, the result is an "exponential" equation. Equations (1) and (3), therefore, are merely special cases of the general type embodied in Equation (5). Of course, this type of equation can be adapted to a considerable range of data, but there is nothing in Mr. Bleich's paper to show that the author has ever attempted to fit his equations to rainfall data outside New York City. It is conceivable that rainfall data for some cities might plot in a form similar to the data for the author's 25-year or 50-year storms. The equations for these storms do not fit the data very closely, and it is probable that, for data of this character, a more complicated equation would be required. Mr. Bleich's recommendation, therefore, should be accepted with some reservations.

The author has proposed a set of rainfall curves for New York City. It is not entirely clear whether he means Greater New York, or merely the Borough of Manhattan. If the former, there is some question whether rainfall curves deduced from Central Park records would not be too severe for some of the outlying sections. It is a peculiar fact, but local conditions seem to exist, that make some parts of the city wetter than others.

A Committee on Sewer Capacity, authorized by the Board of Estimate and Apportionment of the City of New York in 1932, secured rainfall records on an experimental area in the Borough of Brooklyn from 1925 to 1929 and on an area in the Borough of Manhattan from 1927 to 1931. Records were taken continuously from May to November of each year, using three rain-gauges on each area.

The Manhattan area is in the Grand Central section of the Borough, 1 mile south of Central Park, and extends from about the middle of the Island to the East River. The Brooklyn area is in the East New York section of the Borough, 7 miles southeast of the Manhattan area and 4½ miles from the East River. In studying the records obtained on the two areas, the writer was impressed by the relatively greater intensity of the storms gauged on the Manhattan area, and, to obtain some concrete evidence on this point, made two comparative tabulations.

TABLE 12.—COMPARISON OF AVERAGE RAINFALL INTENSITIES, IN INCHES PER HOUR

Year	Location	Number of storms	DURATION, IN MINUTES						
			5	10	15	20	30	60	120
			(*a*) BROOKLYN AND MANHATTAN EXPERIMENTAL AREAS						
1927........	Brooklyn...........	9	1.54	1.27	....	0.97	0.85	....	.....

Table 12(*a*) gives the average yearly intensities for different durations in periods when gauging was in progress on both areas. Besides storms gauged on both areas the table includes a number of storms local to Brooklyn and others local to Manhattan. The total number of storms (29) happens to be the same on each area, but the yearly distribution varies. Many light storms, which would have no bearing on sewer design, were not analyzed and, therefore, are not included in Table 12(*a*). The average intensities for the entire period show that, for durations up to 30 min, the Manhattan storms had nearly twice the intensity of the Brooklyn storms.

Table 12(*b*) gives the average yearly intensities for different durations of identical storms gauged at Central Park and at the Committee's Rain-Gauge No. 3—one of the Brooklyn gauges, located 8½ miles southeast of Central Park and 5 miles from the East River. Storms local to Brooklyn, or local to

Manhattan, are excluded, and Table 12(*b*), therefore, includes a considerable number of "easterly" storms, which were more likely to be gauged at both points. Table 12(*b*) includes the storm of September 6, 1926, which was of moderate intensity at Central Park, but at Gauge No. 3 was a phenomenal double-peaked storm, which, for the 120-min duration, exceeded anything ever gauged at Central Park. The 5-year averages show lighter Brooklyn intensities up to a duration of 30 min and nearly equal intensities for longer durations.

Table 12 indicates that rainfall curves for Manhattan, and for interior parts of Brooklyn, might have somewhat different shapes. The curves would be identical for the 60-min and 120-min durations, but the Brooklyn curve would have lighter intensities for the shorter durations. Of course, the table does not cover a long enough period to make the evidence of much value, but it is of some significance that, in Table 12(*a*), the lighter Brooklyn intensities are in evidence during each of the three years considered and for all four durations. The writer is willing to hazard a guess that the heavier Manhattan storms are caused by the proximity of the Hudson and East Rivers.

To summarize the viewpoint herein expressed: Rainfall curves with frequencies of from 1 year to 10 years, represented by the author's modified exponential equations, are endorsed as being close approximations of existing Central Park rainfall data. It should be recognized, however, that these curves are of a temporary nature and may need revision at any time.

Table 12 suggests that these curves may be too severe for the design of branch sewer systems in interior sections of the Borough of Brooklyn and similarly located territory in the Borough of Queens; but, unfortunately, there are no long-term rainfall records in this territory to form the basis for a rainfall curve. It is probable that branch sewer systems in this territory, designed by the author's curves, would have a large factor of safety.

While the modified exponential type of equation, doubtless, can be adapted to rainfall data in many cities, as previously stated there is nothing in the paper to show that it is of universal application. The writer has been helped in his study of this paper by the clear and concise manner in which the subject-matter has been presented.

JOSE GARCIA MONTES, JR.,[19] ESQ. (by letter).—The writer ventures to suggest that the part of Mr. Bleich's analysis, assuming formulas of the type of Equation (1), could have been improved by plotting on semi-hyperbolic paper.[20] When so plotted the data in Table 4, however, indicate that the intensities from different storms do not follow the law defined by Equation (1); nor, in fact, do corresponding intensities for a single storm follow that law. If there is any general law that applies to these data, the writer believes that it will conform more closely to a duration type of curve than to any other type so far proposed.

[20] *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 211.

The consolidation of records of different types of storms according to present general practice in analyzing frequency of rainfall intensities, and the practice of assuming intensities corresponding to different types, as homogeneous records, is not justified. From a practical standpoint when it is desired to determine exactly the frequency of occurrence of given intensities in different time elements, such consolidation may perhaps be permissible; but what the writer considers unjustified is the practice of representing the interrelationship of various factors by means of mathematical equations, because the best of mathematical formulas can be only gross averages of the actual relationship. The fact that data plotted on arithmetical paper appear to follow the equations that are actually assumed for the particular case, is due probably to the effect of averaging intensities from different records, many of which, individually, might conform to quite different types of curves.

Judged as an empirical equation, Mr. Bleich's formula should be valuable to engineers practicing in and around New York City, who can make use of the data in designing storm sewers more intelligently. Based on local records covering a period of 61 years, the application of such an analysis is certainly justified. Moreover, this record is now of sufficient length to permit a detailed analysis of original values to learn, if possible, the true laws that underlie rainfall duration relations, if such laws exist. The classification of these data according to types and an independent analysis of data that fall in each class may possibly disclose interesting truths that have universal significance.

In analyzing such data statistically, the fact that it is not homogeneous is important. The rainfall probabilities applying to short duration periods must not be studied in the same class as those segregated in longer time units. The two classes of data follow different laws, those for very short time periods tending to be more stable than those for longer periods. If frequencies of the different classes of data were approximately the same, there would be some justification for consolidating the records. The frequencies are not the same, however; for example, in tropical countries, the electric storm is by far the most frequent and, therefore, these control the data pertaining to storms of short duration.

Generally, storms are assumed to fall in two broad classes: (*a*) High-pressure storms including electric storms; and (*b*) cyclones. In the temperate zones the first type yields most of the high rainfall intensities—up to a duration of 2 hr. In the tropics, on the other hand, at least near the Caribbean Sea, the most severe storms are mostly hurricanes or storms in the cyclone class. The latter yield the highest intensities for any duration. If now a record containing both types of intense storms is consolidated, the extreme items, such as those occurring once or twice in 50 years, would be automatically weighted to appear in the same order as storms of 15-year or 20-year occurrence. In the tropics, electric storms of a genuine catastrophic nature occur as rarely as two or three times in 50 years, whereas hurricanes and cyclones occur on the average of eight to ten times in 50 years. Consequently, the intensities and the frequency of occurrence, as well as the duration of these two classes of storms, cannot very well be consolidated. They constitute heterogeneous data that should not be analyzed in one group.

While the writer is not familiar with conditions in the United States from personal experience, his studies lead him to believe that heterogeneity of data may influence the result of analyzing intensities from records that include severe electric storms as well as storms of a cyclonic nature. A multiple electric storm (that is, two or more storms in rapid succession, or that overlap each other), yields a rainfall intensity for periods of 3 hr, or more, that is not at all comparable, by means of probability analyses, with normal cyclonic storms analyzed in the same way. As in the case of comparing West Indian hurricanes with severe electric storms, the exceptionally severe rainfall that accompanies a cyclone is less than the total rainfall produced by a recurring electric storm of 2 to 6 hr duration. In the North, the cyclonic type of storm may yield severe rainfall intensities for periods greater than 6 or 8 hr.

It would appear, then, that rainfall durations between 5 min and 6 hr, and especially between 15 min and 6 hr, are markedly inconsistent when analyzed by probability methods and are even more inconsistent when analyzed mathematically, for the reason that the record contains data of basically different characteristics. A careful classification of the data according to the class in which it belongs will show the trend much clearer, but as yet no definite law can be stated with confidence. Probably some obscure disturbing factors affect the results. Statistical analysis of data carefully segregated for the purpose in view will probably yield the kind of information that can be generalized.

A detailed record of rainfall intensities covering a period of 61 years is unique. Some of the information possible to be gleaned from it, particularly that applicable to New York City, is ably described in this valuable paper by Mr. Bleich; but information of much greater importance can be gained by a thorough classification analysis. In its entirety, information available as to rainfall intensities is quite meager. It is judged that the City of New York can well afford such a detailed study, or at least the expense of publishing the complete data available to date, thus affording an opportunity for independent investigators to extend the analysis further. Other records are available in the United States, which cover periods of nearly 50 years, and a study of two such records, in conjunction with that of Central Park described in this paper, should prove extremely valuable in a correlation analysis.

Rainfall intensity is important to agriculture, as one of the underlying factors affecting water losses. It is also of major importance in determining the yield of water-sheds for water supply and irrigation. Because of the great labor involved in analyzing intensity data, few efforts have been made, except in the sewerage field. With the data now accummulated, it is time to stress the necessity of such analysis in other fields.

RHODES E. RULE,[21] ASSOC. M. AM. SOC. C. E. (by letter).—The results of an analysis of rainfall records are presented in this paper, in which empirical formulas are derived and compared with the results of a parallel study by the probability method. The author finds that the "modified exponential method gives results more in accord with the actual data than the probability method." He adopted the "Type III" curve for use in his application of the probability method, but does not state why it was used except that it "fits the data best". Since goodness of fit was the sole criterion, it should be noted that a better fitting curve could have been obtained by (1) grouping the data; (2) fitting a separate curve to each group; and (3) taking the summation of all such curves to make the final frequency curve. Such a method would be cumbersome, and perhaps difficult to defend on rational grounds but, neverthless, it would be the best fitting curve. Carrying the argument a step further the data could have been plotted in the histogram form, and the fit would be perfect. Does this demonstrate that the data in their unsmoothed form are better than any theoretical smoothing of them?

---

[21] Civ. Engr. (Rule & Rule), Los Angeles, Calif.

Of course, this is not true and the fallacy of the argument lies in the fact that goodness of fit is not the sole test. In the final analysis the propriety of using a given type of curve must rest on a rational demonstration that the data follow some law which is exemplified by curves of the type adopted. Unfortunately, such a demonstration has not been made for the several kinds of curves in use for estimating hydrologic frequencies.

The literature of the application of probability methods to engineering data is practically confined to demonstrations of mathematical methods of curve fitting. The philosophy of the subject has been neglected, and the mathematical nicety of the familiar methods of treating skew frequency curves has too often been mistaken for a soundness of reason for their application to the problems at hand.

That the Pearson curves are not very satisfactory for use in representing hydrologic probabilities is indicated by several systematic departures of the curves from the data. When the same order of departure recurs in a large majority of cases investigation into the underlying causes is indicated as desirable and use of the curves should be made only with full recognition of their shortcomings.

Probably the most important of these systematic departures, and the only one the writer will attempt to discuss, is that of the extremely high values. A considerable number of long-term rainfall and run-off records contain more extremely high values than are indicated as probable by Pearson curves fitted to the data. An example of this is seen in Fig. 5. The 10-min duration curve indicates that an intensity of 9 in. per hr should occur, theoretically, 0.45 times in 100 yr, or once in 220 yr, whereas the actual record was once in 62 yr. The 15-min duration curve shows an intensity of 8 in. per hr to have a theoretical frequency of about 0.55 times in 100 yr, or once in 180 yr. Actually, this intensity was reached twice in the 62-yr period, or once in 32 yr, almost six times the theoretical frequency.

This same kind of departure may be noted in many widely scattered records, strongly indicating that major storms are controlled by a law of their own. If this is the case, the data of hydrology are heterogeneous and do not lend themselves to treatment by Pearson's constructions which are limited by him to homogeneous material.[22]

Even if heterogeneous it might be possible to group such data into sets of essentially homogeneous material, each of which might be treated by probability methods. If entirely heterogeneous some such treatment as that favored by the author would seem to be the most satisfactory. To the extent that his method gives frequencies for the higher intensities more nearly approaching those of the record, it is certainly to be preferred over present probability methods in studies in which the extreme values are sought to be determined within safe limits.

The writer clings to the idea that data of this kind can be handled properly by probability methods, but evidence continues to accumulate to cast doubt on the accuracy of present methods. The author's paper is an addition to this evidence. Surely it would be carrying faith in a method to an extreme to accept a theory that the probable frequency of occurrence of an event is only once in 180 yr when the event has actually occurred twice in 62 yr.

The author deserves the thanks of the profession for an interesting and understandable presentation of a study which contains much valuable information.

S. D. BLEICH,[23] ESQ. (by letter).—The remarks by Mr. Sherman bring out the fact that considerable work could be done to advantage on rainfall studies. While hydrologists appreciate the importance of such work, it is impossible to convince municipal authorities of its desirability. The criticisms made by Mr. Sherman are discussed in the order presented by him:

(1) The published records of the U. S. Weather Bureau Station in Central Park, New York City, were used. The records of the U. S. Weather Bureau Station at Battery Place, New York City, were studied independently, but this work has not yet (1934) been completed. The separate records of the two stations were not compared with each other.

(2) The Weather Bureau publishes the maximum rates of precipitation for 5, 10, 15, 30, 60, and 120 min, and for 24 hr. In the design of sewers for which purpose the formulas were primarily computed, the first six periods mentioned are of importance. Periods longer than 2 hr would be useful for water-sheds considerably greater than those contributing to sewers in New York City. For such areas, other formulas have been devised.[24] It is believed that the formulas given are sufficient for the use of all periods between 5 and 120 min, inclusive, and it would probably be safe to extend them to periods slightly longer than 2 hr.

(3) As stated, the printed records of the Weather Bureau were used and compared with the printed records of the Committee on Rainfall and Run-

[24] "Formulas for Rainfall Intensities of Long Duration", by Merrill M. Bernard, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 592; as well as "Frequency and Intensity of Excessive Rainfalls at Boston, Massachusetts", by Charles W. Sherman, M. Am. Soc. C. E., *Loc. cit.*, Vol. 95 (1931), p. 951.

Off of the Municipal Engineers of the City of New York and with those collected by Mr. Hufeland, and only where discrepancies appeared were the original records consulted.

(4) All the formulas given in the paper are empirical and were designed to fit the given data as closely as possible with the form of equations used. Mathematical niceties and preconceived ideas of the values of the constants and exponents were avoided. The formula devised by Mr. Sherman, as well as the writer's unified Equation (8), may satisfy the æsthetic feeling, but would be difficult to justify logically. It is evident that, by not restricting the values of the constants, formulas would be obtained which will give results that correspond most nearly to the data, as is amply shown by the paper. It is for this reason that Equation (8) was not considered as good as the group of formulas given under Equation (5).

Rain storms are extremely complicated phenomena and are not of a single type. The conditions which are the principal underlying causes of rainfall intensities that occur as often as once a year probably differ from those causing the very severe intensities that occur only rarely, say, once in 15 yr, or in 50 yr. It is not to be expected that the same formula, or the same constants, will express all types of storms equally well.

(5) The rainfall records published in the *Journal* of the Municipal Engineers of the City of New York, as well as Mr. Hufeland's paper, were consulted, and were compared with the records of the U. S. Weather Bureau and only where there were discrepancies were the original records consulted.

(6) The formulas of the late Kenneth Allen, M. Am. Soc. C. E., were given careful consideration. They were designed in a different manner, however, from the writer's formulas; consequently, the results must be interpreted differently. For each duration Mr. Allen selected the heaviest rainfall that occurred in each year and neglected all the other intensities, even though some of them might be heavier than the severest rainfall intensity that occurred in other years. The results given by Mr. Allen's formulas[35] are described by him as giving "the probability percentage of years in which the given intensity of rainfall continuing over a given number of minutes will not be exceeded", whereas the writer's formulas, grouped together, give the frequency or the number of times in a given period of years that a rainfall intensity for a given duration, in minutes, has been equalled or exceeded.

Mr. Montes states that the storms embraced in the study are of a fixed character, some being due to one set of causes and others to entirely different causes. The writer admits his inability to segregate the storms in their proper classification so as to be able to treat each homogeneous set separately. Each kind of storm would probably have its own distinctive law and formula. The writer's problem has been a simpler one, namely, to obtain, as accurately as possible, the aggregate frequency of rain intensities for different durations for all types of storms.

Mr. Montes' discussion is very instructive and brings out important facts which are likely to be forgotten while the investigator is absorbed with the arduous calculations. The study deserves the time and efforts of a few qualified hydrologists, and large cities would find the expense for conducting this research comparatively small and the results very profitable in planning municipal improvements.

---

[35] *Engineering News-Record,* April 7, 1921, p. 588.

Use of the duration type of curve was attempted, as illustrated in the paper, but the result was not altogether satisfactory. Mathematical formulas corresponding to such curves are quite unwieldy.

Professor Slade appears to be of the opinion that the probability method is the proper one for handling rainfall data. The difficulty with the method is that it cannot be justified rationally, particularly when a different coefficient of skew is used for each of the durations.

While it is ingenious, the probability method seems to be artificial and has only the appearance of mathematical logic. To use the values obtained by the skew probability method rather than the actual data in computing the modified exponential formula would result in values that would depart materially from the recorded values which no amount of mathematics could justify. If the physical laws were known, only then would there be good reason for using whatever calculations are necessary with the recorded data in order to obtain the numerical values for the constants in the formula which expresses the physical laws.

In Equation (11) Mr. Bernard presents a uniform expression embracing rainfall intensity, duration, and frequency, which probably could be made to fit the recorded data better than the writer's unified Equation (8), as the former contains five parameters which are to be determined, and the latter only four. For this very reason and also because of the expression proposed for the formula, it would be very laborious to obtain the values of the five parameters which would give results corresponding closely to the given data.

Mr. Seaver has taken considerable pains to check Table 2 giving the chronological records of heavy rainfall intensities at the Central Park gauge, in New York City. He has also made instructive studies which clearly indicate that the results given by rainfall formulas will vary with the number of years of observations, thereby giving rise to the conjecture that the present results may not be final, but will have to be modified with the accumulation of additional data in the future. This is probably true, but, in view of the long period already covered by the Central Park gauge, it is not probable that the results will be varied materially by subsequent studies.

By means of Table 12, Mr. Seaver demonstrates clearly that two locations, only a few miles apart, may have materially different characteristics of rainfall intensities. While only a few years are covered by this comparison, it is probable that extended studies will confirm the truth of this finding. It is important that definite knowledge of this variation be obtained, which can only be accomplished by locating a large number of rain-gauges at several points in each of the Boroughs of Greater New York City, to be accompanied by an exhaustive study of all the records, in order to learn the specific rainfall intensities and frequencies for each location. This would enable sewers to be designed so as to serve properly the areas where they are built, resulting in adequate drainage facilities without waste and in economy of construction which would more than offset the cost of such extended investigation.

FLEXIBLE "FIRST-STORY" CONSTRUCTION FOR EARTHQUAKE RESISTANCE

By Norman B. Green,[1] Esq.

With Discussion by Messrs. Lee H. Johnson, Edward J. Bednarski, Merit P. White and Paul L. Kartzke, Howard G. Smits, H. A. Williams, and Norman B. Green.

Synopsis

A method of analyzing multiple-story, steel-frame buildings to resist earthquakes, is presented in this paper. The theory is based on a flexible first story, without attempting to draw definite conclusions regarding the relative practicability of this type of construction. The conclusions to be drawn from the evidence presented are summarized at the end of the paper.

The problem of constructing high buildings of twenty or thirty stories so that they shall be capable of resisting earthquakes, has brought forth the suggestion that they be provided with a flexible story, upon which the structure shall swing. The original idea was that the earth motion would be absorbed in this flexible story, so that the upper part of the building need not be designed to resist a lateral earthquake force. Actually, such a structure is an elastic vibrating system and its maximum lateral deflection must be determined. Many high buildings on the Pacific Coast are stated to be of this flexible construction. However, no one knows how they will actually behave during an earthquake, since with one or two exceptions no attempt has been made at a dynamic design. In the exceptional cases, recourse was had to a dynamic model tested on the shaking-table. If this type of construction is to be of practical value, it is imperative that some convenient design method be developed, since every engineer does not have access to a shaking-table and, moreover, the experimental method is both costly and time-consuming.

Note.—Published in February, 1934, *Proceedings*.

[1] Structural Engr., San Francisco, Calif.

On a first approach to the problem it would appear that, by reason of the great irregularity of the earth motion (which is demonstrated by nearly any seismograph record), a mathematical solution is impossible. The designer, however, is not concerned with this motion of the earth as recorded by a seismograph, but he is interested in the acceleration and period of acceleration (that is, the time interval between two maxima of acceleration), since it is this change of velocity that provides the impulse to deflect an engineering structure and to set it in vibration. It is only recently that instruments have been available for measuring this acceleration, and an examination of the few available records of this kind taken during an earthquake show clearly that an accelerograph gives a much more regular swing than a seismograph recording the same earthquake. This regularity of swing and the fact of a nearly constant period of acceleration, can be best demonstrated by an examination of the accelerogram shown in Fig. 1, which is

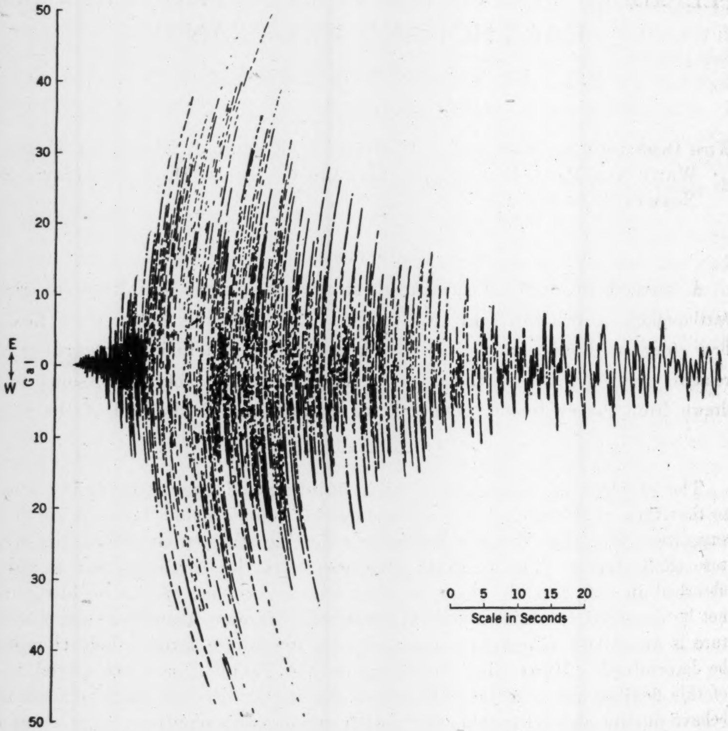

FIG. 1.—ACCELEROGRAM OF SEMI-DESTRUCTIVE EARTHQUAKE, SEPTEMBER 21, 1931, NORTHWEST OF TOKYO, JAPAN.

the record of a semi-destructive earthquake that occurred near Tokyo, Japan, in September, 1931.

The late Dr. K. Suyehiro concluded[3] that in all earthquakes the period of acceleration in a particular locality is confined within a very narrow range and that the motions of an earthquake that cause the predominant accelerations are due to the habitual motions peculiar to the ground. It was found that the prevailing periods for earthquakes in Japan were generally from 0.7 to 0.9 sec on alluvial ground and from 0.3 to 0.4 sec on well-consolidated ground.

A further examination of Fig. 1 will show that the acceleration varies directly with the time. This fact is particularly apparent in the right-hand part of the diagram. It is also apparent that the maximum acceleration is by no means uniform, since a full swing may be followed immediately by a much shorter swing, or by one that is unbalanced; in fact, any combination seems to be possible.

With these facts established, it is feasible to construct an artificial acceleration diagram and to compute what effect the corresponding earth motion will have upon the relatively simple type of elastic structure, as represented by a building with a flexible base. In order that the method shall be general in its application, it must embrace the case of an irregularly varying maximum acceleration as well as the possibility of a varying period of acceleration. This requirement necessitates that the equations of motion be written separately for each swing and that they be solved successively, using the terminal velocity and deflection for one swing as the initial ones for the succeeding swing. This is the method that will now be developed. It may be visualized as a kind of mathematical shaking-table, in which the artificial acceleration diagram has its counterpart in the cam, which is cut so as to impart to the table a motion that simulates a given earthquake.

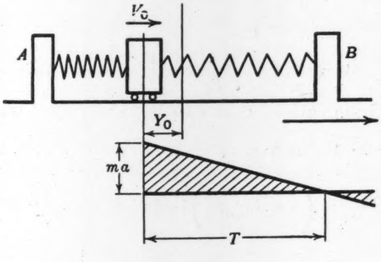

FIG. 2.

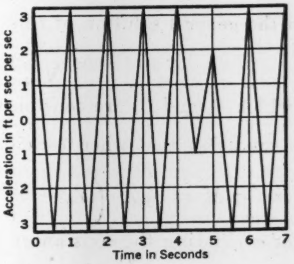

FIG. 3.—ACCELERATION DIAGRAM.

Consider a weight that rests upon rollers and is connected by two springs to Supports *A* and *B*, as indicated in Fig. 2. Assume that this weight is given an initial deflection, Y_0, and velocity, V_0, and that the axis of coordinates is taken through the position of static equilibrium. Assume furthermore that Supports *A* and *B* are accelerated toward the right, starting with an acceleration, a, which decreases as the ordinate of a straight line, to a zero acceleration at the expiration of a time, T, and continues a negative acceleration, as indicated in the lower diagram of Fig. 2. The ensuing motion of the supports, A and B, represents one swing of the artificial earthquake, and the motion of the weight can be determined, using the following notation:

---

[3] *Proceedings*, Am. Soc. C. E., May, 1932, Part 2.

W = weight of vibrating body, in pounds;
g = acceleration of gravity = 32.2 ft per sec per sec;
m = mass of vibrating body = $\frac{W}{g}$
a = initial acceleration of ground at the beginning of the swing, in feet per second per second;
e = elastic constant of vibrating system = $\frac{\text{Lateral force}}{\text{Deflection}}$;
t = independent variable, time, in seconds;
T = elapsed time from initial ground acceleration to zero acceleration;
y = deflection of the body from its position at rest, in feet;
Y_0 = initial deflection at $t = 0$;
V_0 = initial velocity at $t = 0$, in feet per second;
f = maximum deflection during one swing;
t_m = elapsed time from $t = 0$ to the maximum deflection;
v = velocity at any time, t;
v_n = velocity at the end of the nth swing;
y_n = deflection at the end of the nth swing; and,
t_n = elapsed time from the beginning to the end of the nth swing.

If positive forces, deflections, accelerations, and velocities are each taken in the direction of the initial force, $m\,a$, the differential equation of motion is expressed as:

$$m\,\frac{d^2y}{dt^2} = m\,a\left(1 - \frac{t}{T}\right) - e\,y \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and the general solution of this linear equation is:

$$y = C_1 \cos \sqrt{\frac{e}{m}}\,t + C_2 \sin \sqrt{\frac{e}{m}}\,t - \frac{m\,a t}{Te} + \frac{m\,a}{e} \quad \ldots\ldots\ldots\ldots (2)$$

in which C_1 and C_2 are constants of integration, that can be determined from the condition that when $t = 0$, $\frac{dy}{dt} = V_0$ and $y = Y_0$. For simplicity, let $A = \frac{e}{m}$; $M = \sqrt{A}\left(Y_0 - \frac{m\,a}{e}\right)$; $N = \left(V_0 + \frac{m\,a}{T\,e}\right)$; and $P = \frac{m\,a}{T\,e}$; then, after evaluating the constants:

$$y = \frac{M}{\sqrt{A}} \cos \sqrt{A}\,t + \frac{N}{\sqrt{A}} \sin \sqrt{A}\,t - P\,(t - T) \quad \ldots\ldots\ldots (3)$$

and by differentiating again;

$$\frac{dy}{dt} = v = -M \sin \sqrt{A}\,t + N \cos \sqrt{A}\,t - P \quad \ldots\ldots\ldots\ldots (4)$$

The value of t_m may be obtained by setting Equation (4) equal to zero and solving for t, whence:

$$t_m = \frac{1}{\sqrt{A}} \tan^{-1}\left(\frac{M\,N \pm P\sqrt{N^2 + M^2 - P^2}}{M^2 - P^2}\right) \quad \ldots\ldots\ldots\ldots (5)$$

and if the quantity in the parenthesis is set equal to k:

$$t_m = \frac{1}{\sqrt{A}} \tan^{-1} k \qquad (6)$$

The maximum deflection is obtained by substituting the value, t_m, into Equation (3), whence:

$$f = \frac{M}{\sqrt{A}} \cos(\tan^{-1} k) + \frac{N}{\sqrt{A}} \sin(\tan^{-1} k) - \frac{P}{\sqrt{A}} (\tan^{-1} k) + PT \qquad (7)$$

As a special case of Equation (3), suppose that $a = 0$ and $V_0 = 0$, in which case this equation reduces to:

$$y = Y_0 \cos \sqrt{A}\, t \qquad (8)$$

which represents simple harmonic motion. By equating the first derivative to zero and solving for t:

$$t = 2\pi \sqrt{\frac{m}{e}} \qquad (9)$$

which is the period of free vibration of the structure.

As another special case let T equal infinity, which simply means that the acceleration, a, is constant and that Equation (7) then reduces to:

$$f = -\frac{m\,a}{e} (\cos \tan^{-1} 0 - 1) = -\frac{m\,a}{e} (\pm\ 1 - 1) \qquad (10)$$

The minus sign must be used to get the maximum deflection, since the plus sign gives $f = 0$, which is the minimum deflection. Therefore:

$$f = \frac{2\,m\,a}{e} \qquad (11)$$

but $\frac{m\,a}{e}$ represents the static deflection produced by a constant acceleration, a, and it is apparent, therefore, that with a suddenly applied acceleration which is in the nature of an impact, the maximum deflection produced is twice the static deflection. In order that this deflection can be developed, however, it is necessary that the earth motion be of sufficient duration in one direction; but since the effect is entirely independent of the stiffness of the structure (that is, of the value of e), a very stiff structure would require a very short motion. While the earthquake acceleration, of course, is not uniform, it may be considered so for a very short period of time or when the swing is very long.

A glance at Fig. 1 will show that the assumption of an instantly applied acceleration may not be so far from the truth, since the accelerogram starts its major motion with a long swing. This same abrupt start of the major motion is indicated very clearly on many seismograms. To illustrate the sudden start of a violent earthquake in the epicentral region, Dr. Suyehiro gives the evidence of an eye-witness that copper coins in a tin can with a lid, threw off the lid and leaped out, leaving the can standing, at the instant the earthquake began. This effect would require a downward acceleration greater than gravity, with a motion of several inches of amplitude.

The evidence of eye-witnesses to the Long Beach, Calif., earthquake in 1933 also describes a very abrupt beginning of the primary shock. An examination of the California Garage, in Long Beach, which is a three-story reinforced concrete structure, gives clear evidence that the shock began as a sudden jolt or jerk toward the southeast. The columns were shattered at the top in compression on the southeast side, with a corresponding tension crack near the floor on the same side. On the opposite side there was a slight spalling at the floor line and a tension crack near the ceiling. In other words, this injury indicates destructive deformation in one direction only, which may be attributed to a heavy impact effect in the direction of the first swing.

It has been assumed in the foregoing analysis that the entire vibrating mass is concentrated at the point of elastic support, and that the mass is rigid. As regards the first of these assumptions, it is true that the mass of the building structure towers far above the base columns; however, the only uncertainty that this fact introduces, arises from the added horizontal motion that the upper part of the structure may sustain, due to tipping as a unit on the base columns. Calculation shows that for the building presently to be described, this horizontal motion of the top, due to direct column stress, is only about 2% that due to column flexure. The second assumption cannot be true, of course, for an actual building; however, it is the relative stiffness that is of importance and the upper part of the structure can be made very rigid relative to the base, by the use of concrete bracing walls or some other equally efficient construction.

By the use of Equations (3), (4), (6), and (7), the motion of the elastic structure can be completely determined for any number of swings and for any variation of the maximum acceleration and the period of acceleration. For the first swing, Y_0 and V_0 are zero and, having determined the values of Y_1 and V_1, these are used with reversed sign as Y_0 and V_0 for the second swing; the process being repeated indefinitely. This step-by-step solution presents a clear picture of what is happening to the structure and enables the designer to vary the nature of the earth motion as the computations progress, so as to subject the structure to the most unfavorable conditions. These computations may be carried out on a 10-in. slide-rule, but this should be carefully read to at least three significant figures, and four where possible, since the results involve small differences. It is necessary to work accurately, as the results for a given swing affect all succeeding swings.

The computation of f is rather laborious, but it need only be computed for those swings in which y_n is large, since one of these swings will contain the greatest deflection of the entire series. In this connection, it should also be noted that when y_n and v_n are of the same sign, y_n is actually the greatest deflection in that swing, since in this case t_m will be found to be greater than t_n, which simply means that the computed value of f occurs outside the range of the swing. The positive value of k should be used, care being exercised to select that value which gives the maximum deflection within the assumed range of the swing.

The design of the base columns, as well as the determination of their lateral deflection, requires the use of a formula for combined direct stress and bending since, with the large deflections attained, the eccentric moment is of great importance. For the case of a column fixed at the upper end and hinged at the base, the deflection, d, may be expressed as:

$$d = \frac{P}{W}\left(\frac{\tan a\,L}{a} - L\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

in which, L is the length of the column that carries a direct load, W, and a lateral load, P, and $a = \sqrt{\frac{W}{E\,I}}$, in which, E and I are the modulus of elasticity and the moment of inertia, respectively. The value of d in Equation (12) is used in computing the stiffness factor and may also be used to compute the maximum column stress, S, from the familiar relation:

$$S = \frac{W}{A} + \frac{(PL + Wd)\,c}{l} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

in which, A is the area of the column section, and c is the distance from the neutral axis to the extreme fiber.

It should be noted that the column deflection from Equation (12), is a function of the load on the column; but it is also directly proportional to the lateral force, P, so that e is a constant as has been assumed in the analysis.

Application of the Analysis

As an example of the method of computation, consider the case of a 20-story steel-frame building of the office type, with four 20-ft panels in one side and eight 18-ft panels along the other side. Suppose that the story height is 12 ft, except for the first story which has been taken as 24 ft. For a building of this type the weight per cubic foot will be about 17 lb when a 24-lb live load is included, and 15 lb when the live load is neglected. The former value has been used in designing the columns for vertical load, while in computing the mass of the structure the latter value has been used. The first-story columns are assumed as hinged at the base and with hinged second-floor beam connections, in order to increase their flexibility. These columns are designed to resist a wind pressure of 20 lb, with an over-stress of 50%, in which case the lateral deflection from Equation (12) is 0.194 ft and, using this deflection value, the stiffness factor, e, is 3 760 000 and the period of vibration from Equation (9) is 3.58 sec.

The acceleration diagram of Fig. 3 has been constructed, assuming a constant period of 1 sec and a maximum acceleration of 3.2 ft per sec per sec. This diagram represents a total elapsed time of 7.0 sec and contains seven complete vibrations or impulse cycles. It has been constructed so as to produce unfavorable conditions of deflection, but, nevertheless, it is believed to represent a perfectly possible situation.

Computations for this set of conditions are shown in Table 1. It will be noted that the maximum deflection of 0.445 ft occurs in the fourteenth swing, and if this is compared with the maximum allowable deflection of 0.194, the columns are over-stressed by more than 100 per cent.

TABLE 1.—COMPUTATIONS

CONCLUSIONS

In this paper the purpose is simply to present the method of analysis, and no effort has been made to draw definite conclusions regarding the practicability of the flexible-base type of building construction. Certain tentative conclusions may be drawn, however, from the preceding computations and from similar computations that have been made for other sets of conditions. These may be summarized briefly as follows:

1.—The period of acceleration is as important as the acceleration itself, in its effect on the deflection of the structure. A period of 0.7 sec instead of 1.0 sec, cuts the deflections roughly in half.

2.—The impact effect of an acceleration suddenly applied to a flexible structure of this type has little or no effect on the deflection.

3.—An irregular swing gives greater deflections than a uniform and rhythmic swing, and within the range of probable maximum periods of acceleration there is no evidence of resonance if the free period of vibration of the structure is kept above 2.0 or 2.5 sec.

4.—The maximum deflection produced in a structure by a given ground motion, is not much affected by considerable changes in the period of free vibration of the structure. For this reason, the best measure of the earthquake-resistant qualities of a given building of this type is simply the maximum horizontal deflection that it can sustain without exceeding allowable stresses in the columns.

5.—It is likely to be found difficult to provide sufficient lateral flexibility in this type of structure if the most unfavorable period and other conditions of acceleration are assumed. Long base columns will have to be provided, probably with some form of hinged base, in which case the steel that must be added in these columns and in the restraining beams to which they frame at their top, in order to provide a reasonable resistance to wind pressure, will be found to be a large and important item.

DISCUSSION

LEE H. JOHNSON,[3] ESQ. (by letter).—This is a helpful and thought-provoking paper on a subject of some controversy among structural engineers to-day. It is gratifying to note that the author points out that, in determining the effects of a vibration on a structure, the period of the acceleration is just as important as the acceleration itself. It should be emphasized even more strongly that the effects of a vibratory phenomenon, upon any object cannot be determined by considering only the acceleration. This fact seems to have been obscured by an imperfect understanding of the relation between acceleration, frequency, and amplitude of a vibration. Considering the simplest of periodic motions, a simple harmonic motion of the form,

$$y = D \sin \omega t \text{ .... } (14)$$

in which, D = maximum amplitude of vibration, and ω = a constant angular velocity $= 2 \pi F$, in which F = frequency by vibration. The acceleration is given by,

$$\frac{d^2y}{d\,t^2} = - D\,\omega^2 \sin \omega\,t = - D\,F^2\,4\,\pi^2 \sin \omega\,t \text{ .... } (15)$$

from which it is seen that the acceleration is a function of the amplitude, D, times the square of the frequency, F, and that it is, therefore, dependent upon both quantities. It follows from this that the acceleration varies as $D\,F^2$, and that two vibrations, differing widely in character and in their effect on a structure, may yet have the same acceleration. A vibration with a very high frequency and infinitesimal amplitude can perfectly well have the same acceleration as a vibration of relatively low frequency and appreciable amplitude, the product, $D\,F^2$, being the same in each case. However, the effect of a vibration of the former type on a building will, ordinarily, be negligible, while the effect of a vibration of the latter type, such as an earthquake, can be disastrous. If the frequency decreases still more to infinitesimal proportions and the amplitude becomes very great, the acceleration still remaining unchanged, a building would probably suffer no ill effects, although it would be moved a considerable distance from its position of rest. Apparently, this last case does not occur in practice.

Hence, it is necessary to know at least two of these quantities, acceleration, frequency, and amplitude, not only in order to find the effect of a vibration on a structure, but, what is still more fundamental, in order to describe the nature of the vibration itself. Although such a simple relation between these quantities, as the preceding, may not exist in the case of more complex, non-harmonic vibrations, still the quantities are related and are not independent.

The author's mathematical analysis calls for some remarks. To understand these it is well to have the fundamental concepts clearly in mind. A simple harmonic motion of amplitude, D, and frequency, F, may be represented by the motion of the projection upon a fixed line of a vector of magnitude, D, rotating at constant angular velocity, as shown in Fig. 4. In this case, $y = D \cos \omega t$.

---

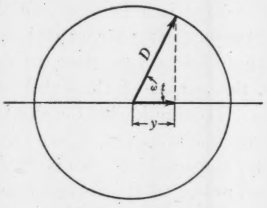

FIG. 4.

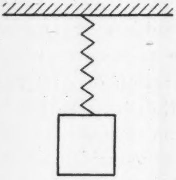

FIG. 5.

Examples of systems that give simple harmonic motion are a mass suspended on a perfectly elastic spring attached to a rigid support (Fig. 5) and a mass resting on frictionless rollers between perfectly elastic springs attached to rigid supports (Fig. 6). The masses are assumed to be non-elastic and the springs are assumed to be weightless.

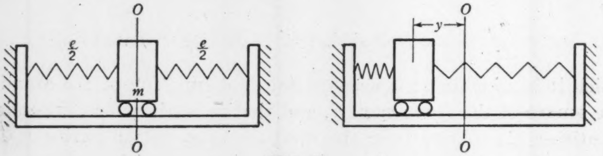

FIG. 6.

The author uses a system of the type shown in Fig. 6 as being analogous to a building supported on flexible columns with its upper stories constituting a rigid mass. The columns act as springs between the mass and the ground. Considering this system, the differential equation for the motion of the mass, m, is:

$$m \frac{d^2 y}{d t^2} = - e y \qquad (16)$$

which means that at any instant the inertia force of the mass must be equal and opposite to the restoring force of the springs, an application of one of the basic laws of dynamic equilibrium. Writing the equation in the form:

$$\frac{d^2 y}{d t^2} = - \frac{e}{m} y \qquad (17)$$

is equivalent to stating, simply, that the second derivative of a function is proportional to the function itself, and since sine and cosine functions are of this type, a solution may be assumed, of the form, $y = B_1 \cos \omega t + B_2 \sin \omega t$, in which, B_1, B_2, and ω are unknown. Substituting this in the differential Equation (17):

$$-B_1 \omega^2 \cos \omega t - B_2 \omega^2 \sin \omega t = - \frac{e}{m} (B_1 \cos \omega t + B_2 \sin \omega t)$$

whence, $\omega^2 = \frac{e}{m}$, $\omega = \sqrt{\frac{e}{m}}$, and $F = \frac{1}{2\,\pi}\sqrt{\frac{e}{m}}$, and the solution becomes:

$$y = B_1 \cos \sqrt{\frac{e}{m}}\, t + B_2 \sin \sqrt{\frac{e}{m}}\, t \;\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

The constants, B_1 and B_2, are determined from the initial conditions of the problem considered. For example, if at the start of the vibration when $t = 0$, the initial amplitude and velocity are given as $y = y_0$, and $\frac{dy}{dt} = 0$ then, substituting for $t = 0$ in Equation (18): $y_0 = B_1 \times 1 + B_2 \times 0$, whence, $B_1 = y_0$. Now,

$$\frac{d\,y}{d\,t} = -\,B_1 \sqrt{\frac{e}{m}} \sin \sqrt{\frac{e}{m}}\, t + B_2 \sqrt{\frac{e}{m}} \cos \sqrt{\frac{e}{m}}\, t$$

and, for $t = 0, 0 = -B_1 \sqrt{\frac{e}{m}} \times 0 + B_2 \sqrt{\frac{e}{m}} \times 1$; whence, $B_2 = 0$. The final solution for this case is, therefore,

$$y = y_0 \cos \sqrt{\frac{e}{m}}\, t \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

This is a simple harmonic motion of amplitude, y_0, and frequency, $\frac{1}{2\,\pi}\sqrt{\frac{e}{m}}$.

Next consider the case in which the supports are not fixed but execute a definite motion of their own, say, $x = x_0 \sin \omega t$ (see Fig. 7). Writing the differential equation of motion of the mass with respect to its position of rest:

$$m\,\frac{d^2y}{d\,t^2} = -\,e\,(y + x) \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

However, the author seems to be interested primarily in the relative deflection of the top and bottom of the first-story columns in a building undergoing vibration which, in his mass and spring analogy, corresponds to the deflection of the mass from the moving support, rather than to the deflection from the position of rest. To find the relative motion of the mass with respect to the moving support it is seen from Fig. 7 that the movement relative to the support is $y + x$. Designating this motion by z: $z = y + x$, or $y = z - x$.

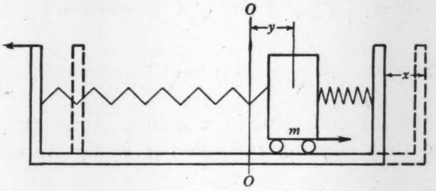

FIG. 7.

Substituting for y in Equation (20): $\frac{m\,d^2\,(z - x)}{d\,t^2} = -\,e\,z$, or,

$$m \frac{d^2 z}{d t^2} = m \frac{d^2 x}{d t^2} - e z \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(21)$$

which is the differential equation for the relative motion between the mass and the support. This corresponds to Equation (1) of the author's paper, except that where, in Equation (21), $\frac{d^2 x}{d t^2} = - x_0 \, \omega^2 \sin \omega t$, he has chosen a function, $\frac{d^2 x}{d t^2} = a \left(1 = \frac{t}{T}\right)$, apparently representing the acceleration of an earthquake more closely than simple harmonic motion. The author's notation for y seems to be at fault. As the writer has shown, Equation (1) gives the motion of the mass relative to the support, which is what the author desires; but y in Equation (1), corresponding to z in the writer's Equation (21), is defined to be the deflection from the position of rest, instead of the relative deflection from the support.

It is to be noted that the natural frequency, or frequency of free vibration, of the system is obtained directly in solving the differential equation of motion and is, for the case considered, $F = \frac{1}{2\pi} \sqrt{\frac{e}{m}} = \frac{1}{2\pi} \sqrt{A}$, using the author's notation for A. The period of free vibration is simply, $T = \frac{1}{F} = 2\pi \sqrt{\frac{m}{e}} = 2\pi \frac{1}{\sqrt{A}}$.

It is not clear what the author had in mind in differentiating Equation (8) of his paper, and in setting the first derivative equal to zero in order to get the period of free vibration. From what has been shown herein, ω, corresponding to $\sqrt{A}$ in the author's Equation (8), is determined directly in solving the differential equation; and T is derived from the fundamental relations, $\omega = 2\pi F$ and $T = \frac{1}{F} = \frac{2\pi}{\omega}$.

Differentiating Equation (8), setting the resultant equation equal to zero, and solving for t, merely gives those values of t for which the velocity of the mass is zero: $\frac{dy}{dt} = 0 = - Y_0 \sqrt{A} \sin \sqrt{A}\, t$, whence, t must be such that $\sin \sqrt{A}\, t = 0$. Therefore, $t = \frac{n\pi}{\sqrt{A}} = n\pi \sqrt{\frac{m}{e}}$, in which, $n = 0, 1, 2, 3$, etc., since the sine of any integral value of π is zero. It is true that the natural period will be the time elapsing between two successive zero points of the velocity; that is, $T = 2\pi \sqrt{\frac{m}{e}}$, but the same would be true for zero points of the amplitude, and it is unnecessary to differentiate at all.

The author's conclusion that the maximum deflection produced in a structure by a given ground motion is not much affected by considerable changes in the period of free vibration of the structure is true only if the range of the periods of free vibration is sufficiently far above the period of the ground motion to avoid all possibilities of resonance.

Until more has been learned about the dynamics of building frames, the writer feels that the assumption that the upper stories of a building with flexible first-story columns constitute a rigid mass is a doubtful one. Simple tests made by the writer on models of various story heights show that the elasticity of the upper stories has a decided effect on the periods of free vibration, as is to be expected from purely theoretical considerations, even when the first-story columns are very flexible with respect to the upper story columns.

The writer believes that Mr. Green should be commended for presenting a method for finding the effect of any arbitrary non-harmonic vibration upon an idealized flexible building. To date, chiefly simple harmonic motions have been used in practical calculations on structures.

EDWARD J. BEDNARSKI,[4] ASSOC. M. AM. SOC. C. E. (by letter).—The author has raised an important question in the analysis of structures, namely, the influence of the connection between the structure and the foundation. He could have chosen several hypothetical variations of Fig. 2 to analyze a structure as, for example, a fixed connection resisting the forces acting in any direction and any moment created by these forces; a hinged connection that can not resist the moment and can take only the forces passing through the center of the hinge; and a connection on rollers or balls that may resist any moment, but takes only the forces directed normal to the plane of rolling.

In the case analyzed in the paper the connection is assumed of this latter type with elastic buffers preventing the structure from being carried away under occasional lateral pressure (see Fig. 2). The author could also have used the arrangement shown in Fig. 8, in which elastic springs are replaced by hydraulic "buffers" interconnected by a pipe and a dash-pot arrangement. This may be considered as an aperiodic connection if elastic expansion of the pipes and the cylinders is assumed to be negligible. Of course, an absolutely elastic or absolutely aperiodic arrangement does not exist.

Connections of this kind may be likened to electric transformers in which the primary and secondary coils are connected with different degrees of looseness, in an electrical sense. In a very loose connection, this transformer will oscillate only at a certain specific frequency; that is, the natural frequency of the coupled circuit. No other frequency would create an oscillatory current.

Theoretically, a structure resting on balls or rollers, devoid of friction, does not re-act to the vibratory movement of an earthquake in a horizontal plane. In practice, however, there may be a possibility of strains due to transferred vibrations. The more flexible the first story of the structure the less will be the lateral forces imparted to it; and the less elastic its connection with the foundation, the less will be the danger of resonant vibrations being set up in it.

---

[4] Structural Engr., San Francisco, Calif.

A connection between the structure and the foundation can not be made plastic and flexible by introducing comparatively slender columns in the first story. The use of a material with a very small elastic modulus and a relatively great plasticity between the structure and the foundation may serve the purpose in a practical sense, if the total shear resistance of the insulating material is great enough to prevent the structure from being moved by the wind pressure. The value of such shear resistance is the critical, maximum, lateral force that could ever be imparted to the structure by the earthquake without the occurrence of resonance in the horizontal plane. Common examples that illustrate this point are the old trick of snatching a napkin from beneath a number of full tumblers without spilling the contents, and the bullet passing through a pane of glass, making a clean round hole in it. The success of the tricks depends entirely on the velocity of movement, on the friction between the napkin and the tumblers, and on the shearing resistance of glass.

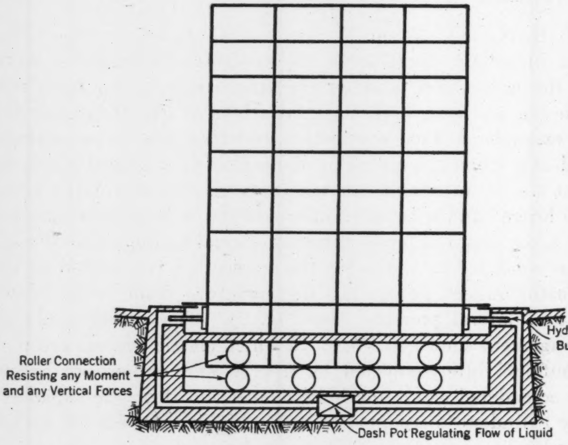

FIG. 8.

In his study[5] of the theory of sound, Sir John Rayleigh introduces quite an extensive analysis to determine the natural period of vibration for a single bar, fixed at one end and free at the other. In his investigation, Mr. Green introduces a formula for the period of vibration of a structure consisting of many bars, connected in many different ways, and supported by a system of columns, hinged at one end and fixed elastically at the other. In the light of this comparison, the formula offered in this paper seems too simple to be true. For one thing, the author has ignored the questions of modes of vibration, the time elapsed between complete rest and maximum acceleration, and internal friction.

---

[5] "The Theory of Sound," by John William Strutt Rayleigh, Second Edition, 1894–96. Vol. I, pp. 255–305.

Equation (1) is the well-known differential equation of forced oscillatory motion, with $m\,a\left(1 - \frac{t}{T}\right)$ substituted for $F \cos n\,t$, in which, F is an external oscillatory force corresponding to $m\,a$. For a constant amplitude this movement may be expressed as:

$$\frac{8\,m\,a}{\pi^2}\left\{\cos(n\,t) + \frac{1}{3^2}\cos(3\,n\,t) + \frac{1}{5^2}\cos(5\,n\,t) + \ldots + \frac{1}{(2\,q+1)^2}\cos\left[(2\,q+1)\,n\,t\right]\right\} \ldots\ldots\ldots\ldots (22)$$

in which, $n = \frac{2\,\pi}{4\,T}$ and q approaches ∞, $2\,q + 1$ being an odd number.

The actual force imparted, at the very beginning, to the structure supported by a flexible connection will be always within the limits of 0 and $m\,a$ for absolutely flexible connection and for absolutely rigid connection. This depends on the value of e, the rate at which the value of a changes, as well as the final value of a.

From the accelerogram, Fig. 1, it seems that the amplitude of the acceleration decreases uniformly from its maximum, to an almost negligible, value, within 55 sec. This value of the amplitude may be expressed as $a\,(1 - s\,t)$, in which, s = a decrement coefficient. For $t = 55$ sec, $1 - 55\,s = 0$; or $s = \frac{1}{55}$. Then the differential Equation (1) will take the form,

$$\frac{m\,d^2 y}{d\,t^2} + r\,\frac{dy}{dt} + e\,y = \frac{8\,c\,m\,a}{\pi^2}(1 - s\,t)\left\{\cos(n\,t) + \frac{1}{3^2}\cos(3\,n\,t) + \frac{1}{5^2}\cos(5\,n\,t) \ldots + \frac{1}{(2\,q+1)^2}\cos\left[(2\,q+1)\,n\,t\right]\right\} \ldots\ldots (23)$$

This, the writer believes, is a more general formula for the problem. The correction factor, c, which is introduced to allow for the flexibility of the connection, is not a constant, of course; but it may be considered constant between certain limits. Likewise, the damping factor, r, is introduced to allow for the influence of internal frictional resistance.

When the connection is constructed so that the maximum force which can be imparted to the structure at the beginning is known beforehand the only danger lies in the possibility of synchronization of the vibration of the foundation with the vibration of the structure itself. It may be solved by the use of Equation (23), in which, $e = n_0^2\,m$ (in which, $n_0 = \frac{2\,\pi}{t_0}$ and t_0 is the time of the natural period, determined independently), and if the solution is not too complicated. In the latter case the check to determine the possibility of resonance may be made by the method introduced[8] by R. R. Martel, M. Am. Soc. C. E.

---

[8] "The Dynamic Behavior of Some Simple Bents Subjected to Established Harmonic Motion," by R. R. Martel, M. Am. Soc. C. E., *Proceedings*, World Eng. Congress, Tokyo, Japan, 1929, Vol. VIII, pp. 213–217.

The author deserves credit for introducing a step-by-step method of solving this problem. The interval of 7 sec chosen in the numerical example ("Application of Analysis") compared with 3.58 sec of the natural period for the structure includes less than two periods and it is not quite clear why a greater maximum than $f = 0.445$ ft would not occur. Were the computations extended a little further showing that the curve of maximum values of f is descending after 7 sec, the assertion regarding the maximum deflection would carry more weight.

Merit P. White,[7] Esq., and **Paul L. Kartzke**,[8] Esq. (by letter).—Although investigations have been carried on for several years at various laboratories in the United States and in Japan, there is still considerable to be learned in regard to the effect of earthquakes on structures. The author's assumptions that seismic acceleration is a linear function of time and that the initial shock is sudden seem as reasonable as any others that might be made for his analysis. Actually, the final results will be practically independent of either assumption. However, the evidence of an eye-witness of one of the Japanese earthquakes that copper coins in a can were thrown out at the first shock is not proof of a sudden initial acceleration unless the can happened to be so connected to the ground as to follow the ground motion.

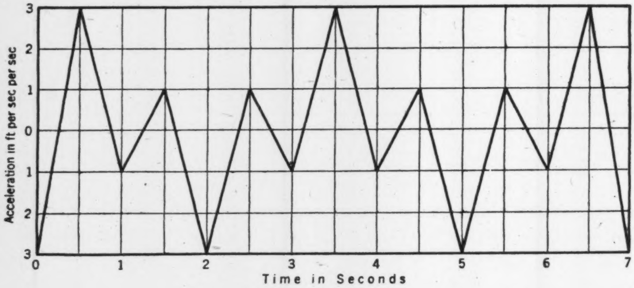

Fig. 9.—Acceleration Diagram

The author's use of plus and minus signs is rather confusing. His values of Y_n and V_n at the end of each half-second period (Table 1) apparently are considered positive if in the direction of the acceleration at the beginning of that period, and are reversed in sign when they become initial conditions (Y_0, V_0) for the next period. It would seem more logical to give the plus sign to deflections and velocities to the right, and the minus sign to those to the left. Incidentally, if the second integral of the author's acceleration curve is taken it will be found that the base of the building is displaced about 20 in. assuming it to start from rest.

Fig. 9 shows an acceleration diagram somewhat similar to Fig. 3, except for the presence of a rather long period acceleration ($3\frac{1}{2}$ sec), in addition to the shorter waves. This acceleration pattern was applied to Mr. Green's building. The computations, based on the following equations,

---

[7] Asst. in Eng., California Inst. of Technology, Pasadena, Calif.

[8] Student, California Inst. of Technology, Pasadena, Calif.

$$Y_n = 0.639\ Y_o + 0.4385\ V_o + 0.202\ \frac{a}{T} - 0.117\ a \ \ldots\ldots\ldots (24)$$

and,

$$V_n = -\ 1.350\ Y_o + 0.6392\ V_o + 0.117\ \frac{a}{T} - 0.4385\ a \ \ldots\ldots (25)$$

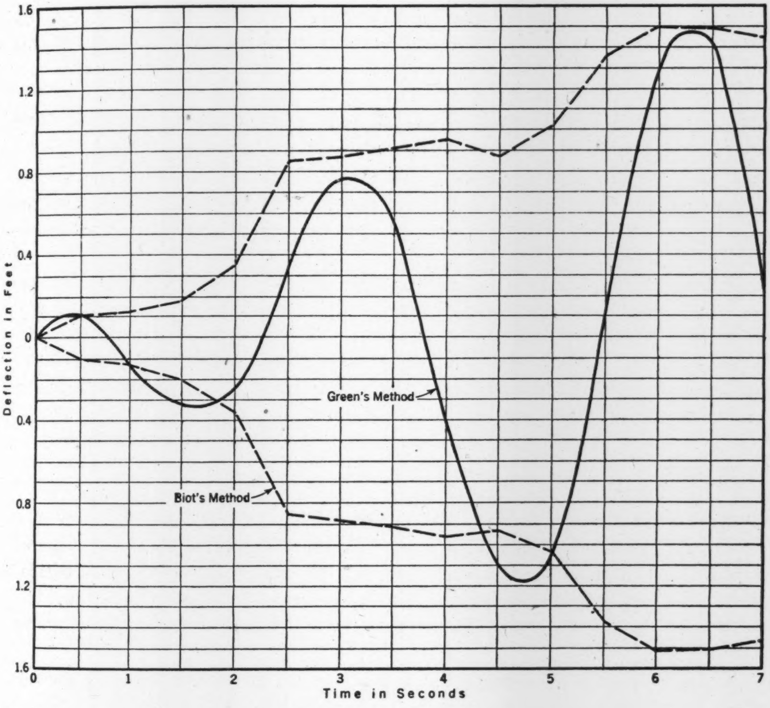

FIG. 10

yielded the deflections plotted in Fig. 10. The maximum deflection is about 1.5 ft, which is more than six times the deflection obtained by Mr. Green. Probably the next swing would be still greater.

Objection may be taken to the writers' use of a long-period acceleration, particularly in view of Mr. Green's reference to Dr. Suyehiro's conclusion that in all earthquakes the period of acceleration in a particular locality is confined to a very narrow range. An examination of the Long Beach, Vernon, and Los Angeles, Calif., records of the Long Beach earthquake of March, 1933, shows[9] the presence of waves of relatively long period. It is probable that these caused a great part of the damage to buildings with a long free period.

As an independent check on the foregoing results a calculation was made using a method of analysis[10] developed by Dr. M. Biot. This analysis was developed for a building with any number of flexible stories, in which all the stories above the first have the same flexibility. Very briefly, this method consists of considering the actual ground displacement curve, applying appropriate constants which depend on the characteristics of the building, and, by using graphical integration, obtaining an envelope (limiting curve) which will give the limits of the actual displacement curve of the floor for which calculations are made. For the flexible first-story building the equation of this envelope becomes:

$$u^2_o = \left[\int g(t) \sin 2\,\pi\,\nu_o\,t\,dt \right]^2 + \left[\int g(t) \cos 2\,\pi\,\nu_o\,t\,dt \right]^2 \ldots . \text{(26)}$$

in which, $g(t)$ is the ground displacement curve and ν_o, the fundamental frequency of the building. The results obtained are shown in Fig. 10. Dr. Biot's method of analysis has been checked by comparison with actual deflections of a model upon a shaking-table. The agreement is quite satisfactory.

The deflections obtained in this example are obviously excessive. Furthermore, it can be seen that a careful choice of an acceleration pattern will give a similar result for any given structure. The results obtained from Mr. Green's method (or any similar method) will depend on the original choice of acceleration pattern. If one could be sure that all earthquakes in a given region would be alike, this method would be very valuable. Unfortunately, this is not the case and, hence, this method of analysis, as it stands, may be misleading.

HOWARD G. SMITS,[11] ESQ. (by letter).—The analysis developed by Mr. Green is interesting; it is quite a new thought as applied to the problem of duplicating, mathematically, such complex vibrations, as earthquake oscillations. Undoubtedly, complex earth motions can be approximated by this method of description more closely than by the usual periodic sine curve or cosine curve expressions.

It is to be noted, however, that the same general method of utilizing unequal maximum accelerations may be used with the customary harmonic theory. Substituting Fig. 11 for Mr. Green's acceleration diagram (Fig. 3), it will be seen that, in general, the periods and accelerations are the same in the two cases with the exception that with the curved diagram the acceleration is zero when $t = 0$. At any given time the ground is moving with simple harmonic motion, such that the acceleration of the ground is $a \sin \frac{\pi}{2\,T}\,t$.

[9] *Engineering News-Record*, June 22, 1933.

[10] *Proceedings*, National Academy of Science, February, 1933.

[11] Chf. Designing Engr. for Oliver G. Bowen, Los Angeles, Calif.

Using Mr. Green's nomenclature the differential equation for the horizontal deflection of the tops of the columns from their bases is:

$$m \frac{d^2y}{dt^2} = m\,a \sin \frac{\pi}{2\,T}\,t - e\,y \qquad (27)$$

and the general solution of this equation is:

$$y = C_3 \sin \sqrt{\frac{e}{m}}\,t + C_4 \cos \sqrt{\frac{e}{m}}\,t + \frac{a}{\dfrac{e}{m} - \dfrac{\pi_2}{4\,T^2}} \sin \frac{\pi}{2\,T}\,t \qquad (28)$$

in which, a = maximum acceleration, and T = time for acceleration to decrease from the maximum to zero (one-fourth the full period of oscillation).

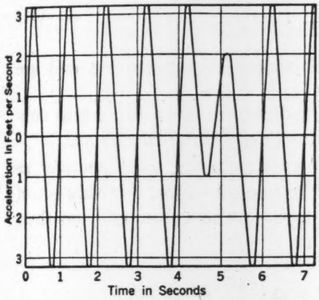

FIG. 11.—ACCELERATION DIAGRAM.

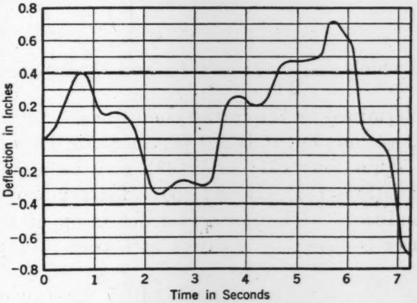

FIG. 12.—DEFLECTION DIAGRAM.

Two constants of integration, C_3 and C_4, are involved which are similar to C_1 and C_2 in Mr. Green's analysis. These constants are evaluated from the initial conditions, namely, when $t = 0, \frac{dy}{dt} = V_0$; $y = Y_0$; and,

$$Y_0 = C_4 \qquad (29)$$

and,

$$V_0 = C_3 \sqrt{\frac{e}{m}} + \frac{\dfrac{a\,\pi}{2\,T}}{\dfrac{e}{m} - \dfrac{\pi^2}{4\,T^2}} \qquad (30)$$

Let $\sqrt{\frac{e}{m}} = Q$, $\frac{\pi}{2\,T} = R$, and $Q^2 - R^2 = b$. Then, solving for C_3 and C_4 and substituting in Equation (28):

$$y = \left(\frac{V_0}{Q} - \frac{a\,R}{b\,Q}\right) \sin Q\,t + Y_0 \cos Q\,t + \frac{a}{b} \sin R\,t \qquad (31)$$

and,

$$\frac{dy}{dt} = v = \left(V_0 - \frac{a\,R}{b}\right) \cos Q\,t - Q\;Y_0 \sin Q\,t + \frac{a\,R}{b} \cos R\,t \qquad (32)$$

The maximum deflection may be taken as that given by Equation (31) at the time, t, that the ground acceleration is a maximum. The error of this assumption is slight except in the region of resonance; that is, when the period of the ground approaches the free period of the columns.

Mr. Green might have included damping in his discussion. Damping, which is caused by the absorption of energy by the building, may be taken as proportional to the first power of the velocity. If p is taken as the proportionality constant, Equation (1) becomes:

$$m \frac{d^2y}{dt^2} + p \frac{dy}{dt} = m\,a\left(1 - \frac{t}{T}\right) - e y \quad \ldots\ldots\ldots\ldots (33)$$

and the general solution of this linear equation is:

$$y = e^{-j}\left[C_5 \sin \sqrt{\frac{e}{m} - \left(\frac{p}{2\,m}\right)^2} + C_6 \cos \sqrt{\frac{e}{m} - \left(\frac{p}{2\,m}\right)^2}\,\right] + \frac{m\,a}{e}\left[1 + \frac{p}{e\,T} - \frac{t}{T}\right] \quad \ldots\ldots\ldots\ldots (34)$$

in which $j = \frac{p}{2\,m}\,t$; and C_5 and C_6 are the constants of integration and are determined by the initial conditions. Actually, damping is an important consideration; but it is not pertinent to the conclusions of this discussion.

Equations (31) and (32) may be applied in much the same manner as Equations (3), (4) and (5). Table 2 shows the computations for this set of conditions. The horizontal deflection of the tops of the columns from their bases is shown as it varies with time in Fig. 12.

TABLE 2.—COMPUTATIONS

Duration from beginning of motion, t_a	Duration of uniform periodic motion, t_p	T	a	INITIAL CONDITIONS		R	b	FINAL CONDITIONS	
				Y_0	V_0			Y_n	V_n
4.50	4.50	0.250	3.2	0	0	6.29	—36.4	+0.312	+0.525
4.83	0.33	0.165	1.0	+0.312	+0.525	10.40	—105.0	+0.453	+0.121
5.50	0.67	0.335	2.0	+0.453	+0.121	4.70	—19.0	+0.502	—0.392
7.25	1.75	0.250	3.2	+0.502	—0.392	6.29	—36.4	—0.718	—0.157

Conclusions.—If the ground had continued to oscillate with the same motion with which it began, the maximum possible deflection would have been 0.402 in. (indicated by the broken lines in Fig. 12). The introduction of this slight variation of the ground has increased the maximum possible deflection approximately 79 per cent. This is the most important point brought out by this discussion, because it shows that a very slight variation of steady ground motion, opportunely injected, causes a deflection much in excess of that indicated by the "magnification factor" often used in vibration philosophy.

One should use caution in applying these theories in analyzing multi-story buildings, even if the first story is flexible, because the equations under discussion do not apply. While the top stories may be considerably stiffer than the first story, this does not preclude the possibility of vibration in the top stories—and, in some cases, resonance in these upper stories at a higher frequency than that with which the base or first story is vibrating. These vibrations of the upper stories materially affect the motions of the first story. The conclusions given are applicable only to a one-story bent and not to a multi-story building.

H. A. WILLIAMS,[12] ASSOC. M. AM. SOC. C. E. (by letter).—The assumption is introduced in this paper that, if the first story of a building is made flexible, the remainder of the superstructure can be considered a rigid mass in so far as the dynamic analysis is concerned. The writer has made a number of shaking-table experiments in the Vibration Laboratory at Stanford University with two modifications of a dynamic model of a 17-story building (originally designed and built by Professor L. S. Jacobsen) to ascertain to what extent the author's assumption is valid.

For brevity in the discussion, the nomenclature will be given at once:

e = elastic or spring constant (the same as that used by the author); e_1 is the constant for the first story; e_2, that for the second story; etc.

$\gamma = \frac{e_2}{e_1}$ = ratio of flexibility.

T_n = fundamental period of vibration of model, in seconds, when the superstructure is not considered rigid. It is approximately equal to:

$$T_n = 2\,\pi\,\sqrt{\frac{\Sigma\,W\,\Delta^2}{g\,\Sigma\,W\,\Delta}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

in which, W is the weight of one floor of the model, in pounds, and Δ is the horizontal deflection of that floor from the position of static equilibrium when the entire model is subjected to a horizontal force equal to the pull of gravity.[13]

T_r = fundamental period of model, in seconds, when superstructure is considered rigid. It is equal to:

$$T_r = 2\,\pi\,\sqrt{\frac{m}{e_1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

in which, m is the mass of the entire superstructure.

T_t = period of the shaking-table, in seconds.

The first model was dynamically similar, as far as shear distortions are concerned, to a symmetrical 17-story steel frame office building of conventional design. The 8-story model was dynamically similar to the same building with the upper nine stories removed. Frictional effects in the models were not dynamically similar to those in the actual buildings. The weight per floor for Floors 2 to 13, inclusive, was 2 650 500 lb. The next three floors averaged approximately 2 500 000 lb, and the roof, 2 120 000 lb. The elastic constant, e_2, was 57 000 000 lb per in.; the constant, e_{16}, was 27 000 000 lb per in. The intermediate constants varied approximately as a straight line between these two values. The approximate ratio of height to width was 3 to 2 for the 17-story building and 2 to 3 for the 8-story building.

---

[12] Instructor in Civ. Eng., Stanford Univ., Stanford University, Calif.

[13] "Vibration Problems in Engineering", by S. Timoshenko, p. 63.

The shaking-table on which the model was placed, weighed more than $3\frac{1}{2}$ tons. Hence, the motion of the model did not affect the motion of the table, which was anchored at one end by a set of springs, in such a manner that it would be set in motion by dropping a pendulum against a bumper spring on the other end. After the impact, the table had a damped harmonic motion, as shown by the lower curve in Fig. 13. The period of of motion was changed for some of the tests by changing the anchor springs. The amplitude was varied by changing the height of the pendulum drop.

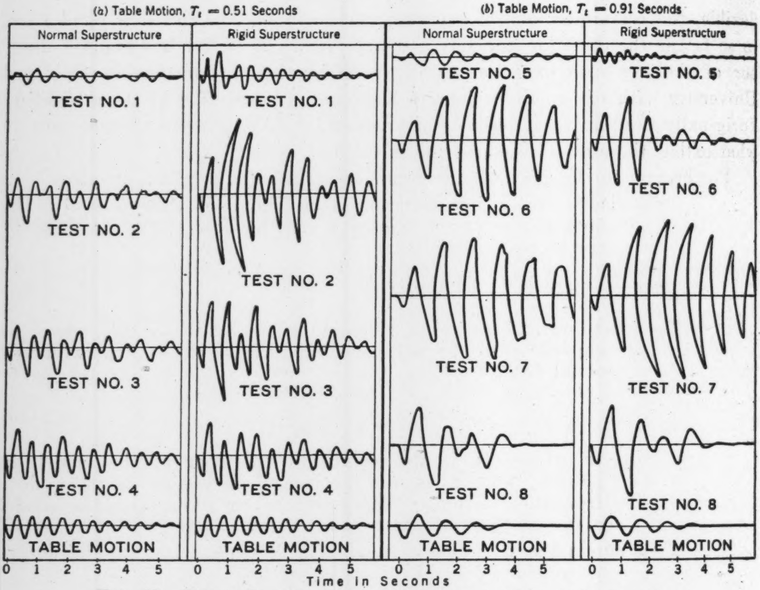

FIG. 13.—TESTS RESULTS FOR A MODEL OF A 17-STORY BUILDING.

The apparatus was arranged so that one record giving the relative motion of the second floor of the model with respect to the table and another giving the motion of the table with respect to the laboratory floor, were obtained simultaneously. In terms of an actual building, these records correspond to the relative motion of the second floor with respect to the ground and the absolute motion of the ground, respectively. In the test records, the table amplitude should be divided by 2 when compared quantitatively to the model amplitude.

For Test No. 1, the value of e_1 for the model corresponded to an elastic constant of 60 800 000 lb per in. in the actual building. Hence, the flexibility ratio was $\gamma = \frac{e_2}{e_1} = 0.95$ (see Table 3(*a*)). This ratio of flexibility would correspond to that found in some conventional buildings of this height.

The computed fundamental period of the model for this value of γ was $T_n = 0.75$ sec. The computed period of the second mode of vibration was approximately 0.25 sec. The table was then given the motion indicated by the record at the bottom of Fig. 13, and the corresponding motion of the second floor of the model was recorded with the superstructure in the normal condition of flexibility. The superstructure of the model was then braced so that it acted as a rigid mass, and the same test was repeated. The motion of the second floor for this condition is shown by the right-hand record for Test No. 1.

TABLE 3.—COMPUTED PERIODS OF VIBRATION OF BUILDING MODELS

17-STORY BUILDING (SEE FIG. 13)						8-STORY BUILDING				
Test No.	Ratio of flexibility, γ	Periods of Vibration				Test No.	Periods of Vibration			
		Normal Structure		Rigid Structure			Normal Structure		Rigid Structure	
		T_n, in seconds	Ratio, $\frac{T_n}{T_t}$	T_r, in seconds	Ratio, $\frac{T_r}{T_t}$		T_n, in seconds	Ratio, $\frac{T_n}{T_t}$	T_r, in seconds	Ratio, $\frac{T_r}{T_t}$
(a) PERIOD OF TABLE MOTION, T_t, EQUALS 0.51 SECONDS

7......	9.60	1.07	1.18	0.85	0.93	15......	0.60	0.66	0.55	0.60
8......	38.80	1.82	2.00	1.65	1.81	16......	1.10	1.21	1.00	1.10

The first story was then made more flexible and the same procedure was followed for Test No. 2, etc. Since the table motion was the same for all tests in Fig. 13(*a*), it is shown only once, at the bottom.

Repetition of the same tests for the 17-story model, using a different table motion, gave the results shown in Fig. 13(*b*). The upper nine stories were then removed and the same procedure was followed for the 8-story model. It should be noted that an 8-story building with such large elastic constants would be quite stiff for the height involved.

The test records in Fig. 13 indicate that the second-floor motions with the two types of superstructure are not alike for this particular 17-story building when γ is less than approximately 40; and, even then, they are not exactly alike. The second mode of vibration whan γ was 38.8 was approximately 0.36 sec. It is quite probable that, if the table motion happened to have the same period as the second mode of vibration of the model, the favorable comparisons obtained in Tests Nos. 4 and 8, Fig. 13, would not hold.

The test records for the 8-story model are not shown, but they also give little evidence in favor of assuming a rigid superstructure in the 8-story building when γ is much less than 40.

Tests Nos. 1 to 4 might lead one to conclude that the assumption of a rigid superstructure is on the side of safety, because all the curves on the right-hand side of Fig. 13(*a*) have larger amplitudes than those on the left-hand side. Tests Nos. 6, 10, and 15 indicated that such a conclusion is erroneous. In general, if the ratio, $\frac{T_n}{T_t}$, is approximately 1.00 (exact resonance for the fundamental mode of vibration) and, at the same time, is closer to unity than $\frac{T_r}{T_t}$, the amplitude of the second-floor motion for the normal superstructure will be larger than when the superstructure is assumed to be rigid.

The experiments have covered a comparatively narrow range. Definite conclusions applying to all types of structures cannot be drawn from these few tests, or from any theoretical step-by-step method of analysis. In general, it would appear that if the elastic constants and floor weights are of the order of those given herein, there is little reason to believe that the author's method of analysis should apply to buildings higher than eight or ten stories unless the flexibility ratio, γ, is at least 40. This ratio can probably be somewhat less for buildings of fewer stories if the superstructure is fairly rigid. It probably should be increased if the building exceeds fifteen stories.

The writer understands that Mr. Green has in mind flexibility ratios as large as 50 or 60. The period of 3.58 sec for the building which he used in his illustration would indicate as much. The practicability of using a flexibility ratio of even 40, of course, is open to debate. Observation of the model on the shaking-table makes one dubious of the success of such a building. A small movement of the ground can set up a rather large relative motion of the structure even though the system is considerably removed from the resonance condition. Hence, certain practical difficulties must be overcome to prevent damage to the flexible story from every slight earth shock.

Some engineers believe it is practical to construct the first-story walls and ceiling so that the motion of the superstructure will result in no damage to the flexible story. If such a building has a flexibility ratio of 40, or more, its behavior in wind storms would have to be determined. It has also been suggested that hollow tile walls, for instance, could be installed in the flexible story to prevent damage from small ground motions and also to stiffen the building against gusts of wind. In a severe quake, these walls would soon shatter and allow the flexible story to come into full play. Until the tile walls are badly shattered, it is quite possible that vibrations will be set up in the superstructure and, also, that the elastic constant for the flexible story will be non-linear. These factors should be borne in mind when interpreting any mathematical analysis of such a building.

If it is granted that large flexibility ratios are practicable, Mr. Green's method of analysis, when used by one thoroughly familiar with the dynamic principles involved, should give some indication of the action of the building in an earthquake. Obviously, any quantitative results of such an analysis should be accepted with strong reservations. Even though the designer is skilful in simulating probable earth motions, there are several important factors which he would usually neglect because of lack of time or lack of reliable information.

For example, if a building is tall and narrow, direct stress in the columns and load-bearing walls will result in a certain amount of flexibility in the superstructure. This factor can be included when computing the elastic constants. If it is neglected, the flexibility ratio will be too high. Moreover, the rotation of the ground at the foundation line affects the motion of any building, the effect being dependent on the width and height of the building and on the nature of the ground below the foundation line. Another factor is damping friction which decreases the amplitude of motion. Little is known at present about the magnitude of these two factors as far as buildings are concerned.

NORMAN B. GREEN,[14] ESQ. (by letter).—The active interest in this subject, as evidenced by the discussion, is gratifying. One of the main objects of the paper was to elicit ideas and criticism from other engineers, since the fundamental idea involved is relatively new.

The flexible first story, perhaps, may be considered as an expedient for rendering the structure susceptible of dynamic analysis. The only other alternative is to utilize the so-called "rigid" type of design, in which the entire building is assumed to move with the ground and is subjected to the ground acceleration. This assumption is only permissible if the free vibration period of the structure is very short, which limits this type of construction to low buildings having some very stiff form of bracing, such as masonry walls.

The entire analysis of the building with a flexible base devolves upon the assumption that the upper part of the structure may be considered as a rigid mass. This assumption has been called in question by Mr. Johnson and Mr. Smits. The writer believes that the question is not as to whether the assumption is valid, but rather within what limits it is valid. One extreme would be a wide building of two stories, having concrete second-story walls with a small window area, supported on long first-story steel columns. In this case there seems to be no question but that the assumption is valid. On the other hand, a narrow building of thirty stories, having a large window area, would offer considerable uncertainty. The problem presented by the assumption is not susceptible of theoretical analysis, and the writer is therefore greatly indebted to Mr. Williams for his experimental investigation along this line. Reference to Fig. 13 of Mr. William's discussion will show that the displacement curves for the normal and rigid structure for Tests Nos. 4 and 8, are very closely the same. This favorable result was secured with a ratio of second-story stiffness to first-story stiffness of only 38.8. The writer believes that a much greater stiffness ratio than this can easily be secured.

---

[14] Structural Engr., San Francisco, Calif.

Consider, for example, the 20-story steel frame building described by the writer and to which he applied the analysis. The effective height of the flexible first story is 36 ft, which gives an elastic constant of 3 760 000. If it is assumed that the earth motion is parallel to the short dimension of the building, the lateral load acting on the upper or "rigid" part is resisted by the two end walls, each consisting of four 20-ft bays with an over-all width of 82 ft. If there are two 4 by 7-ft windows in each bay, the window area will be 23% of the total, which is a fair average condition for buildings of this type. As an approximation it may be assumed that the lateral distortion in any one story is produced by the shear and bending deflection of the individual piers between the windows, these being taken as fixed at the window head and sill. On this basis, with a 10-in. concrete wall, the elastic constant for one story is 840 000 000 and the ratio of this constant to that for the first story is 223. This computation neglects that part of the story distortion that arises from the bending of the spandrels and the consequent rotation of the ends of the piers. Inasmuch as the spandrels are relatively very deep and short and since about one-half the total deflection of the average pier is due to shear, it is not likely that the error involved is large.

The writer is indebted to Messrs. White and Kartzke for their analysis of the 20-story building, utilizing the acceleration diagram of Fig. 9, in which a condition of resonance is approached. The long waves of this diagram have an acceleration period, not of $3\frac{1}{2}$ sec as they state, but of 3 sec—so that complete resonance with the building having a free period of 3.58 sec is not attained. Even so, an examination of Fig. 10 shows a rapid increase in the building deflection. The important point demonstrated is that only one or two long swings of a period fairly close to the period of the building, are necessary to produce destructive deflections.

Messrs. White and Kartzke are certainly correct in stating that a careful choice of an acceleration pattern will lead to destructive deflections for any given structure; but it is also possible to conceive of a type of gravity loading that will cause the failure of any structure. The occurrence of an acceleration pattern of the character of Fig. 9, having a period of 3 sec and an acceleration of 10% gravity, is not probable in the light of present knowledge of the subject. Referring to the accelerograph records of the Long Beach earthquake of March, 1933,[15] it will be found that there is a well-marked association of long-period waves with low accelerations and short-period waves with high accelerations. The longest waves recorded had a period of about 2.5 sec, with a maximum acceleration of from 1% to 4% gravity; the highest recorded accelerations of from 20 to 30% of gravity, on the other hand, were associated with short periods of from 0.7 to 0.3 sec. If this proves to be characteristic of all earthquakes, the design of so-called "rigid" structures offers serious difficulties, since to be consistent very high accelerations and seismic coefficients should be applied. On the other hand, the flexible-base structure is relatively immune to the effects of these very high short-period accelerations.

---

[15] *Engineering News-Record*, June 22, 1933.

As demonstrated by Messrs. White and Kartzke the acceleration diagram of Fig. 3 shows a total ground displacement of about 20 in. The ground motion is periodic up to the end of the fourth second, with an amplitude of motion of 1.6 in. At this point the equilibrium is disturbed by the introduction of an irregularity in the acceleration diagram, so that the ground motion thereafter is of varying velocity, in a constant direction. Obviously, this same diagram could not be extended indefinitely, since it would result in an unlimited ground displacement; however, the progressively increasing ground movement can be halted at any point by the insertion of another appropriate irregularity into the diagram. This simply illustrates the desirability of integrating each acceleration diagram before it is employed in the analysis of a structure. This can be done quite easily by making use of the fact that the algebraic sum of the areas enclosed between the acceleration diagram and the axis of zero acceleration up to any time, is equal to the velocity at that time; the algebraic sum of the areas enclosed between the velocity diagram and the axis of zero velocity gives the displacement during that period of time. The areas can readily be determined by plotting the acceleration diagram and the velocity diagram on cross-section paper.

In this connection the important point is that introduced in the discussion by Mr. Smits, namely, that the insertion of a slight irregularity in the acceleration diagram, which institutes a progressive ground motion in one direction, produces large deflections of the building. No such result can be revealed by the conventional investigation in which only a simple harmonic motion of the ground is considered. The effect is entirely independent of resonance.

The question may arise as to whether any such sustained motion of the ground in one direction is possible. This type of motion cannot be recorded during the progress of the earthquake by any existing seismograph or displacement meter; however, precise surveys made before and after the San Francisco earthquake of 1906[18] indicate large permanent displacements. This is illustrated by Fig. 14 which has been plotted from the results of these surveys. A survey line crossing the main fault at right angles (and which was straight prior to the earthquake) was subsequently found to be broken at the fault, the west half having been displaced 3.6 m toward the north and the east half, 2.3 m toward the south. This lateral displacement of the ground progressively decreased each way from the fault line, as indicated on the diagram, so that a large area of land suffered a permanent shear distortion.

Mr. Smits has extended the writer's equations to include the effect of damping, making this proportional to the relative velocity. Since the lateral load is intended to be resisted in the flexible story by means of steel columns alone and without the help of exterior walls or interior partitions, it does not appear that there would be any considerable damping as long as the stress in these columns is kept within the elastic limit of the material. Further application of the analysis to flexible-base buildings might indicate, however, the desirability of introducing some form of artificial damping, so as to limit the effects of possible resonance with the ground motion. Perhaps, this could be done by locating the flexible story below the ground, with the base of the rigid superstructure at the first-floor level, so that damping devices could be introduced at this point to re-act against the earth. With this position of the flexible story, all walls and partitions above the ground level could be made rigid and the practical difficulties mentioned by Mr. Williams, attendant upon securing a flexible story in the superstructure, would be eliminated. In this case, the flexible story would also meet the theoretical requirement of a strictly constant value of the elastic factor, *e*, so that there is no uncertainty as to the starting conditions. As stated by Mr. Williams, this will not be the case if it is necessary to rupture first-story walls and partitions before the lateral load is carried by the steel columns in the flexible story.

[18] Rept. of the California State Earthquake Investigation Comm., Vol. 11.

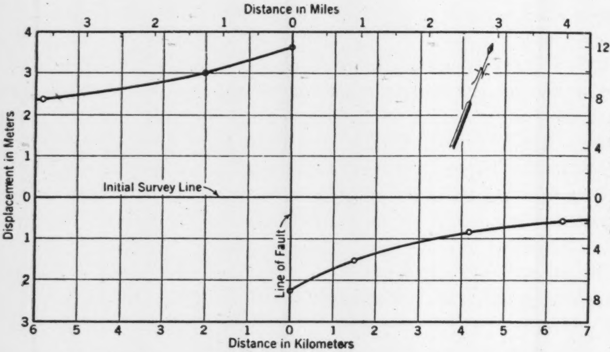

FIG. 14.—PERMANENT GROUND DISPLACEMENTS IN THE SAN FRANCISCO EARTHQUAKE OF 1906

Mr. Johnson states that the effects of a vibratory phenomenon upon any object cannot be determined by considering only the acceleration. This is not true for non-harmonic vibration of the type the writer has utilized in the analysis, since in this case the acceleration may be established entirely independently of both the amplitude and the frequency. Given an arbitrary acceleration diagram, the first integration establishes the velocity and the second determines the displacements or ground motion. Two constants of integration are introduced, which are known if the initial conditions of velocity and displacement are known. The motion is then completely determined. The statement referred to is correct in the case of simple harmonic motion, the fundamental definition of which establishes a relation between acceleration, amplitude, and frequency.

The discussion by Mr. Johnson mentions an uncertainty regarding the writer's notation for *y*. This quantity, *y*, is defined as the deflection of the body from its position at rest; that is, at rest relative to the support.

In other words the variable, y, is relative displacement. It would be a clearer statement of the dynamic relation, perhaps, if the writer's Equation (1) had been written in the form:

$$\frac{d^2 y}{d t^2} = a \left(1 - \frac{t}{T}\right) - \frac{e\, y}{m} \qquad \text{(37)}$$

which is simply an algebraic relation between three accelerations, considered as vector quantities. It states that the acceleration of the mass relative to the support is equal to the absolute acceleration of the support minus the relative acceleration impressed on the mass by the spring. The conventional form of equation representing a forced vibration involves two variables: (1) The absolute displacement of the support; and (2) the absolute displacement of the vibrating mass. The difference between these two variables is the displacement of the mass relative to the support. The writer considers it simpler and more direct in this case to introduce one dependent variable only, which is the relative displacement that it is desired to determine.

The idealized system shown in Fig. 2, in which the vibrating mass is assumed to move only in a straight line in the plane of the paper, has one degree of freedom and only one mode of vibration. The natural period of this vibration is correctly given by Equation (9), which Mr. Bednarski believes to be too simple to be true. It is this very simplicity of dynamic analysis which recommends the flexible-base building. On the other hand the dynamic analysis of a bar fixed at one end and free at the other, cited by Mr. Bednarski, involves harmonics and is a much more involved problem. Such a cantilever beam is similar, in general, to a high building that is flexible throughout its height, and well illustrates the uncertainties and difficulties attendant upon any dynamic analysis of such a structure.

An actual flexible-base building has two degrees of freedom for motions of translation; however, the columns should be arranged so as to give the same elastic constant about either axis, so that its natural frequency will be the same for vibrations in either direction. In case the center of mass of the structure does not coincide with the center of elastic resistance, a couple is introduced, which will produce rotatory vibrations superimposed upon those of translation. This case is outside the scope of the writer's paper.

No mention has heretofore been made of the seismic forces acting on the upper or "rigid" parts of the structure; but these forces must be considered in designing the bracing system, since the requisite strength as well as stiffness must be secured. The acceleration of the upper part of the building is produced by the horizontal reaction of the top of the base columns and, therefore, it will be a maximum when the deflection of the base columns is a maximum. Then, if a_m is the maximum acceleration to which the upper part of the building is subjected:

$$a_m = \frac{e \times \text{maximum column deflection}}{m} \qquad \text{(38)}$$

Consider, for example, the 20-story building referred to under the heading "Application of the Analysis" in the paper. The mass of the rigid part of this building is 1 220 000; the elastic constant, e, is 3 760 000; and, from

Table 1, the maximum column deflection is 0.445 ft. Substituting these values in Equation (38), the acceleration is found to be 1.37 ft per sec per sec. The maximum deflection that occurs during the first 4 sec of periodic ground motion, is 0.145 ft which gives to the building superstructure an acceleration of 0.45 ft per sec per sec. This is only 14% of the full ground acceleration and illustrates the large reduction in earthquake stresses that may be produced by a flexible story when the ground motion is periodic and even if it is of fairly long period.

INVESTIGATION OF WEB BUCKLING IN STEEL BEAMS

BY INGE LYSE,[1] M. AM. SOC. C. E., AND
H. J. GODFREY,[2] ESQ.

WITH DISCUSSION BY MESSRS. R. L. MOORE AND E. C. HARTMANN,
AND INGE LYSE AND H. J. GODFREY

SYNOPSIS

The results of an investigation on the web failure of structural steel beams are reported in this paper. Tests were made on rolled sections as well as on sections made from plates by means of electric arc welding. The depth-thickness ratio of the web of the beams varied considerably; however, all the beams gave indication of initial failure due to shear. At the initial failure of the beam (its yield point), the computed maximum horizontal shearing stress in the web was found to correspond very well with the shearing yield-point stress of the material. The conclusion is drawn that the shearing stresses developed in the web, rather than buckling, determine the usefulness of a beam for depth-thickness ratios of 70 or less. The trend of the relationship indicated that buckling of the web might occur at a depth-thickness ratio of approximately 80.

INTRODUCTION

Since the degree of web buckling in beams and girders has long been a moot question, and since experimental data are scarce, an investigation of this subject was an urgent need. A theoretical study[3] was presented by Professor S. Timoshenko in 1933, but as no experimental results were offered

[3] "Stability of Plate Girders Subjected to Bending," by S. Timoshenko, Preliminary Publication, International Assoc. for Bridge and Structural Eng., Paris, 1932, p. 129; abstracted in *Civil Engineering*, August, 1933, p. 456.

in support of this theory, the question remained unsolved. In that paper Professor Timoshenko presents such a complete discussion of earlier experimental results that the inclusion of a bibliography in this paper is obviated.

For the purpose of securing reliable experimental information, a cooperative investigation was undertaken by the Bethlehem Steel Company and the Fritz Engineering Laboratory of Lehigh University, Bethlehem, Pa. All the beams where designed and furnished by the Bethlehem Steel Company and tested at the Fritz Engineering Laboratory. Special acknowledgment is made to Jonathan Jones and C. H. Mercer, Members, Am. Soc. C. E., Chief Engineer, and Consulting Engineer, respectively, of the McClintic-Marshall Corporation, and to V. E. Ellstrom, Manager of Sales Engineering, Bethlehem Steel Company, for their valuable assistance in carrying out the investigation.

Since the usefulness of a beam is determined by the maximum load it can sustain without excessive deflection, the determination of its yield point becomes the most important factor in the testing. Emphasis was placed, therefore, upon securing the actual yield-point strength instead of the ultimate. The ultimate load has little significance beyond the fact that it is a measure of the toughness of the beam after it has lost its usefulness. In the study of the data the yield-point strength of the beam was used as the criterion for its load-carrying capacity.

PROGRAM

In order to obtain a suitable method of testing for use in the major investigation, a preliminary series of tests was run. This series included four Bethlehem B12–28 rolled sections, two of which had free ends; the remaining two had steel plates welded to the end sections to prevent failure by end twisting. A 1-ft sample section of each beam was furnished for the preparation of test coupons, on which the tensile and shearing properties of the material were determined.

Two groups of beams, designed to secure a definite failure in the web, constituted the major investigation. The first group consisted of five beams, three of which were made by welding steel plates together; the remaining two were rolled sections reinforced with cover-plates welded to the flanges. The second group consisted of five beams, all of which were welded sections. Since the design formulas make the depth-thickness ratio of the web the criterion for the working stresses, beams having high ratios were included in these tests. The highest $\frac{h}{t}$ ratio for rolled sections was about 55, and for welded sections about 70. (In this paper, h represents the clear distance between the flanges, and t, the thickness of the web.)

PRELIMINARY INVESTIGATION

Information relating to the four beams tested in the preliminary investigation is presented in Table 1(*a*). It is noted that these beams had

an $\frac{h}{t}$ ratio of about 40. They were tested in the 300 000-lb screw-power machine, the load being applied at the rate of 0.05 in. per min. The sizes of all beams were measured with micrometers and were found to differ slightly from those listed in handbooks. The properties based on the actual dimensions are given in Table 1(*a*).

The beams were supported by a roller at one end and by a spherical bearing-block at the other end. The load was applied through a roller and a spherical bearing-block at the quarter-points of the span. At that side of the center line where a roller was used as a support, a spherical bearing-block was used for the application of the load, and *vice versa*, as shown in Fig. 1. Lateral deflections of the web were measured by dial gauges placed on both sides of the web along a line connecting the loading point and the support. A movement of 0.0001 in. could be read directly by these gauges. On the first beam tested (No. 1, Table 1(*a*)), the gauges were supported by a frame attached to the table of the machine. This arrangement was not satisfactory, however, due to the relative movement between the beam and the table. For the remaining three beams the frame holding the gauges was clamped directly to the flanges of the beams. Vertical deflections were also observed on the two beams that had plates welded to the end sections.

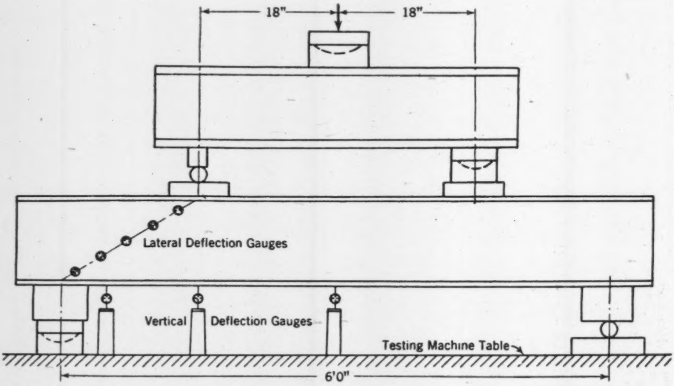

FIG. 1.—LOADING ARRANGEMENT FOR PRELIMINARY INVESTIGATION

In the first free-ended beam the center of the web was $\frac{3}{16}$-in. off center with respect to the top flange. The web of this beam began to scale at a load of 110 000 lb, which was taken as the yield point. However, it continued to take load until a total of 120 000 lb had been applied. At this load one end twisted sidewise. The eccentricity of the top flange may have contributed to an earlier twisting than would otherwise have occurred.

The greatest lateral web deflection occurred in Beam No. 2, Table 1(*a*), near the top flange where, at a load of 110 000 lb, the deflection was about

0.075 in. To a load of 60 000 lb the increase in lateral deflection was nearly constant for each increment of load. Beyond 60 000 lb the rate of increase in lateral deflection became greater for each additional increment. Strain-gauge measurements were also taken at points shown in Fig. 2, by means of a 2-in. strain-gauge. The compressive strains obtained are shown in Fig 3. It is noted that at a load of 110 000 lb none of the gauge lines showed strain near the yield-point strain of the material in the web, but there is a tendency for the rate to increase. The beam first began to scale at a load of 120 000 lb which was taken as the yield point. The beam continued to take load until a maximum of 129 000 lb was reached, at which time the ends twisted sidewise.

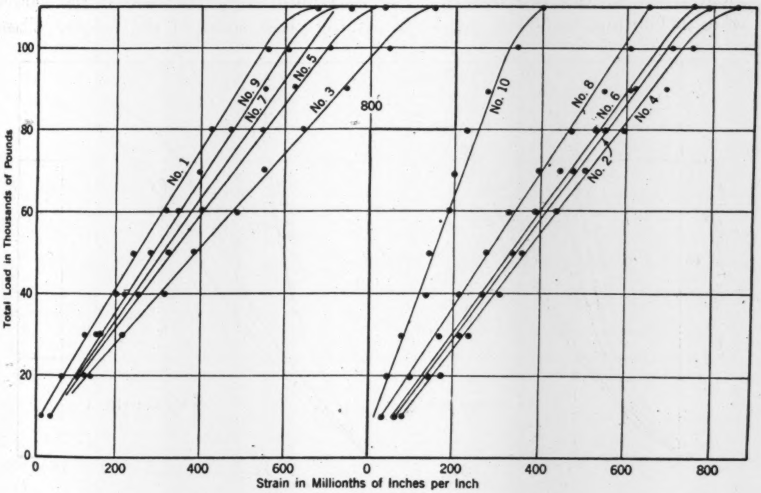

Fig. 3.—Average Strain in Compression Along Line Connecting Loading Point and Support

Table 1(*a*) shows that the test coupons gave shearing yield-point stress in the web of 23 650 and 22 500 lb per sq in., respectively, for Beams Nos. 1

and 2. The average yield point and ultimate strength in tension, as determined by tests on the coupons from the flanges of these beams, were 37 700 and 59 000 lb per sq in. The shearing yield-point stress was thus about 64% of the yield-point stress in tension. The computed maximum shearing stresses in the web were 18 550 and 20 250 lb per sq in. at the yield point of the two beams. The maximum fiber stresses in the flanges were 29 000 and 31 600 lb per sq in. at the yield point of the beams. These data show that the yield point of the material had not been reached, either in shear or in tension, at the load at which scaling occurred. Furthermore,

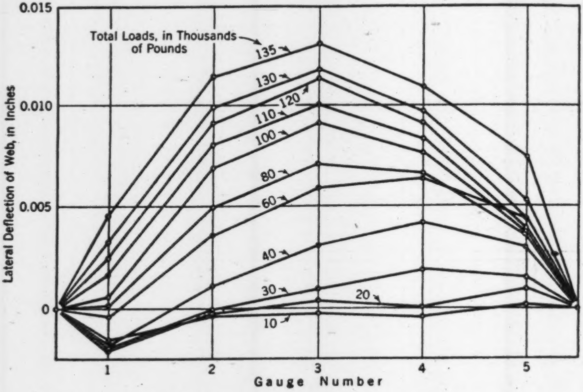

FIG. 4.—LATERAL DEFLECTION OF WEB OF BEAM NO. 3, TABLE 1

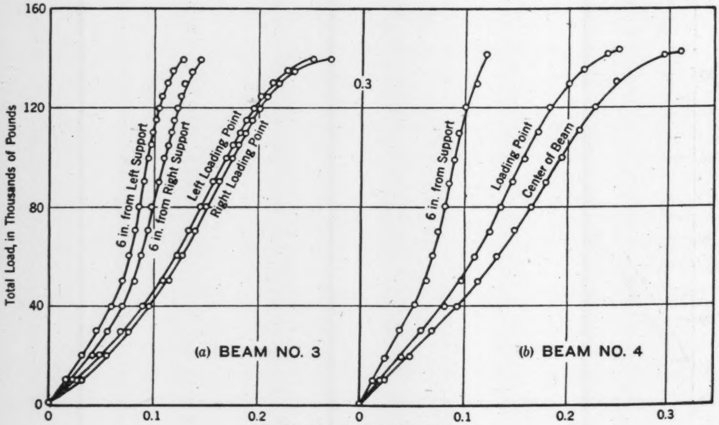

FIG. 5.—DEFLECTION CURVES FOR BEAMS NOS. 3 AND 4, TABLE 1 (ULTIMATE LOAD, BEAM NO. 3, 141 500 POUNDS; BEAM NO. 4, 144 450 POUNDS)

the failure was due to end twisting instead of web buckling or shear. In order to prevent end twisting steel plates were welded to the ends of the remaining beams.

Both vertical and lateral deflections were observed for the beams with end plates. These beams were whitewashed before the testing so that strain lines could be observed more readily. The loading arrangement is shown in Fig. 1. The lateral web deflections for Beam No. 3, shown in Fig. 4, were similar in shape to those for Beam No. 4. However, the lateral deflection of Beam No. 4 became less after a load of 50 000 lb had been applied, whereas in Beam No. 3 the deflection increased throughout the test. It should be noted that at a load of 135 000 lb, the lateral web deflection of Beam No. 3 was only 0.013 in. The similarity of the vertical deflection curves was also very marked, as shown in Fig. 5. The yield point for these two beams was taken as the point at which the slope of the tangent to the deflection curve was twice as large as the slope of the straight part of the curve. The loads at the yield points were 130 000 and 131 000 lb. The beams continued to take load beyond the yield point until maximum loads of 141 500 and 144 450 lb were reached, at which time, end twisting occurred in a manner similar to Beams Nos. 1 and 2.

FIG. 7.—MAKE-UP AND LOADING ARRANGEMENT FOR MAJOR INVESTIGATION, GROUP *A*

At a load of about 110 000 lb, the first strain lines appeared on both beams in the form of horizontal lines, at the root of the web near the support. With increased load, more strain lines appeared over the support and also below the loading point. At loads of 138 500 and 134 500 lb, respectively, for Beams Nos. 3 and 4, the yielding was so great that it produced a drop in the lever of the testing machine. Further increase in the load produced vertical strain lines in the web between the support and the loading point. All these lines were evidently due to shear. An illustration of the progressive formation of the strain lines is shown in Fig. 6.

Computed maximum shearing stresses in the web at the yield point, were found to be 22 400 and 22 600 lb per sq in. for Beams Nos. 3 and 4. These agree closely with the yield-point stresses in shear (22 300 and 24 500 lb per sq in.) obtained on the test coupons. At the yield point of the beams the maximum fiber stresses in the flanges were 35 100 and 35 400 lb per sq in. Since the tensile yield-point stresses of the coupons were 40 800 and 39 550 lb per sq in., the yield point of the beam was not caused by the flexural stresses. If the flexural stresses were computed for loads corresponding to the drop of the beam, they would still be less than the yield-point stress of the material. It may be concluded, therefore, that the yield point of these beams was determined by the yield point in shear of the material in the web.

It was demonstrated that no web buckling appeared for $\frac{h}{t}$ ratios of 40. In the major series the $\frac{h}{t}$ ratios were considerably greater than 40, and it was deemed advisable to restrain the ends of the beams in order to prevent end twisting.

Tension specimens made from the outer edge of the flange usually were of higher strength than those made from the center of the flange. Tension specimens were also made from the web, and were found to be uniform for all four beams. Shearing strengths of the material in the web were obtained on slotted plate specimens tested in a tension machine.[4]

MAJOR INVESTIGATION, GROUP *A*

Group *A* (see Table 1(*b*)) consisted of five beams, three of which were all welded sections and two were reinforced rolled sections. The welded beams (*WB*-1, *WB*-2, and *WB*-3) were made of $\frac{1}{4}$-in. tank plates for the web, and $1\frac{1}{2}$-in. plates for the flanges; these had $\frac{h}{t}$ ratios of 56.6, 54.9, and 58.9, respectively. All the beams had reinforcement plate stiffeners at the loading points and supports. Steel plates were welded to each end section to prevent end twisting. In addition, Beam *WB*-3 had two angle stiffeners on each side of the web in one of the panels between the support and the loading point. The make-up and the loading arrangement for these beams are shown in Fig. 7. Both vertical deflections of the beam and lateral web deflections were observed during the testing of these beams. The location of the gauges was similar to that of the beams in the preliminary tests. The beam designated in Table 1(*b*) as *WB*-2 was not whitewashed, and strain-gauge observations were taken with a 2-in. gauge length at points of the web, as indicated in Fig. 7. All other beams in this group were whitewashed and had no strain-gauge observations. The properties of the beams based on their actual dimensions, and the results of the tests are given in Table 1(*b*).

---

[4] Description of these tests is given in a paper entitled "Shearing Properties and Poisson's Ratio of Structural and Alloy Steels," by Inge Lyse, M. Am. Soc. C. E., and H. J. Godfrey. *Proceedings*, Am. Soc. for Testing Materials, Pt. II, p. 274, 1933.

For Beam *WB*-1 the first local strain lines appeared under the loading point near the junction of the web and the top flange, at a load of only 50 000 lb. At a load of 125 000 lb horizontal and vertical strain lines appeared in the panel between the loading point and the support. The size and number of strain lines increased with an increase in load. The yield point at 155 000 lb was determined from the deflection curve in the same manner as that used in the preliminary investigation. The beam continued to take load until a maximum of 218 500 lb was attained and, at this point, the load fell off, accompanied by a gradual sagging of the beam.

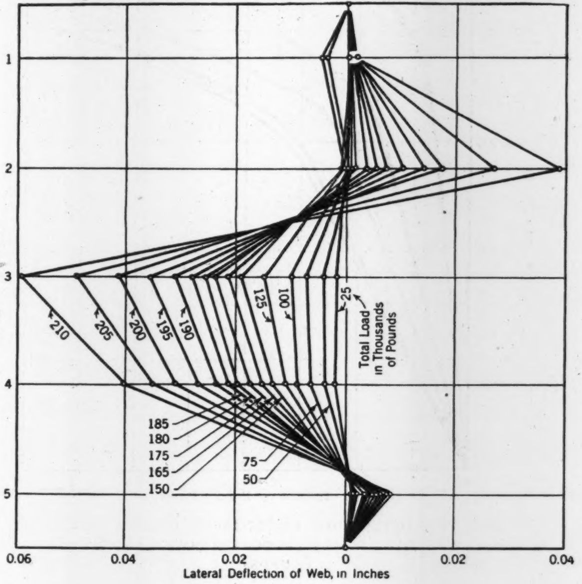

FIG. 8.—LATERAL DEFLECTION OF WEB OF 17-INCH WELDED BEAM *WB*-1, TABLE 1(*b*) (ULTIMATE LOAD, 218 500 POUNDS)

Lateral web deflections for Beam *WB*-1 are given in Fig. 8. It is noted that the center of the web deflected in opposite directions to the deflections at the top and bottom. The web deflection at the yield point of the beam was only 0.02 in., indicating that buckling was not the cause of yielding. The vertical deflections of this beam are given in Fig. 9. It is seen that a fairly sharp increase in the rate of deflection took place at a load of

155 000 lb. This load produced a computed maximum shearing stress of 20 400 lb per sq in. The coupon gave a shearing yield-point stress of 22 000 lb per sq in., which does not differ greatly from the computed shearing stress at the yield point of the beam.

Fig. 10 shows the appearance of Beam *WB*-1 (Table 1(*b*)) at the yield-point load. It is to be noted that the horizontal and vertical strain lines are predominating. Furthermore, a number of local strain lines are grouped along the welds. After the beam had reached the maximum load, the buckling of the web could easily be seen.

Beam *WB*-2 was tested in a manner similar to Beam *WB*-1, except that strain-gauge observations were also taken. The location of the observation points is indicated in Fig. 7. The first strain lines on the web appeared at a load of 68 000 lb while the yield point, as determined from the deflection curve, was found to be at a load of 190 000 lb. The vertical deflections are shown in Fig. 11. The beam continued to take load beyond the yield point and reached a maximum of 255 600 lb, at which time a slight buckle could be seen in one of the web panels. The computed maximum shearing stress at the yield point of the beam was 24 400 lb per sq in. This compared very well with the shearing yield-point stress of 24 500 lb per sq in., obtained on the coupons. The strains obtained by means of the 2-in. gauge are plotted in Fig. 12. It is noted that certain gauge lines showed strains approaching the yield-point strains at a load of 175 000 lb.

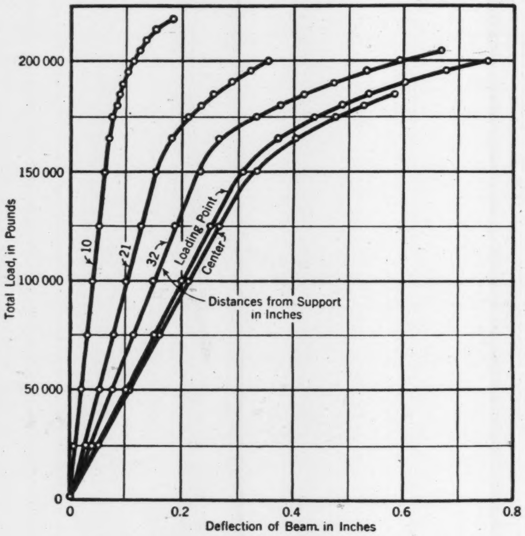

FIG. 9.—DEFLECTION OF 17-INCH WELDED BEAM *WB*-1, TABLE 1(*b*) (ULTIMATE LOAD, 218 500 POUNDS)

Welded Beam *WB*-3 was tested in the same manner as Beam *WB*-1. The first local strain lines appeared at a load of 38 000 lb. After a load of 50 000 lb had been applied the load was released to 1 000 lb and a set reading observed. This was also done after every following increment of loading up to the maximum load. The extent to which the lateral web deflections became set increased considerably after the yield point of the beam had been reached. The vertical deflections in Fig. 13, showed only very small sets at low loads. The yield point of the beam was reached at a load of 230 000 lb, and the vertical permanent set increased considerably after this load had been exceeded. The computed maximum shearing stress at the yield point of the beam was 24 700 lb per sq in. This compares favorably with a shearing yield-point stress of 26 470 lb per sq in. for the coupons. While there is no indication of web buckling at the yield point of the beam, definite web buckling appeared at a maximum load of 278 000 lb. Welded beams proved very satisfactory and showed no indication of distress in the fillet welds.

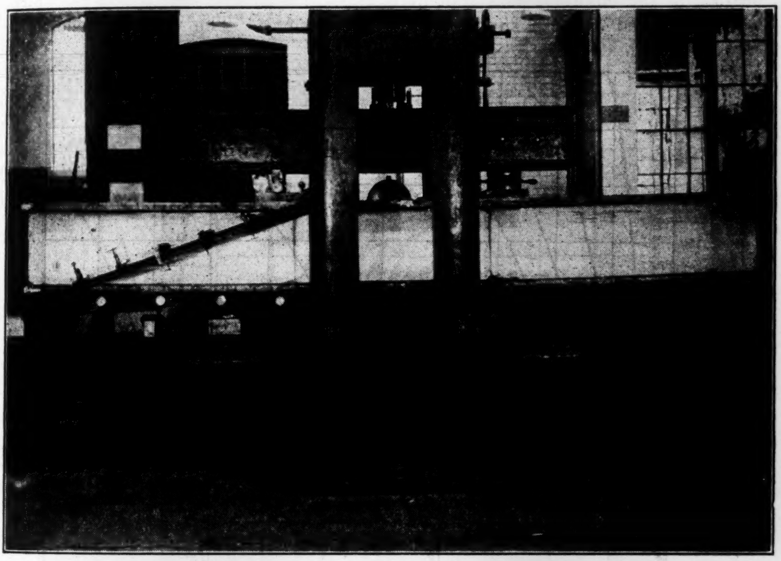

Fig. 10.—Welded Beam, *WB*-1, Showing Web Failure Due to Shear

Beam *WB*-4 was a rolled Bethlehem B28-91 section, the make-up of which is shown in Fig. 7. This beam had plate stiffeners welded to the web at points of support and loading and also had riveted angle stiffeners in one of the end panels. In order to prevent flexural failure, cover-plates that extended to within a short distance of the supports, were welded to the flanges.

Due to the size of this beam, it was necessary to use the 800 000-lb testing machine. As the load was applied the entire beam deflected sidewise to some extent until at a load of 475 000 lb that end of the beam which was supported by the spherical bearing-block twisted. The deflections showed that up to the load at which twisting occurred there was no indication of yielding.

Since the twisting of one end of the beam evidently was due to the loading arrangement, it was deemed advisable to re-test this beam under more favorable conditions. Consequently, lateral restraint for the ends of the beam, in the form of channels bolted to the supporting beam, was used in the re-testing. The friction between the upper flange of the beam and the channels was kept at a minimum by the use of rollers, which were also used at both supports in the re-testing. The vertical deflections obtained during the re-testing are shown in Fig. 14, from which the yield point of the beam was determined at the load of 560 000 lb. Set readings were observed at a load of 25 000 lb, and it was noted that the lateral set was very small in comparison to the lateral web deflection. This may be due either to the better restraint on the ends of the beam by the use of channels, or to the substitution of the roller for the spherical bearing-block. The beam began to twist at a load of 325 000 lb. This rotation continued with the increase in load until at the maximum of 597 600 lb the beam

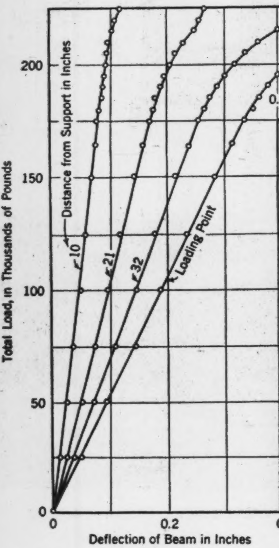

FIG. 11.—DEFLECTION OF 17-INCH WELDED BEAM *WB*-2 (ULTIMATE LOAD, 255 600 POUNDS).

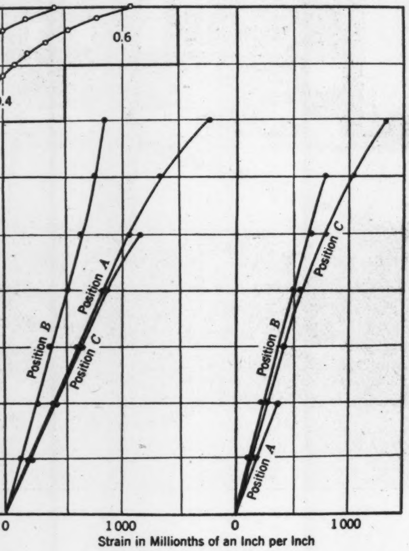

FIG. 12.—AVERAGE TENSION AND COMPRESSION STRAINS ON WEB OF BEAM *WB*-2

twisted so much that the entire loading rig was out of position. At the maximum load, the web did not scale except on the stiffeners and along the junction between the web and the flange.

At the yield-point load the computed maximum shearing stress in the web was 24 200 lb per sq in. in the section between the support and the cover-plates on the flanges, and 21 130 lb per sq in. in the section having cover-plates. The yield-point stress in shear obtained from tests of coupons was 22 000 lb per sq in. For this beam also, the shearing yield-point stress obtained from the material agreed very well with the shearing stress computed for the web at the yield point of the beam.

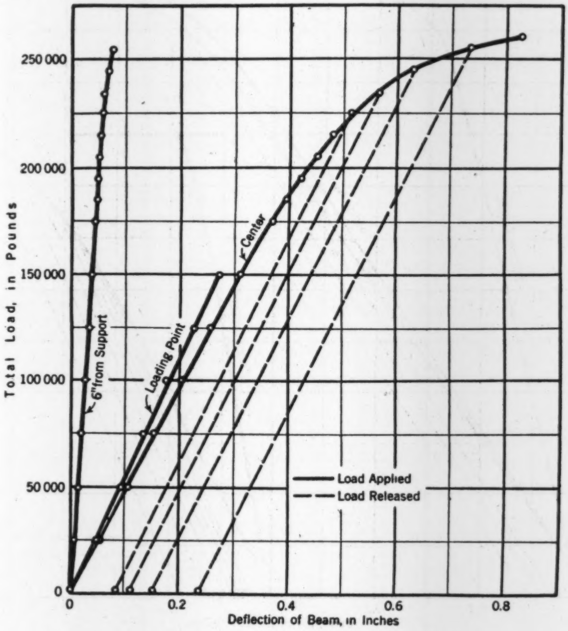

FIG. 13.—DEFLECTION OF 19-INCH WELDED BEAM *WB*-3 (ULTIMATE LOAD, 278 000 POUNDS)

Beam *WB*-5 was a 22-in., 62-lb I-beam reinforced with plate stiffeners and cover-plates, as shown in Fig. 7. The first appearance of scaling on the web was discovered at a load of 50 000 lb. As the load was increased, the scaling increased, especially at the stiffeners. The strain lines on the web were primarily horizontal, indicating shearing stress. Since the scaling had no relation to the yield point of the beam, it may have been caused by high internal strains in the material. The vertical deflections and sets are given in Fig. 15, from which the yield point of the beam was determined at a load of 420 000 lb. The lateral deflections increased until a load of 275 000 lb was reached. For greater loads there was a tendency for the web to return to its original position. The beam continued to take load until a maximum of 450 000 lb was reached, at which time it continued to deflect vertically without any increase in the load. It showed no indication of web buckling, even at the maximum load when most of the whitewash had flaked off in the parts between the support and the loading point.

At the section of the web between the support and the cover-plate, the computed maximum shearing stress at the yield point of the beam was 25 700 lb per sq in. and 23 250 lb per sq in. in the section having cover-plates. These values are somewhat less than the shearing yield-point stress of 29 200 lb per sq in. for the coupons, which was considerably greater than any of the values obtained from coupons of the other beams. The latter showed shearing yield-point stresses between 22 000 and 26 470 lb per sq in. It seems, therefore, that the value of 29 200 lb per sq in, may be somewhat in error. For Beams *WB*-1 to *WB*-4 the ratio between the yield point in shear and that in tension varied between 0.506 and 0.534. However, the

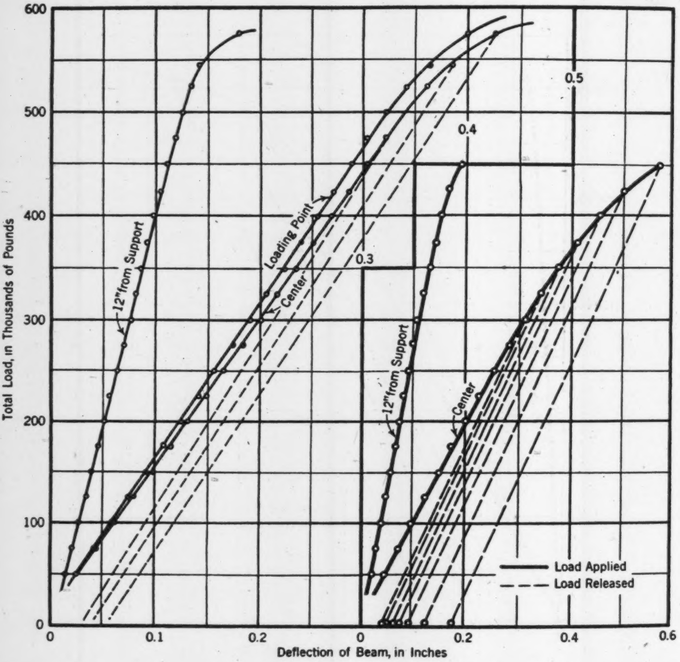

FIG. 14.—DEFLECTION OF A REINFORCED B-22-INCH, 62-POUND, BETHLEHEM I-BEAM, *WB*-5 (ULTIMATE LOAD, 450 000 POUNDS)

FIG. 15.—DEFLECTION OF A REINFORCED B-22-INCH, 62-POUND, BETHLEHEM I-BEAM, *WB*-5 (ULTIMATE LOAD, 450 000 POUNDS)

ratio obtained for Beam *WB*-5 was 0.569, which is considerably more than the other ratios. Granting that the yield-point stress of the coupons was in error, Beam *WB*-5 also showed a fair agreement between the computed maximum shearing stress at the yield point of the beam and the shearing yield-point stress of the material.

As seen from Table 1(*b*), the computed maximum fiber stress in the flanges at the yield point of the beams in this group was only 21 700 lb per sq in. This is so much less than the yield point of the material, which had for a minimum 43 500 lb per sq in., that it is quite evident that the beams did not yield in flexure.

Major Investigation, Group *B*

Group *B* consisted of five welded beams (*WB*-6 to *WB*-10, Table 1(*c*)), all of which were whitewashed before being tested in the 300 000-lb machine. The load was applied to the center of the beam through a spherical bearing-block, and rollers were used at both supports. To prevent end twisting, plates were welded to each end section of the beams, as was done in Group *A*. Plate stiffeners were welded on the web at the supports and loading points so that local failure would not occur. The make-up and loading arrangement of these beams are shown in Fig. 16. Vertical and lateral deflections were observed, and strain-gauge readings were taken on various parts of the beams by a 10-in. Whittemore strain-gauge.

FIG. 16.—MAKE-UP AND LOADING ARRANGEMENT FOR MAJOR INVESTIGATION, GROUP *B* BEAMS

Table 1(*c*) gives the properties of these beams based on actual dimensions. It is to be noted that the $\frac{h}{t}$ ratios ranged from 49.4 to 70.0. The mild steel plates used for the webs were found to be very ductile for all the beams in this group. Consequently, the lever of the testing machine dropped decidedly at a load that was taken as the yield point of the beam.

Beam *WB*-6 had a web ratio of 70. The lateral gauges were placed along the web in one of the panels, and strain-gauge readings were taken in the center of the other panel. The strain-gauge lines were at 45° with the horizontal so that both compressive and tensile strains were measured. Strain-gauge readings were also taken in the center of the bottom flange, in order to determine the maximum flexural stresses developed. The position of the gauges and strain-gauge holes are shown in Fig. 16.

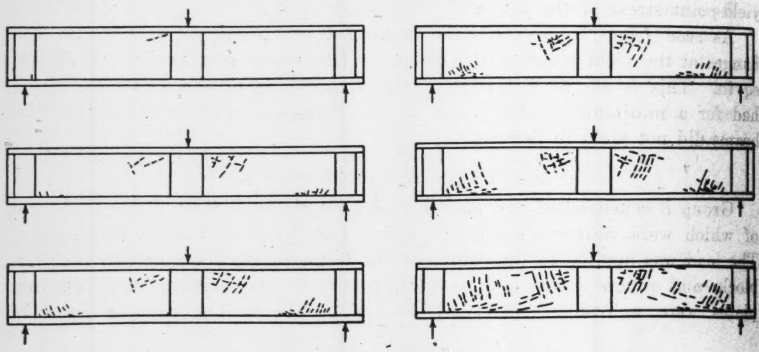

FIG. 17.—GENERAL FORMATION OF STRAIN LINES ON WEB OF BEAMS

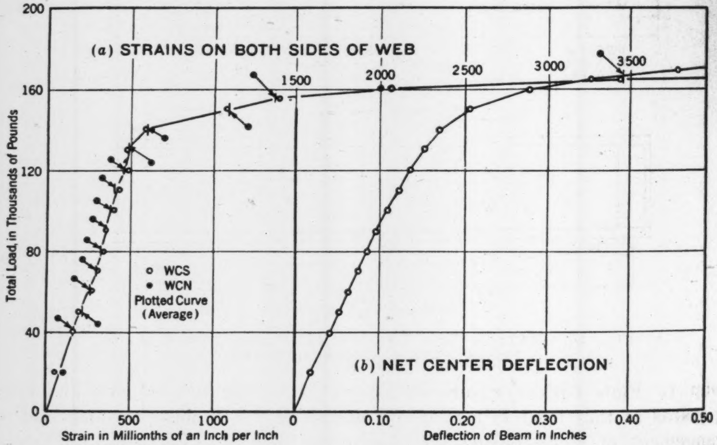

FIG. 18.—COMPRESSIVE STRAINS AND NET CENTER DEFLECTIONS, BEAM *WB*-6 (ULTIMATE LOAD, 192 600 POUNDS)

Flaking occurred first at a load of 24 000 lb, in the form of vertical lines, at the top corner of the web below the loading point. As the load increased, approximately vertical and horizontal strain lines extended across the web. At a load of 50 000 lb, strain lines appeared in the web near one of the supports. A gradual increase in the strain lines followed an increase in load. The general formation of strain lines as they appeared on the beams is shown in Fig. 17.

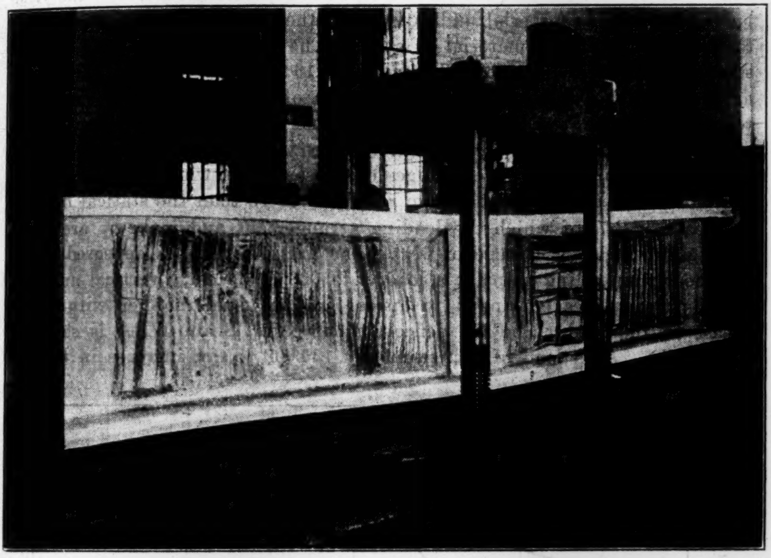

FIG. 19.—APPEARANCE OF BEAM *WB*-6 AT THE MAXIMUM LOAD OF 192 600 POUNDS

Net deflections (difference between the center and end deflections) of Beam *WB*-6 are shown in Fig. 18(*b*), from which it is noted that an increase in the rate of deflection occurred at a load of 140 000 lb. At a load of 150 000 lb, the rate of deflection increased very sharply, and a decided drop of the lever was observed at a load of 157 600 lb. No buckling was observed at this load, and the maximum lateral web deflection was only about 0.008 in. at a load of 150 000 lb; it decreased with further increase in load. The strains observed for the flange indicated that the stress in the flange was very low at the yield point of the beam. The tensile strains in the web increased regularly until a load of 120 000 lb was reached. At 140 000 lb there was a decided increase in the tension strains. The compressive strains in the web are shown in Fig. 18(*a*), in which the strains on both sides of the web have been plotted separately in order to bring out the buckling behavior. It was found that the strains on each side coincide almost exactly throughout the test, indicating that no buckling took place within the loads for which observations were taken. Had buckling occurred, the strains on one side of the web would have increased much faster than those on the opposite side, due to the bending effect.

Fig. 18(*a*) is, therefore, a good illustration of the fact that no buckling took place at the yield point of the beam. The beam continued to take load until a maximum of 192 600 lb was attained. With further motion of the head of the testing machine the web in one of the panels buckled considerably, as shown in Fig. 19. Table 1(*c*) shows a close agreement between the shearing stress in the web at the drop of the lever and the yield-point stress of the material, indicating that the yielding of the beam was due to the yielding of the material in shear. The computed maximum shearing stress at the yield point of the beam was 16 800 lb per sq in. This value agrees with the yield-point stress in shear of 17 450 lb per sq in., as determined by the test coupons. It is noted that the maximum shearing stress is less than the total shear divided by the net area of the web. This is due to the unusually thick flanges on these beams, which tend to increase the moment of inertia of the beam relatively more than the statical moment.

Beam *WB*-7, of which the loading arrangement and make-up are shown in Fig. 16, had a web ratio of 60.6. The first strain lines appeared on the web near the loading point at a load of 20 000 lb. Nearly vertical and horizontal strain lines continued to appear in the usual manner with an increase in the load. The net deflection curve for Beam *WB*-7 is shown in Fig. 20(*b*). At a load of approximately 130 000 lb, an increase in the rate of deflection was noted and, at a load of 148 200 lb, the lever dropped decidedly. The lateral deflection reached a maximum of about 0.025 in. at a load of 150 000 lb. A decided increase in the tension strains was noted at a load of 120 000 lb, while the flange strains showed no indication of yielding at the yield point of the beam. The compressive strains are shown

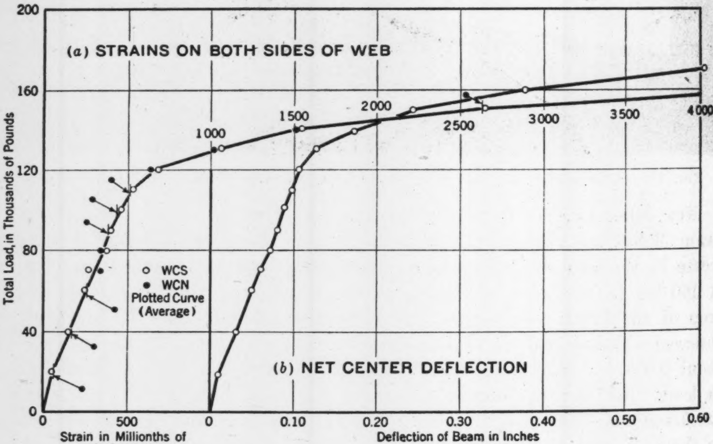

FIG. 20.—COMPRESSIVE STRAINS AND NET CENTER DEFLECTIONS, BEAM *WB*-7 (ULTIMATE LOAD, 190 100 POUNDS).

in Fig. 20(*a*). They were almost the same on both sides of the web throughout the test, indicating that no buckling occurred. A sharp increase in the compressive strains is noted at a load of 120 000 lb, which agrees with the behavior of the tensile strains. The beam continued to take load until one of the web panels began to buckle at a maximum load of 190 100 lb. The computed stresses are given in Table 1(*c*). The maximum shearing stress in the web at the drop of the lever was 17 800 lb per sq in., which agrees with the yield point in shear of 18 600 lb per sq in., as determined from the coupons.

Beam *WB*-8 was a companion of Beam *WB*-7 and had a web ratio of 59.7. Instead of lateral gauges being placed along one of the web panels, strain-gauge readings were taken in both panels to determine whether the load was evenly distributed on both sides of the loading point. The loading arrangement and make-up are shown in Fig. 16. This beam behaved similarly to Beam *WB*-7 throughout the loading, and the strain curves indicate a fairly even distribution of load. An increase in the rate of deflection occurred at a load of 130 000 lb, and a pronounced drop of the lever took place at a load of 143 100 lb. The tensile strains for both panels showed an increase in strain at a load of 120 000 lb. The compressive strains for both sides of the web also indicate that buckling did not take place within the range of loading for which observations were made. The beam continued to take load after the yield point was reached, until a buckle in both panels began at a maximum load of 199 500 lb. The results, as given in Table 1(*c*), show maximum shearing stress in the web of 16 250 lb per sq in. at the drop of the lever. This value is somewhat less than that obtained for Beam *WB*-7 and also less than the yield-point stress in shear as found by the test coupons.

Beam *WB*-9, the loading arrangement and make-up of which are shown in Fig. 16, had a web ratio of 50. Strain lines were visible on the web near the loading point at a load of 20 000 lb. Both vertical and horizontal strain lines appeared with an increase in load in the same manner as described for the other beams in this group. The deflection curves showed an increase in the rate of deflection at a load of 100 000 lb, and a decided drop of the lever took place at a load of 118 900 lb. A maximum lateral web deflection of 0.0045 in. was observed at a load of 130 000 lb, which indicates that buckling had not occurred up to that point. A decided increase in the web strains occurred at a load of 90 000 lb. The compression strains for both sides of the web indicate that at loads greater than the yield point of the beam they are slightly greater on the north side than on the south side. The maximum load carried was 184 000 lb, at which both web panels buckled. The results which are given in Table 1(*c*), show a good agreement between the shearing stresses in the web at the drop of the lever and the yield-point stress of the material. The maximum shearing stress was 17 250 lb per sq in., and the plate coupons gave 18 480 lb per sq in.

Beam *WB*-10 (Table 1(*c*)) was a companion to Beam *WB*-9. The first strain lines appeared on the web at a load of 20 000 lb near the loading point. Vertical and horizontal strain lines appeared in the usual manner as the load was increased. The deflection curve showed an increase in the rate of deflection at a load of about 120 000 lb, and a drop of the lever occurred at a load of 121 800 lb. Both tensile and compressive strains in the web showed an increase in the rate of strain at a load of 100 000 lb. The agreement of the strains on both sides of the web indicated that buckling did not occur. The beam continued to take load until a maximum of 188 000 lb had been reached. The recults, which are given in Table 1(*c*), show a good agreement between this beam and its companion, Beam *WB*-9. The computed shearing stresses at the drop of the lever check the yield-point stress in shear as found by the test coupons.

In all these beams the maximum stresses in the flanges at the drop of the lever were less than one-half the yield-point stress in tension of the material.

EFFECT OF $h:t$ RATIO

In order to study the relation between the $\frac{h}{t}$ ratio and the shearing stresses developed, Fig. 21 was prepared. The beams in Group *B* were the only ones that lent themselves to such a study. It is noted that the shearing stress at the drop of the lever of the testing machine was very nearly the same for all beams, regardless of their slenderness ratios. This indicates that up to an $\frac{h}{t}$ ratio of 70 the yield-point stress in shear of the web material determines the useful load-carrying capacity of the beam. For $\frac{h}{t}$ ratios of 70, or less, there seems to be no reason for designing beams on the basis of web buckling.

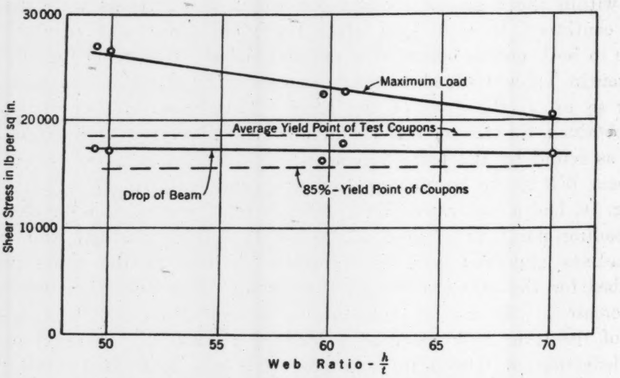

FIG. 21.—COMPUTED MAXIMUM SHEARING STRESS IN WEB OF BEAMS AND YIELD-POINT STRESS IN SHEAR OF TEST COUPONS

The shearing stress at maximum load is also shown in Fig. 21. The stress developed in the web is greater for beams having a low slenderness ratio than for beams having a high ratio. The maximum shearing stress decreased quite regularly with the increase in the $\frac{h}{t}$ ratios, indicating that the toughness of the beam decreased with the increase in the ratio.

If the web had buckled in any of the beams, the maximum load would have been equal to, or less than, the yield-point load. The trend of the relationship indicates that buckling of the web might occur at an $\frac{h}{t}$ ratio of about 80. This value compares very favorably with Professor Timoshenko's theoretical value of 90 for an assumed yield-point stress in shear of 20 000 lb per sq in. for structural steel.

SUMMARY

Although the number of beams tested in this investigation was too small on which to base final conclusions, the results obtained indicated that:

1.—The beams with free ends did not develop the full yield-point strength of the material, either in shear or in tension, due to failure in end twisting.

2.—At the yield point of all the beams which had plates welded to the ends, the computed maximum shearing stress in the web corresponded very well with the yield point in shear of the material.

3.—No beam showed any evidence of buckling at, or below, its yield point, indicating that with $\frac{h}{t}$ ratios up to 70 there is no danger of web buckling. Buckling may be expected to occur at $\frac{h}{t}$ ratios of 80 or more.

4.—The yield point of the beam, rather than the maximum load, should be used as a criterion for the factor of safety. In general, the average shearing stress in the web should be based on net area; that is, on $h\ t$, rather than on gross area, $D\ t$.

5.—The first appearance of strain lines had no relation to the yield point of the beam.

6.—The yield point of the beam was not affected by the $\frac{h}{t}$ ratio of the web. The maximum load, however, decreased with an increase in the $\frac{h}{t}$ ratio.

7.—The shearing yield-point stress of the material was the important factor for all the beams included in this investigation.

DISCUSSION

R. L. MOORE,[5] ESQ., and E. C. HARTMANN,[6] JUN. AM. SOC. C. E. (by letter).—Web failures in beams may occur in any one of the following ways: (1) Yielding of the web material; (2) shear or diagonal compression buckling; and (3) buckling at points of load concentrations. The tests reported by Messrs. Lyse and Godfrey, on steel beams with depth-thickness ratios of 70 or less, involved principally the first type of failure. While their observations are a valuable contribution to present knowledge of web behavior, the investigation can scarcely be considered as one dealing with the interesting phenomena of web buckling and its related problems.

This discussion contains a brief description of a series of tests on aluminum alloy I-beams and girders involving web failures of each of the aforementioned types conducted at the laboratories where the writers are employed. Table 2 is a summary of the results obtained on several different sizes of rolled and extruded I-beams of the duralumin type of alloy known as 17S-T. The following are the nominal mechanical properties of this material: Tensile strength, 58 000 lb per sq in.; yield strength, 35 000 lb per sq in.; elongation in 2 in., 20%; modulus of elasticity, 10 000 000 lb per sq in.; shear strength, 35 000 lb per sq in.; and shear yield strength, 20 000 lb per sq in.

All the beams in Table 2 failed in the web. In Tests Nos. 1, 2, 7, 8, and 9, the web failed by buckling as a column over the reaction. In Test No. 10, failure occurred by buckling as a column under the load point. In Tests Nos. 3, 4, 5, and 6, failure occurred by yielding of the material, complicated in the cases of Tests Nos. 3 and 4 by some column buckling of the web. None of the foregoing failures resulted from elastic instability in the web, permanent set being encountered in every case. This is not surprising, however, since the depth-thickness ratios ranged from about 20 for the 5-in. I-beams to about 25 for the 12-in. I-beams. According to the theory of buckling of flat plates in shear, elastic buckling in Alloy 17S-T becomes critical for depth-thickness ratios of 52, or more.[7]

It is interesting to note that most of the failures occurred by column buckling at points of load concentrations. Failures of this type seem to occur when the average compressive stress exceeds the column strength of the web. In computing this stress it has been found that the load or reaction may be considered uniformly distributed over an area equal to:

$$a = t\,(b + h) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

in which, in addition to the notation of the paper, b = effective length of bearing-block, in inches. This area should be considered as symmetrically placed with respect to the load or reaction and should be altered in the case of the latter if the overhang of the beam is shorter than $\frac{1}{2}$ $(b + h)$. In beams of normal proportions, without stiffeners, column buckling of the web at points of concentration is more likely to occur than any other type of web failure. Messrs. Lyse and Godfrey prevented this behavior, except in the preliminary tests, by means of web stiffeners, end plates, and suitable bearing-blocks at points of concentrated load and reaction.

Test No. 5 (Table 2) is an interesting example of what may be accomplished by the use of stiffeners in increasing the web strength of beams. A load corresponding to an average computed web shear of 64 200 lb per sq in., almost double the nominal shearing ultimate stress, was carried without producing complete failure in the beam. In Test No. 3, without stiffeners, the average stress at failure was only 35 700 lb per sq in. A similar comparison is found in Test No. 4 and Test No. 6, although the strengthening effect of the stiffeners was not nearly so pronounced. Fig. 22 is a view of Specimens Nos. 5 and 6 showing the shearing distortion possible without actual rupture of the metal.

Values of ultimate strength and corresponding average shearing stresses in the web have been given in Table 2. No values have been given for the yield points of the beams because the load deflection curves break over too gradually to permit the selection of values which are consistently satisfactory. Theoretically, beams will begin to yield when either the web or flange stresses first exceed the elastic range of the material, and since the ordinary formulas of mechanics are quite accurate within the elastic range, the load corresponding to the first yielding of a beam can be calculated quite definitely if the stress-strain relations of the material are known in tension, compression, and shear. It should be pointed out in this connection that aluminum alloys have no pronounced yield point such as mild steel and, for this reason, the yielding occurs very gradually and the point of first yield does not represent a distinct change of behavior of a beam under load. The ultimate load-carrying capacity of a beam, as determined experimentally, is generally a much more definite value to use in comparison of beams which do not fail by elastic buckling and one which, in the opinion of the writers, is of considerable importance to the designer.

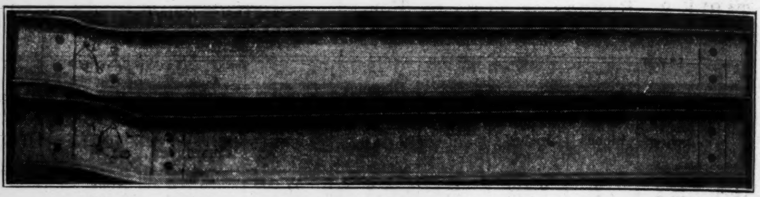

FIG. 22.—WEB FAILURES IN 5-INCH I-BEAMS (TESTS NOS. 5 AND 6, TABLE 2).

Figs. 23 and 24 show the distribution of stress in the 12-in. I-beam used in Test No. 10. The stress determinations were made by a 2-in. Berry strain-gauge, all measurements on the web being taken on rosettes (four gauge lines intersecting at a point) spaced on $2\frac{1}{2}$-in. centers over the area adjacent to the load and reaction point. All readings were taken on both sides of the web and averaged. In view of the recommendation of Messrs. Lyse and Godfrey that the average web shear be computed on the basis of the net area of the web (h t), attention is called to Fig. 24(b). The agreement there between the measured stresses and the average shear on the gross area (D t) is very

satisfactory. The use of net area seems even less justifiable when, as shown for the welded beams of the steel series, it gives average values greater than the maximum as computed by the rational formula.

Fig. 25 shows an aluminum alloy plate girder, 30 in. deep (24-in. clear depth) with a $\frac{1}{4}$-in. web, on which numerous tests have been made in connection with a study of elastic buckling phenomena. Strains and lateral deflections in the web were determined for different positions of load, sizes of bearing-block, and arrangements of vertical and horizontal stiffeners. While the results obtained are too comprehensive to be presented here in detail, it is believed a few observations will be of interest.

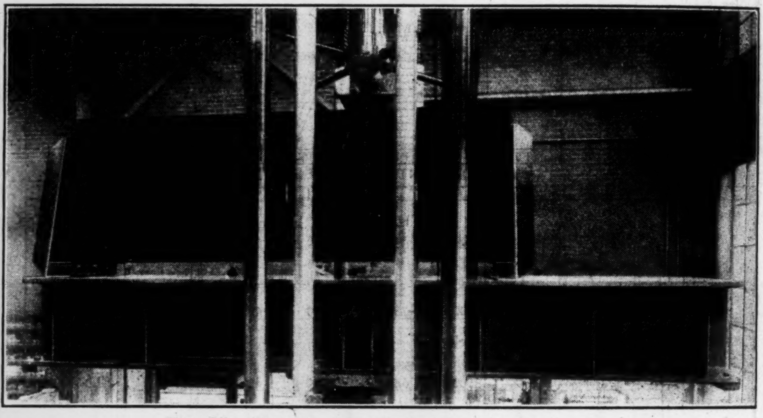

FIG. 25.—TEST OF ALUMINUM ALLOY PLATE GIRDER.

When no web stiffeners were used, failures of the web occurred by elastic buckling as a column directly under the load. It was found that the loading required to produce this type of failure could be predicted reasonably well by the same method outlined previously in connection with the discussion of Table 2. This same type of failure also occurred when stiffeners were used and the load was applied between the stiffeners. In such cases it was found, however, that in computing the average compressive stresses the load should be considered uniformly distributed over an area equal to:

$$t\,(b + h)\left[1 + 2\left(\frac{h}{s}\right)^2\right] \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which, s = the clear distance between stiffeners, and the other terms are as previously defined.

When the web was properly stiffened at points of concentrated load, shear or diagonal compression buckling was obtained. Since the lateral deflections occurred gradually, however, almost from the first application of the load, it was difficult to select a point at which the buckling of the web might be said to be critical. In some instances, deflections of as much as $\frac{1}{4}$ in. were observed without permanent set. While this behavior made it impossible to obtain a precise experimental check on the theory of elastic buckling,[7] the writers believe the theory to be satisfactory for predicting loads at which the lateral deflections may become appreciable. It was quite evident, however, that the computed buckling strength of the web was not necessarily a criterion of its ultimate load-carrying capacity.

A double-web box girder of Alloy 17S-T was investigated for web buckling in much the same manner as previously described. The webs in this girder were 15 in. deep by $\frac{1}{16}$ in. thick, having a ratio of unsupported depth to thickness of 172. The results of the tests on this specimen tended to confirm those obtained on the plate girder. It was particularly noticeable in this case that the elastic buckling of the web was not a definite indication of the ultimate load-carrying capacity of the specimen. Even after relatively large lateral deflections were observed, the girder continued to carry higher loads with no evidence of permanent set or other distress. This is a point of considerable interest to designers because there is sometimes a tendency to over-emphasize the importance of elastic buckling. In structures in which the load-carrying capacity considerably exceeds the point of elastic buckling, the writers can see no reason why both factors should not be considered in design.

In concluding this discussion, the following points may be summarized:

1.—In normally proportioned beams, without stiffeners, column buckling of the web at points of load concentrations is more likely to occur than any other type of web failure.

2.—When stiffeners are used at points of concentrated load and reaction, the ultimate load-carrying capacity of a beam may exceed to a considerable extent the point at which yielding of the web material begins.

3.—Since there is no marked yield point in aluminum alloy beams the ultimate load-carrying capacity seems to be the most essential information to be obtained from beam tests in which no elastic buckling occurs.

4.—The measured distribution of stress in the web of a 12-in. I-beam indicates that the average shearing stress should be computed on the basis of gross area of the web rather than on net area, as recommended by Messrs. Lyse and Godfrey.

5.—The buckling of thin webs is a gradual rather than a sudden phenomenon so that it is difficult to obtain a precise experimental check on the theory of elastic buckling. However, the theory apparently provides a satisfactory means of determining the loads at which the lateral deflections may become appreciable.

INGE LYSE,[8] M. AM. SOC. C. E., AND H. J. GODFREY,[9] ESQ. (by letter).—The data on aluminum alloy beams presented by Messrs. Moore and Hartmann are valuable additions to the results obtained on steel beams by the writers. Unfortunately, the data on the aluminum beams give only the ultimate load with no indication of the load at which the beam would become useless due to excessive deflections. As already stated in the paper, the load at failure has no significance except that it is a measure of the toughness of a beam after it has passed its usefulness. In structural design, the load at which the deflection exceeds the maximum permitted by the usefulness of the building must be taken as the basis for estimating the factor of safety. Since all the aluminum alloy beams had depth-thickness ratios of only 25 and less, buckling of the web would not take place at stresses less than the yield-point stress of the material.

---

[8] Research Associate Prof. of Eng. Materials, in Chg., Fritz Eng. Laboratory, Lehigh Univ., Bethlehem, Pa.

[9] Former Research Fellow in Civ. Eng., Lehigh Univ., Bethlehem, Pa.

No information is given as to the stress in the web at the yielding of the beam and, consequently, Messrs. Moore and Hartmann give little support to their criticism of the writers' recommendation that the average web shear be computed on the net area ($h\ t$) rather than on the gross area ($D\ t$). The observed stresses presented in Fig. 24(*b*) do not necessarily represent the stresses that cause yielding of the beam. H. M. Westergaard, M. Am. Soc. C. E., has shown that the concentration of shearing stress at the fillet between the web and the flange of the beam may become significant for beams having relatively small fillets. Fig. 21 also shows that the computed stresses at the yielding of the beam, instead of being greater (as they should be according to Messrs. Moore and Hartmann) are less than the yield-point stresses of the web material.

One-half the beams reported by Messrs. Moore and Hartmann failed by what has been termed web crippling. While web buckling is a failure produced by lateral instability of the web as a whole, web crippling is a local failure produced by excessive compressive stresses. An investigation of web crippling was also conducted at Lehigh University with the co-operation of the Bethlehem Steel Company and its subsidiary, the McClintic-Marshall Corporation, at the time of the tests of web buckling. The results were not included in the paper, in order to make a definite distinction between the two types of stress condition. They are presented herewith.

Web crippling is principally a local failure produced by excessive compressive stresses, and the problem of preventing its occurrence is most common in the design of structural beams supported on seat angles. The aim of the investigation was to establish the stress at which yielding due to web crippling took place.

The program included the testing of six 22-in., 58-lb, rolled, Bethlehem beams, four of which were cut from the same section and two from another section. The information for these beams which had an $\frac{h}{t}$ ratio of about 52, is given in Table 3. Three of the beams were designed to fail at the point of application of the load and the other three, at the supports. The nominal bearing lengths were 7 and 11 in. for the center failures, and $3\frac{1}{2}$ and $5\frac{1}{2}$ in. for the end failures.

In order to prevent failure due to end twisting, steel plates were welded to the bottom flange at each end of the beam. In each end plate, at a height even with the top flange, there was a slot which served as a guide for bars welded to the center of the top flange. This arrangement, as shown in Fig. 26, allowed the top flange to deflect vertically, but restrained it from moving laterally.

* Doubtful, due to thin bearing plates.

All the beams were supported by rollers and loaded at the center of the span. A roller was also used for the application of the load for Beams Nos. 1 and 2, but a spherical bearing block was used for this purpose in the testing of the remaining four beams. Steel bearing plates of the proper length were used to transfer the load from the rollers and bearing-block to the beam. Vertical deflections and strain-gauge observations were taken on all beams. Except for Beam No. 1, all beams were whitewashed before testing.

FIG. 26.—BEAM *CT*-5, SHOWING END PLATE FOR PREVENTION OF END TWISTING.

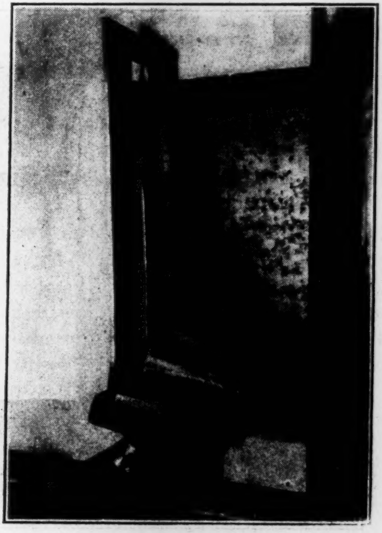

FIG. 27.—BEAM *CT*-1, SHOWING FAILURE AT THE SUPPORT DUE TO WEB CRIPPLING.

Strain lines in the web appeared at both supports at a load of 115 000 lb, and, at the center, at a load of 200 000 lb in Beam No. 1. At a load of 190 000 lb, the strains increased greatly, indicating that the actual yielding of the beam occurred. The strains observed at a point immediately above the flange indicate that the yield point of the material in the web was reached at considerably lower loads. However, this local yielding did not have any effect on the beam as a whole, which continued to take load until a maximum of 202 000 lb was reached, at which time the web crippled at the end, as shown in Fig. 27.

In computing the actual bearing length at the root of the web it was assumed that the stress was distributed through the flange on an angle of 45 degrees. The total bearing length thus equals the length of the bearing plate plus twice the thickness of the flange at the root of the web. The thickness of the flange was measured by micrometers at a point next to the fillet, as indicated in Table 3. The length of the bearing plate was $3\frac{1}{2}$ in. at the supports where the beam was designed to fail. The compressive stress at the root of the web at the yield point of the beam was 50 500 lb per sq in., which compares very well with the average tensile yield-point stress of 49 000 lb per sq in. for the web material. The full yield-point stress of the web was thus utilized in this beam.

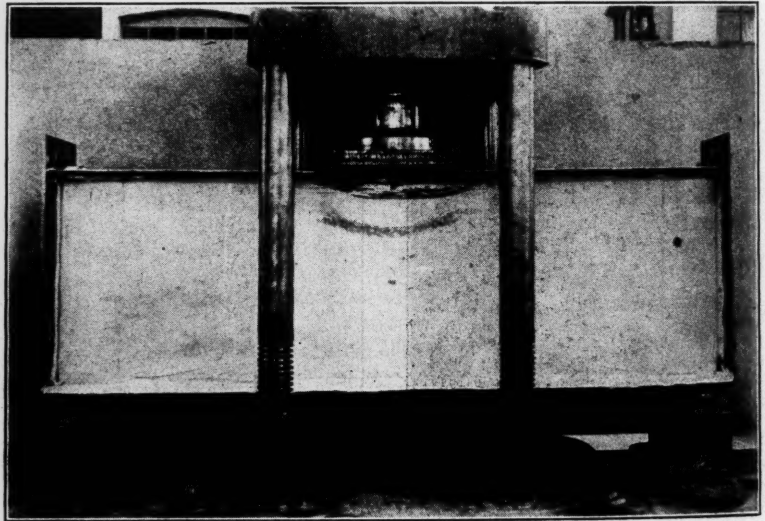

FIG. 28.—BEAM *CT*-4, SHOWING FAILURE AT THE CENTER DUE TO WEB CRIPPLING.

Beam No. 2 was designed to fail at the loading point where the length of the bearing plate was 7 in. Strain lines appeared at the supports at a load of 100 000 lb and at the loading point at 140 000 lb. Since the failure of this beam occurred at the loading point no definite indication of yielding could be obtained from the deflection curves. The strain-gauge results showed that the strains near the root of the web increased at a high rate above a load of 120 000 lb. The strains measured at the center of the web indicated a yielding at a load of 160 000 lb, which was taken as the yield-point load of the beam. The beam continued to take load until a maximum of 223 000 lb was reached, at which time the web crippled at the loading point.

At the yield point of the beam the maximum compressive stress at the root of the web was 49 000 lb per sq in., or the same as the tensile yield-point stress of the web material.

Beam No. 3 was designed to fail at the supports where the length of the bearing plates was 5½ in. To prevent failure at the center, stiffeners were welded to both sides of the web at this point.

The first strain lines appeared in the web near the center at a load of 60 000 lb. The strain lines continued to form and, at a load of 110 000 lb, they appeared in the web at the supports. The observed strains indicated yielding at a load of 220 000 lb, which was taken as the yield point of the beam, while the deflection curves indicated yielding at a load of 230 000 lb. At the maximum load of 231 500 lb, the web crippled at one of the supports. The bearing plate used for this beam was too thin for effective distribution of the load from the roller to the flange of the beam and, consequently, contributed to a concentration of stress at the center of the plate, causing local failure at low average stress.

The maximum compressive stress at the root of the web was 41 000 lb per sq in. at the yield point of the beam. This is considerably less than the tensile yield-point stress of 50 000 lb per sq in. for the material in the web.

As Beam No. 4 was designed to fail at the center, stiffeners were welded to the web at the supports. The length of the bearing plate at the center of this beam was 11 in.

The first strain lines appeared in the web at the supports at a load of 90 000 lb and, at 120 000 lb, they appeared under the loading point. The observed strains indicated a yielding at a load of 210 000 lb which was taken as the yield-point load. The beam continued to take load until a maximum of 264 400 lb was reached, at which time the web crippled at the center of the beam, as shown in Fig. 28. Also, for this beam, the bearing plate was too thin for uniform distribution of the load.

At the yield-point load the maximum compressive stress at the root of the web was 43 200 lb per sq in., which is considerably less than the tensile yield-point stress of the web material.

Beam No. 5 was similar to Beam No. 1, having a bearing length of 3½ in. at the supports where it was designed to fail. The first strain lines appeared in the web at the supports at a load of 60 000 lb, and at the loading point at a load of 130 000 lb. The vertical deflections, as well as the strains, showed that the beam yielded at a load of 160 000 lb. A slight crippling of the web at the support was noted at 190 000 lb, and, at a load of 205 000 lb, the web crippled.

At the yield-point load of 160 000 lb, the computed stress at the root of the web was 41 900 lb per sq in., which compares favorably with the yield-point stress of 44 660 lb per sq in. for the web material.

Beam No. 6 was similar to Beam No. 2, having a bearing length of 7 in. at the loading point. As this beam failed at the center, the vertical deflections indicated that there was no yielding of the beam as a whole. The strain curves, however, indicated a bending tendency in the web at a load of 80 000 lb. The rate of strains increased sharply at a load of 150 000 lb, which was taken as the yield point of the beam. The beam continued to take load until a maximum of 209 500 lb was reached and, at this load, the web crippled under the center.

At the yield-point load of the beam the maximum compressive stress at the root of the web was 45 000 lb per sq in., which is close to the yield-point stress of 44 660 lb per sq in. for the web material.

Both the flexural and shearing stresses were low in all these beams, so there was no indication of yielding due to these stresses.

Since only six beams were tested in this investigation, no general conclusions can be drawn. However, the results indicate that:

1.—The appearance of the first strain lines has no relation to the yielding of the beam as a whole, but is an indication of high local stress.

2.—The compressive stress at the root of the web at the yield point of the beam corresponds quite well with the tensile yield-point stress of the material for properly designed bearing plates.

3.—The yielding was caused by the compressive stresses at the root of the web.

4.—The following formula may be used in computing the compressive stress at the root of the web: $f_c = \frac{R}{t(A + 2\ N)}$, in which, $f =$ compressive stress; $R =$ load on bearing plate; $t =$ thickness of web; $A =$ length of bearing plate; and $N =$ thickness of flange at edge of fillet.

ANALYSIS OF SHEET-PILE BULKHEADS

By PAUL BAUMANN,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JACOB FELD, R. L. VAUGHN, M. A. DRUCKER, RAYMOND P. PENNOYER, D. P. KRYNINE, E. h. O. FRANZIUS, THEODOR VON KÁRMÁN, E. LOHMEYER, AND PAUL BAUMANN.

SYNOPSIS

The introduction of the deep-arch, steel, sheet-pile section in 1912 has gradually led to the construction of bulkheads of unprecedented height. During this development the designer has been confronted by serious difficulties because of the uncertainties as to the effective passive resistance of the ground and the interlock efficiency of the piles. Only since the end of the World War have large-scale experiments on these important questions been made in the United States and Europe, the outstanding ones on passive resistance of soil being those by Professor E. h. O. Franzius in the hydraulic laboratory of the Institute of Technology, Hanover, Germany.

The exploration of the phenomenon of passive resistance of soil still being in its infancy, the present design of bulkheads is based on the convenient assumption that passive resistance of soil may be represented by static forces that vary linearly with the depth, irrespective of the magnitude of movement of the wall. The elastic behavior of the soil is thereby ignored.

The object of this paper is: (1) To outline and to interpret the result of full-sized tests on a steel sheet-pile bulkhead, particularly in regard to the effective, passive resistance of sand and the interlock efficiency of deep-arch sheet-piling; (2) to offer suggestions pertaining to a possible stress distribution in the passive prism between the wall and the surface of rupture; and (3) to present a new theory of the stability of bulkheads, which takes into consideration the elasticity of both wall and soil and which treats the problem as statically indeterminate.

NOTE.—Published in March, 1934, *Proceedings*.

[1] Asst. Engr., in Chg., Mountain Div., Los Angeles County Flood Control Dist., Los Angeles, Calif.

INTRODUCTION

During the construction, in 1929-1930, of the Outer Harbor of the City of Long Beach, Calif., the steel, sheet-pile bulkhead failed in two places (see Fig. 1); that is, in 12 ft and 25 ft of water, more or less, respectively. As the City and the contractor disagreed on the cause of these failures, a suit was filed by the latter, which was tried in the Superior Court of Los Angeles County during the second half of 1932.

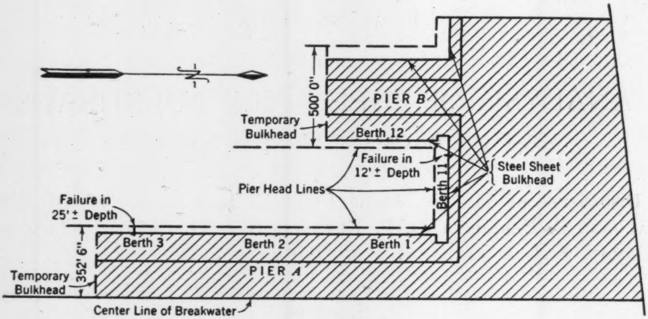

FIG. 1.

In substance the plaintiff claimed that the failure was due to faulty design and sea action on the toe slopes, while it was the defendant's contention that the failure was caused by faulty construction, particularly due to overdredging the toe slopes and failure to place a preliminary fill behind the bulkhead.

At both places, the pushing out of the steel sheet-piling was directly attributable to the removal of material below the theoretical toe slope (Fig. 7) by whatever agency that caused it.

The toe slopes were undercut by a suction dredger as in ordinary side-slope work, which was a dangerous procedure in view of the importance of the toe material relative to the stability of the bulkheads.

On the other hand, a terrific storm occurred during the dredging operation, which demolished part of the break-water and caused considerable agitation in the harbor basin, and it was probably this evidence more than anything else that prompted a judgment substantially in favor of the contractor.

For the purpose of establishing facts in connection with this case the following tests were made: (1) Soil tests on samples from the fill area and from the channel; (2) tests to establish the depth of water standing in the fill area; (3) tests to establish the passive resistance of the fill; and (4) tests to establish the minimum interlock efficiency of steel sheet-piling.

SOIL TESTS

The soil tests were made in the City Laboratory in Long Beach, in accordance with the standards of the American Society for Testing Materials where such standards existed, and with methods adopted by the supervising engineers, Charles T. Leeds, M. Am. Soc. C. E., Frederick J. Converse, Assoc. M. Am. Soc. C. E., and the writer. These tests were concerned particularly with the determination of the angle of repose "in the dry" and under water.

For the determination of the angle of repose in the dry, a standard inverted 12-in. slump cone was set on a smooth steel plate and filled with dry material. The cone was then lifted slowly, permitting the material to escape at the bottom (smaller) opening and to form a cone. Without exception these cones were very regular, and the angle of repose differed little at various locations.

Three methods were investigated to determine the angle of repose under water. In this connection, a water-tight container, about 2 by 2 by 2 ft, with a glass front, was used.

With the first method, a dry cone was produced in the empty container which was then gradually flooded until it was completely submerged. Complete saturation was indicated when air bubbles no longer escaped, after which the water was siphoned off carefully and the angle of repose measured in at least three different places.

With the second method, saturated material was released through the large opening of a 6-in. slump cone into the filled container; the water was then siphoned off and the angle of repose measured as before.

Finally, with the third method, a 6-in. slump cone was set on the bottom of the empty container in an inverted position and was weighted down so as to make it water-tight at the bottom. The container was then filled to within ½ in. from the top of the cone and the latter was filled with dry material. The cone was then raised slowly until all the material had escaped at the bottom and had formed a cone. When the water was siphoned off, the angle of repose was measured as before.

As the last method consistently gave smaller angles of repose than the first and second methods, only the results due to Method 3 were recorded.

Standing Water in the Fill Area.—For the purpose of establishing the standing water level, two holes, roughly 30 ft in diameter at the surface and with the bottom at mean lower low water, were excavated and the water-surface elevation was recorded three times daily for a period of several weeks. This work was done in the fall of 1930. The observations showed a very small variation of the water-surface elevation from + 3.50 at a distance of 50 to 75 ft from the bulkhead.

TESTS TO ESTABLISH THE PASSIVE RESISTANCE OF THE FILL

Test Equipment.—For the purpose of establishing the passive resistance of the fill, steel sheet-piling was driven in the fill area of Pier *B* (Fig. 1) so as to form a tank, as shown in Fig. 2.

The face of the tank, consisting of seven sheets, 28 ft long, and driven to a maximum of 12 ft into the ground, was free to deflect (fully 10 in.) within the yield of the copper seals. To each of three alternate sheets (see Fig. 2(*b*)), being convex to the outside, six ½-in. threaded rods were brazed, 3 ft on centers, so as to have the bottom rods coincident with the ground surface. The copper seals were carried to a depth of 7 ft, more or less (minimum, 5 ft), below the surface.

At a vertical distance of 15 ft above the ground surface, four of the seven sheets forming the test wall were anchored to the back-wall by means of 1-in. rods, but walers were omitted to prevent interference with slipping along the interlock. As sea water was the medium that produced pressure, the interlocks of the test wall were made partly water-tight through oakum and mastic, the first being loosely placed, not caulked, and serving to keep the mastic from squeezing through the joints.

FIG. 2.

Five 3-in. valves, 3 ft on centers, were welded to one of the sheets of the back-wall for the purpose of regulating the water surface during the test.

The deflections were measured by means of a transit set up 100 ft from the tank and sighting parallel to the test wall approximately flush with the free ends of the indicator rods. While the transit remained stationary, a nut was screwed on each indicator rod until its flat side was in line with the vertical hair of the transit. Each indicator nut was secured in its position by a lock nut. The distances on the indicator rods corresponding to the deflections were determined with a pair of dividers and were then sealed by means of a special rule reading to 0.01 in.

Prior to the test the fill in front and immediately adjacent to the tank was flooded with sea water and was kept wet during the tests. A test hole made with a 6-in. auger immediately before the final test showed the ground to be in a wet condition between the surface and the limit of capillary attraction which appeared to be about at Elevation + 4.50, or 1 ft above standing water.

Test Results.—The average sand in this location is believed to be closely represented by Sample *L* in Table 1; that is, the average specific weight was 2.70, and the percentage of voids, 50, which gives a weight per cubic foot of about 85 lb. The average moisture content in the sand was estimated at from 15 to 20% by weight, which means a 50% saturation, more or less. The effective weight of the material, offering passive resistance, was estimated at 100 lb per cu ft. The angle of internal friction (30°) was assumed to coincide with the angle of repose under water.

TABLE 1.—TESTS ON SAMPLES OF FILL MATERIAL

The active pressure below the ground surface is subject to estimation, since a theoretical analysis of such pressure is impossible, due particularly to the uncertainty of the hydrostatic pressure under the influence of percolation. The average fineness of the material at this location (Sample *L*, Fig. 3), permits a small percolation velocity, and the corresponding pressure on the sheet-piling was assumed to vary parabolically rather than linearly between the ground surface and the bottom of the sheet-piling, the latter coinciding approximately with standing water level. The parabolic distribution of pressure (in contradistinction to the usual assumpton of linear distribution with a zero lateral pressure at the bottom of the sheet-piling) is believed more nearly to represent the true condition due to the relatively short duration of the test. The influence on the stability of the structure of this assumption, as compared to the linear distribution, is small.

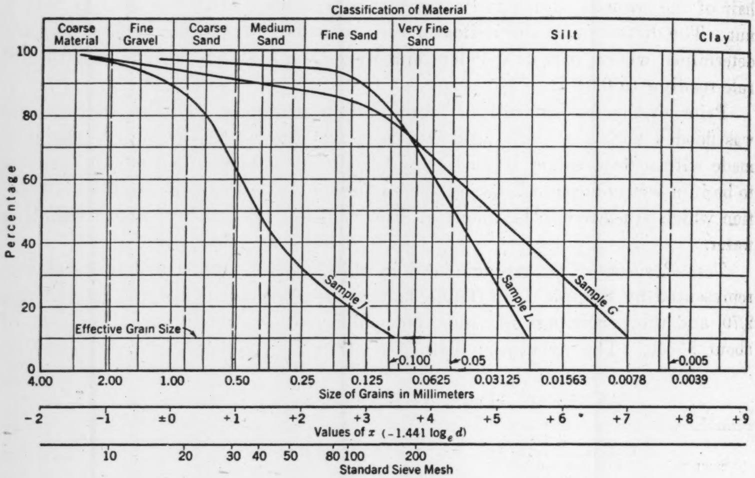

FIG. 3.

Under these assumptions the active forces are determined, the principal one being the water pressure between the upper support and the ground surface, which is known exactly. The active forces below the ground surface are not known exactly, but can be approximated with reasonable accuracy. The error that may be involved affects the ratio between the actual passive resistance and that based on Coulomb's formula, to a small degree.

DETERMINATION OF EFFECTIVENESS FACTOR OF PASSIVE RESISTANCE

The equilibrium conditions were analyzed for passive resistances of 100, 125, 150, and 175%, respectively, of the one due to Coulomb's formula for a frictionless wall. The Coulomb formula is:

$$E_p = \frac{1}{2} \; \gamma \; t^2 \tan^2 \left(45 + \frac{\phi}{2}\right)$$

in which, E_p is the passive resistance of earth, in pounds; γ, the weight per cubic foot of sand; t, the penetration of sheet-piling, in feet; and ϕ, the angle of internal friction assumed to be equal to the angle of repose under water = 30 degrees.

The equilibrium conditions for each case were based on the interlocked section modulus, namely, $S = 9.30$ in.^{3} and a modulus of elasticity of $E = 29 \times 10^6$ lb per sq in. These elastic lines were finally plotted (see Table 2) to the same scale as the observed line, with the result that an effectiveness factor of 1.68 was found to represent the actual conditions most closely. The following values, per foot of wall, apply in the case of Table 2:

For a single sheet-pile,

$$S_{x\text{-}x} = 4.17 \text{ in.}^3$$
$$I_{x\text{-}x} = 2.94 \times 4.17 = 12.25 \text{ in.}^4$$
$$EI_{x\text{-}x} = 12.25 \times 29 \times 10^6 = 355 \times 10^6 \text{ in}^2\text{-lb.}$$

For interlocked sheet-piling,

$$S_{n\text{-}n} = 9.30 \text{ in.}^3$$
$$I_{n\text{-}n} = 2.94 \times 9.30 = 27.35 \text{ in.}^4$$
$$EI_{n\text{-}n} = 27.35 \times 29 \times 10^6 = 793 \times 10^6 \text{ in}^2\text{-lb.}$$

The interlock efficiency—that is, the effective moment of inertia of the wall about the axis of symmetry—was found by interpolating the D-weights for 1.68 E_p and by determining the polar distances of the string polygon (Table 2), which coincides with the observed deflection curve. The effective index of rigidity, $E\,I$, in percentage of its maximum value for $E = 29 \times 10^6$ lb per sq in. and $I = 27.35$ in.^{4}, is found to be:

$$E\,I = \frac{\text{Polar distance} \times 100}{H_{\text{max.}}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and the effective section modulus was found by trial and error; that is, by determining corresponding E-values which, in turn, will check the stress-strain diagram of the average of seven samples as shown in Fig. 4. The moments for 1.68 E_p were not interpolated, but those for 1.75 E_p were used instead. As these latter moments are slightly smaller than the first ones, the result is in keeping with the purpose of the test, namely, to establish minimum values of interlock efficiency.

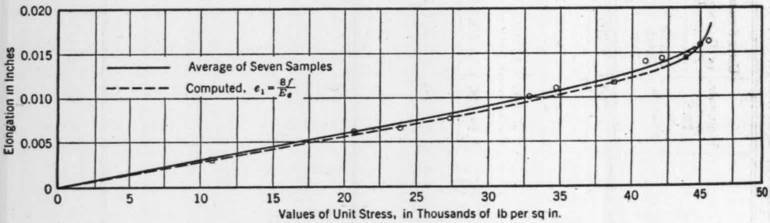

FIG. 4.

METHOD OF GRAPHICAL ANALYSIS

The method of analyzing equilibrium conditions for various effectiveness factors of passive resistance is shown in Fig. 5 for the single case of one and three-quarters times passive resistance due to Coulomb. In principle it is the method outlined by Dr. Lohmeyer[2], which shows decided refinements as compared to methods heretofore used in the statical analysis of bulkheads. These refinements are due particularly to the recognition of the effect of

FIG. 5.

restraint in the ground, which has been comprehensively treated by Raymond P. Pennoyer, Assoc. M. Am. Soc. C. E.[3]

The passive resistance on the active side, that is, back of the wall, is of the same order of magnitude as the one in front and, in most cases, may be assumed to be equal to the latter as an upper limit. An opinion is extant[4] to the effect that the passive resistance on the active side is greatly reduced, due to friction between the soil and the wall, as compared to the passive resistance that would develop without wall friction. The writer does not agree with this viewpoint. Such a condition could exist only as long as no movement of the bottom part of the sheet-piling toward the back of the wall occurred; or, in other words, as long as the piles were subjected to active pressure. As soon as deflection begins and the bottom of the wall, or the part adjacent to it, moves backward (thereby displacing the particles) the forces getting into play are due to passive resistance, as on the other side of the wall. Any friction between the soil and the wall is augmenting this passive resistance, and the principal difference between the two cases is the angle of inclination of the sheet-piling in front of the wall, which (due to its "overhang") tends to increase the slope of the resistance vector, while back of the wall it tends to decrease it.

If the back requires a smaller allowance for passive resistance than the front of the wall, it is due to this difference in slope and the relative movement of the sheet-piling, which is governed by the distance of the point of rotation above the bottom. To produce a certain passive resistance at a certain depth requires a certain movement tending to displace the particles and thereby compress them. This movement is not entirely elastic, however; it is partly plastic. There is a certain lost motion, so to speak, that does not meet appreciable passive resistance. However, it must be remembered that due to the driving of the sheet-piles the adjacent ground is already compressed, due to a displacement which is equal to the thickness of the piles. The magnitude of this compression is reflected in the frictional resistance to both driving and pulling of the sheets. "Refusal" is due to this friction, which can only develop under compression; and so also is the enormous resistance to raising a pile after it has been driven to refusal.

Due to the forward deflection of the sheet-piling above the point of rotation, the ground stretches on the active side, and its density is thereby reduced, which would lead to a reduced, passive resistance. In the case of an ordinary bulkhead, however, the fill back of the sheet-pile wall acts as a surcharge and, in most cases, will more than compensate for the stretching. As to the test under consideration, the passive resistance behind the wall was assumed to be 70% or less of the passive resistance in front, because the surcharge was water.

The writer's opinion on this important phase of bulkhead design is strengthened by observations of the shape of sheets pulled at Berth 3, Pier *A* (Fig. 1), after the bulkhead had blown out with approximately 27 ft of fill behind it; and of the shape of sheets used in the test (Fig. 6). As to piles that were pulled after the failure at Berth 3 (Fig. 1), a statical analysis, for the original conditions, shows no restraint (Fig. 7), while the sheets, after pulling, showed decided counterflexure, which would have been impossible under the contention[4] that passive resistance on the active side is only 18% of that in front of the wall.

---

[3] "Design of Steel Sheet-Piling Bulkheads," *Civil Engineering*, Vol. 3, No. 11, November, 1933.

[4] "Der Grundbau" von Brennecke-Lohmeyer, Vol. II, p. 83.

Returning to the statical analysis, the next step will be to ascertain whether or not there is a restraint. For this purpose subtract the active from the passive pressure area and extend the resulting passive pressure area; that is, the λ_p–λ_a line indefinitely downward (Fig. 5(a)), divides the pressure area conveniently, and combines the corresponding active and passive forces in a force polygon. Then draw the moment diagram (Fig. 5(b)), which will be S-shaped, and extend it far enough downward to cover the entire known or probable penetration.

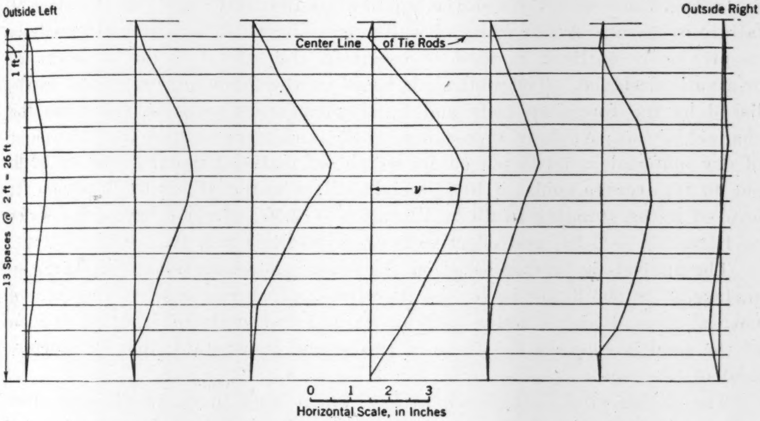

FIG. 6.—PERMANENT DEFORMATION OF TEST PILES FACING TEST WALL.

The minimum, theoretical penetration is then immediately found by means of a line through the upper support point and tangent to the moment line. The depth of the point of contact below the natural ground surface is then equal to the minimum theoretical penetration.

The next step will be to determine the practical minimum penetration, in which case the passive resistance at the bottom of the sheet-piling must be zero. At this penetration there is no restraint, but any additional penetration will cause part, and finally full, restraint.

In graphic statics, the three equilibrium conditions — $\Sigma H = 0$; $\Sigma V = 0$; and, $\Sigma M = 0$ — are satisfied if both the polygons close, the force polygon satisfying $\Sigma H = 0$ and $\Sigma V = 0$, and the string polygon being such that the sum of all the moments about an arbitrary point is zero ($\Sigma M = 0$).

If the penetration is given, as in this case, the problem is to find the most unfavorable load distribution for which equilibrium exists. If the penetration is such as to permit restraint to develop, the problem is again facilitated in using a single force, which, in this case, must go through the point of rotation of the sheet-piling; that is, the point some distance above the bottom which, during deflection, remains stationary. Force F (Fig. 5) again must be found by trial; it represents the resultant resistance of the cross-hatched area behind the sheet-piling. The final load distribution is found by deducting the cross-hatched resistance area on the active side from that on the passive side, and by drawing Line d'-e' so as to balance the differential areas above and below this line.

In Fig. 7 a section through the bulkhead at Berth 3 (Fig. 1) at the place of failure is shown. A 1-ft width of wall is considered. The method of analysis as previously outlined is used to ascertain the safety of the structure as originally designed. The analysis is based on the following properties, established by the foregoing tests and by supplementary tests on soil from the channel bottom; Angle of repose, dry, = 35° and, under water, = 30°; weight of dry material = 90 lb per cu ft; weight of material under water = 52 lb per cu ft; average voids = 40%; weight of sea water, W, = 64 lb per cu ft; level of water, standing in fill = Elevation + 3.50; effective lowest low water = Elevation − 1.50; and effective hydrostatic head = 5 ft.

The analysis is further based on the following assumptions: Surcharge on surface, p_1 = 500 lb per sq ft; the effectiveness factor of passive resistance of natural ground and a rough wall = 2; and the angle of internal friction of the sand is equal to the angle of repose and is constant, that is, independent of the depth.

The timber piles (not shown in Fig. 7), at least 16 in. in diameter, that support the relieving platform, take one-third the active earth pressure. The spacing of these piles in the first row, which is 2 ft 6 in. back of the steel sheet-piling, is 2 ft 11 in. (average) from center to center. This assumption is believed to be conservative, as nearly one-third the volume of the active prism is retained by the timber piling without the aid of arching.

The influence of the reinforced concrete encasement beam at the top of the sheet-piling was neglected, but the restraint of the sheet-piling due to the part that was encased in the cantilever end of the reinforced concrete relieving platform, was considered. The critical section of the platform has an over-all depth of 22 in. and the center line of the reinforcing steel, consisting of $\frac{3}{4}$-in. square bars, 8 in. on centers, is 19 in. from the top.

The load area due to earth pressure was determined by means of the relations, $\lambda_a = \gamma \tan^2\left(45 - \dfrac{\phi}{2}\right)$ and $e_a = \dfrac{\lambda_a\, p}{\gamma}$. The influence on the bulkhead of earth and surcharge above the relieving platform was included.

The minimum passive resistance, E_p, of the material below the theoretical toe slope was determined graphically by means of Culmann's E-line method at 20 400, or 64% of the minimum passive resistance for a level ground surface at Elevation — 24.50.

FIG. 7.—EXAMPLE OF BULKHEAD ANALYSIS.

The analysis shows that the lower end of the bulkhead is not restrained and that it is a case of practical, minimum penetration. The findings may be summarized as follows:

Net passive resistance, $E_p = 13\,400$ lb
Lower reaction, $B_0 = 5\,530$ lb
Safety against push-out,

$$S_p = \frac{13\,400}{5\,530} = 2.42$$

Average stress in anchor rod and bars,

$$f_a = \frac{10.50 \times 7\,555}{2.30 \times 20 \times 0.39} = 7\,850 \text{ lb per sq in.}$$

Maximum fiber stress in steel sheet-piling used,

$$f_s = \frac{6.60 \times 10\,000 \times 12}{25.86} = \pm\ 30\,600 \text{ lb per sq in.}$$

Stresses in critical concrete section:

Maximum compression in concrete = 460 lb per sq in.
Maximum tension in reinforcing steel = 17 400 lb per sq in.

Maximum deflection of steel sheet-piling,

$$\Delta\ (\text{max.}) = \frac{1.20 \times 10^6 \times 8.50 \times 12^3}{29 \times 10^6 \times 25.86 \times 5.687} = 4.13 \text{ in.}$$

The average of twenty-eight tests of specimens cut at random from the steel sheet-piling showed a yield point of 45 782 lb per sq in. and a breaking strength of 75 510 lb per sq in.

If the distance from the original ground surface at the center line of the sheet-piling to the zero point of the load area is termed a_0, and the distance from there to the bottom is t_0, then it may be shown[5] that the total penetration is,

$$t = a_0 + 1.20\ t_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

The distance, X_0 (Fig. 7), which is the point of zero moment below the original ground surface, reaches a minimum value for full restraint, and the same is given at approximately 0.10 h_0, provided the angle of repose of the ground under water is at least 30 degrees. The height of the top of the fill above the natural ground at the center line of the sheet-piling is denoted by h_0.

From the equation for the restraining or negative moment and from Equation (2), a formula for the penetration, t_f, for full restraint is obtained, which when simplified reads,

$$t_f = 1.60\ a_0 - 0.06\ h_0 + 1.20 \sqrt{\frac{6\ B_0}{2\ \lambda_p - \lambda_a}} \ \ldots\ldots\ldots\ldots (3)$$

---

[5] "Der Grundbau," von Brennecke-Lohmeyer, Vol. II, p. 85.

and, in which, in order to get t, in feet, a_0 and h_0 are introduced, in feet, B_0, in pounds, and,

$$\lambda_p = \gamma \tan^2 \left(45 + \frac{\phi}{2}\right) \dots\dots\dots\dots\dots\dots (4)$$

and,

$$\lambda_a = \gamma \tan^2 \left(45 - \frac{\phi}{2}\right) \dots\dots\dots\dots\dots\dots (5)$$

Equation (3) represents a valuable contribution to the art of bulkhead design, as it eliminates all the trial work previously described as far as the condition of full restraint is concerned. The deflections were determined graphically by Mohr's method; that is, by using the moment area as load area for a constant index of rigidity, $E\,I$.

From a standpoint of safety only, full restraint is always desirable, but the corresponding penetration is not necessarily the most economical one. The section modulus, S, of steel sheet-pile sections varies approximately with the square of the weight, G, per unit length. Thus,

$$\frac{S_1}{S_2} = \frac{G^2_1}{G^2_2}\text{, or } \frac{G_1}{G_2} = \sqrt{\frac{S_1}{S_2}} \dots\dots\dots\dots\dots\dots (6)$$

On the other hand, the required section modulus, based on a limiting fiber stress, is directly proportional to the maximum moment. Therefore,

$$\frac{G_1}{G_2} = \sqrt{\frac{M_1}{M_2}} = \sqrt{\frac{\zeta_1}{\zeta_2}} \dots\dots\dots\dots\dots\dots (7)$$

if $M_1 = H_0\,\zeta_1$ and $M_2 = H_0\,\zeta_2$.

If the length of sheets in a wall with part restraint is l_1, and that for full restraint is l_2, the required theoretical steel weight per unit length of l_2 in percentage of l_1 is,

$$G = 100\,\frac{l_2}{l_1}\sqrt{\frac{\zeta_2}{\zeta_1}} \dots\dots\dots\dots\dots\dots (8)$$

which is not necessarily less than 100. The practical economy factor may differ from the theoretical because it is governed by the available sections. This is illustrated in the example shown in Fig. 7. The section used was such as to resist a maximum moment of 6.60 × 10 000 × 12 = 792 000 in-lb, and the total length of sheet-piling was 42 ft, of which, 27.75 ft is above the ground and 14.25 ft is penetration. To produce full restraint 19.40 ft of penetration would be required, which would make a total length of sheets of 27.75 + 19.40 = 47.15 ft, and which would reduce the maximum moment to $\frac{4.60}{6.60} \times 792\,000 = 552\,000$ in-lb.

To keep within the same stress, namely, 30 600 lb per sq in., the section modulus of the next lighter section would be insufficient making the use of the original section for both cases necessary. Instead of a saving, there would actually be a greater cost for total restraint, due to additional length.

It must be understood that the load distribution below the original ground surface, shown in Fig. 7, is merely an approximation of the actual distribution. The latter could easily be arrived at by mere examination and trial, but would be of no advantage from the standpoint of safety, because the triangular distribution as used in the analysis gives greater maximum moments and calls for greater penetration.

The bulkhead, as shown in Fig. 7, differs from the test wall (Fig. 2) in that the sheets are partly restrained at the top due to a reinforced concrete encasement and in that the ground in front of the bulkhead is dredged to a 1 on 2½ slope, leaving a berm of about 6.75 ft.

In view of the fact that an effectiveness factor of 1.68 was established by the test in the artificial fill, the assumption of a factor of 2.00 for natural ground is believed to be safe even for sloping ground.

ANALYTICAL DETERMINATION OF INTERLOCK EFFICIENCY

The observed, elastic line is closely approximated by two hyperbolic spirals with a common point and tangent at the point of minimum radius of curvature; that is, maximum moment. This curve becomes faulty near the top support where it is of small importance, as the radius of curvature remains finite. However, it closely checks the elastic line in the vicinity of minimum radius of curvature.

The equation of the upper spiral going through the upper point of support is,

$$\sqrt{(u_1 - z)^2 + (v_1 + y)^2}\left\{\text{arc tan}\ \frac{v_1 + y}{u_1 - z} + \alpha_1\right\} = a \ldots\ldots.(9)$$

and the equation of the lower spiral, going through the observed point at the ground surface, is:

$$\sqrt{(u_2 + z)^2 + (v_2 + y)^2}\left\{\text{arc tan}\ \frac{v_2 + y}{u_2 + z} + \alpha_2\right\} = a \ldots\ldots(10)$$

The constants, u_1, u_2, v_1, v_2, α_1, α_2, and a, are determined from the observed elastic line, and the tangent in any point may then be determined for the upper curve through,

$$\frac{dy}{dz} = \frac{a\,(u_1 - z) - (v_1 + y)\sqrt{(u_1 - z)^2 + (v_1 + y)^2}}{a\,(v_1 + y) + (u_1 + z)\sqrt{(u_1 - z)^2 + (v_1 + y)^2}} \ldots\ldots(11)$$

and through,

$$\frac{dy}{dz} = \frac{-a(u_2 + z) + (v_2 + y)\sqrt{(u_2 + z)^2 + (v_2 + y)^2}}{a\,(v_2 + y) + (u_2 + z)\sqrt{(u_2 + z)^2 + (v_2 + y)^2}} \ldots\ldots(12)$$

for the lower curve.

Further, the radius of curvature for the upper curve is expressed as:

$$\rho_1 = \frac{\sqrt{(u_1 - z)^2 + (v_1 + y)^2}}{\sin^3\left\{\text{arc tan}\ \frac{a}{\sqrt{(u_1 - z)^2 + (v_1 + y)^2}}\right\}} \quad \ldots\ldots\ldots(13)$$

and for the lower curve,

$$\rho_2 = \frac{\sqrt{(u_2 + z)^2 + (v_2 + y)^2}}{\sin^3\left\{\text{arc tan}\ \frac{a}{\sqrt{(u_2 + z)^2 + (v_2 + y)^2}}\right\}} \quad \ldots\ldots\ldots(14)$$

The common point follows from $\rho_1 = \rho_2$, which is the case for $z = 10.17$ ft. As the moment, $M = A_o z - \frac{64\ z^3}{6}$, must be a maximum at this point: $\frac{dM}{dz} = 0 = A_o - 32\ z^2$; and $A_o = 3\,310$ lb. This reaction checks very closely the one determined graphically for 1.68 E_p by interpolation.

Fig. 8 shows ρ as a function of z. The dotted line at the lower end indicates a correction, based on the boundary condition that ρ must become infinite for $z = 18 \pm$. A horizontal line through $z = 18$, therefore, should be asymptotic to the ρ-curve. It is believed that these corrected ρ-values are a better approximation of the actual condition, and it is for this reason that they were used in the computation of the interlock efficiency. The lower

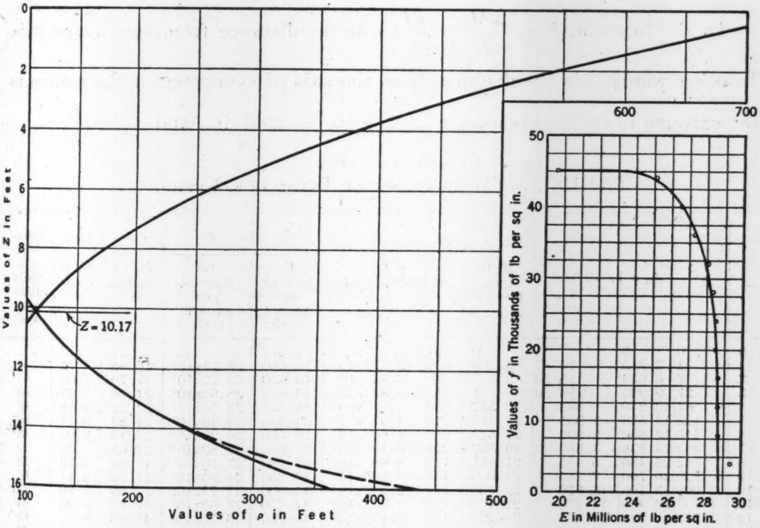

FIG. 8.—RADIUS OF CURVATURE.

FIG. 9.—RELATION BETWEEN f AND E.

spiral is subject to greater error than the upper one, because it does not go through the origin of co-ordinates and is governed by fewer check points.

In Fig. 9, the fiber stress, f, is shown as a function of the modulus of elasticity, E, based on the average of seven tests. Knowing ρ and M as functions of z, the next step is to find a relation between ρ and E, which follows from the simplified equation of the elastic line,

$$\frac{d^2y}{dz^2} = \frac{1}{\rho} = \frac{M}{EI} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

Notwithstanding the fact that the test involves material deflections which are not negligible as compared to the over-all dimensions of the wall, the error in using the approximate term, $\frac{d^2y}{dz^2}$, for $\frac{1}{\rho}$, instead of $\frac{\frac{d^2y}{dz^2}}{\left[1 + \left(\frac{dy}{dz}\right)^2\right]^{\frac{3}{2}}}$, is small since $\frac{dy}{dz}$ varies within a range of 0.07 which means that the maximum value of $\left(\frac{dy}{dz}\right)^2$ is about 0.005.

In the formula, $E = \frac{\rho M}{I} = \frac{\rho f}{e}$, e is the distance from the neutral axis. In other words, e is the distance from the axis of symmetry of the section to the extreme fiber, in this case, $e = 2\frac{15}{16}$ in. $= 2.937$ in., and $\frac{f}{E} = \frac{e}{\rho}$.

TABLE 3.—COMPUTATION OF INTERLOCK EFFICIENCY

z	z^3	$A_0 z$	$10.67z^3$	M, in foot-pounds	EI, in foot²-pounds	f In pounds per square inch	E In pounds per square inch	I_e, in inches	S_e, in inches	Interlock efficiency (percentage)

In Table 3 the interlock efficiency and the effective section modulus are computed and the resulting fiber stresses are shown in Fig. 10. It is interesting to note that near the upper support the effective section modulus is smaller than the one for the single sheet which can only be interpreted as the effect of flattening out, due to the anchor pull and the lack of a waling and of lateral support.

The same effect probably accounts for the rapid drop of the interlock efficiency toward the point of minimum radius of curvature since the sheets did not have any lateral support, because the wall is short; they would tend to flatten due to lateral thrust. As the ground is approached and penetrated, the lateral freedom disappears rapidly and the interlock efficiency only shows the effect of longitudinal slippage. In fairness to the manufacturers of this steel sheet-piling, the writer has indicated a dotted line in Fig. 10, which he believes would be a close approximation of the actual interlock efficiency of a bulkhead of equal height as the one used in the test, but with waling at the tie-backs, lateral support, and, last but not least, back-filled with saturated earth instead of water.

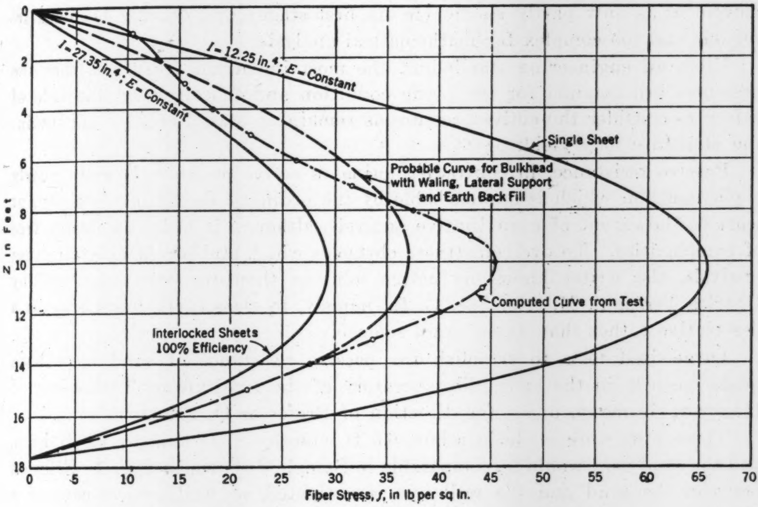

FIG. 10.—FIBER STRESSES COMPUTED FROM TEST.

In the case of a sheet-pile wall driven in natural ground and held at the top by a concrete beam (Fig. 7), or otherwise, but so as positively to prevent slippage, the section modulus for the interlocked sheets as given by the manufacturer could be used without hesitancy.

PASSIVE RESISTANCE AS A FUNCTION OF BOTH z AND y

In the foregoing, both active pressure and passive resistance of earth were treated as a statically determinate problem in accordance with the present theory. In other words, earth was treated like a fluid of smaller or greater unit weight than earth for active pressure and passive resistance, respectively.

Evidently, this is not the true condition, but is an approximation that may lead to satisfactory results for practical purposes if properly applied. In the case of active pressure on an unyielding wall, it is an exact interpretation, because then the problem is statically determinate.

The pressures for this condition are maximum and decrease as the wall begins to yield, due to a stretch in the grain structure; and, finally, they reach a minimum immediately before the grain structure collapses. This movement is only partly elastic (in its first stage) and quickly becomes irregular and too complex for mathematical analysis.

From an engineering standpoint, the most important feature is that the pressures are maxima for the static condition and that it is on the side of safety to consider the active pressure as remaining static, even if the retaining structure may yield.

Passive resistance, in contradistinction to active pressure, is more nearly a phenomenon which is approachable by the ordinary theory of elasticity, at least to the extent of a qualitative analysis, although it is by no means free of complexities. To overcome these obstacles which stubbornly defy an exact analysis, the writer knows no better solution than the one suggested[6] by Charles Terzaghi, M. Am. Soc. C. E., namely, to class earth mechanics as a descriptive rather than as an exact science.

Large-sized tests to establish the passive resistance of sand have been made recently in the hydraulic laboratory of the Institute of Technology of Hanover, Germany, under the direction of Professor O. Franzius.[7]

These tests were made in a box, 6.6 ft wide by 23 ft long by 6.6 ft high, and the sand used would be comparable to Sample *J* shown in Fig. 3. Friction between the sand and the wall was investigated, as well as the case of a frictionless wall, the latter being produced by letting the wall rise (exactly counterbalanced) under the influence of friction. Values of E_p for various heights of fill are shown as functions of y, which is the horizontal movement of the wall; and likewise for the coefficient of friction, tan δ, between the sand and the wall; the latter, however, is in too small a scale to be used quantitatively. In all cases the sand was filled in in thin layers and tamped. The outstanding result of all the tests is the fact that with or without wall friction, y is a steady function of E_p and that the coefficient of friction between sand and wall decreases with the depth.

The relation between the movement, y, of the wall and E_p is satisfactorily expressed by,

$$y = f_1\,E_p + f_2\,E^{(n_0)}_p \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which, f_1 and f_2 are constants for one and the same height of fill $(z - h)$, and n_0 is an exponent which, according to Professor Terzaghi[8] is approximately 2, which checks the value found by Franzius for wet sand.

---

[6] "Erdbaumechanik auf bodenphysikalischer Grundlage," von Charles Terzaghi, Franz Deutike, 1925.

[7] *Der Bauingenieur,* 9 Jahrgang, 1928, Hefte 43 und 44.

[8] "Erdbaumechanik," by Charles Terzaghi, p. 332.

For $y = 0$ there is active (static) pressure only; that is, $E_p = E_o$. Therefore, $0 = f_1 + f_2 E_o$, and,

$$E_o = -\frac{f_1}{f_2} = \frac{\gamma\, \xi_o\, (z - h)^2}{2} \quad \text{.................} (17)$$

in which, ξ_o, according to Professor Terzaghi,[9] is of the order of magnitude of 0.42.

Introducing Equation (17) into Equation (16),

$$y = f_2\, (-E_o\, E_p + E_p^2) \quad \text{..................} (18)$$

from which, f_2 may be determined for values of y and E_p obtained by test. The value, f_1, then follows from Equation (17) and, obviously, is negative.

Factors f_1 and f_2 can be expressed as steady functions of $(z - h)$, or, in general terms,

$$f_1 = -\frac{a}{(z-h)^m} \quad \text{..........................} (19)$$

and,

$$f_2 = \frac{b}{(z-h)^n} \quad \text{..........................} (20)$$

Solving Equation (16) for E_p and making $n_o = 2$:

$$E_p = \frac{-f_1 + \sqrt{f^2_1 + 4 f_2 y}}{2 f_2} \quad \text{.................} (21)$$

and, because $dE_p = e_p\, dz$, or $\dfrac{d E_p}{dz} = e_p$:

$$e_p = \left[f_2 \left(-\frac{df_1}{dz} + \frac{f_1 \dfrac{df_1}{dz} + 2\, y\, \dfrac{df_2}{dz}}{\sqrt{f^2 + 4 f_2 y}} \right) - \left(f_1 + \sqrt{f^2_1 + 4 f_2\, y} \right) \frac{df_2}{dz} \right] \frac{1}{2 f^2_2} \quad \text{..............} (22)$$

Introducing Equations (19) and (20), and differentiating:

$$e_p = \left\{ \frac{b}{(z-h)^n} \left[-\frac{a\, m}{(z-h)^{m+1}} + \frac{-\dfrac{a^2 m}{(z-h)^{2m+1}} - 2\, y\, \dfrac{b_n}{(z-h)^{n+1}}}{\sqrt{f^2_1 + 4 f_2 y}} \right] + \left[\frac{a}{(z-h)^m} + \sqrt{f^2_1 + 4 f_2 y} \right] \frac{b n}{(z-h)^{n+1}} \right\} \frac{(z-h)^{2n}}{2 b^2} \quad \text{......} (23)$$

or,

$$e_p = \frac{a\, (n-m)\, (z-h)^{(n-m)-1}}{2\, b} \left\{ 1 + \frac{a}{R\, (z-h)^m} \right\} + \frac{n y}{(z-h)\, R} \quad \text{...} (24)$$

in which, $R = \sqrt{\dfrac{a^2}{(z-h)^{2m}} + \dfrac{4\, b y}{(z-h)^n}}$.

---

[9] "Erdbaumechanik," by Charles Terzaghi, pp. 187 and 195.

From the aforementioned tests by Professor Franzius and, particularly, for $y = 100$ mm $= 0.328$ ft; for wet sand and a rough wall, the following numerical values were found, based on the assumption that the passive resistance, E_p, as determined by test, is due to a width of 6.6 ft (2 m): $a = 10.00 \times 10^{-6}$; $b = 0.476 \times 10^{-6}$; $m = 0.535$; and, $n = 2.535$.

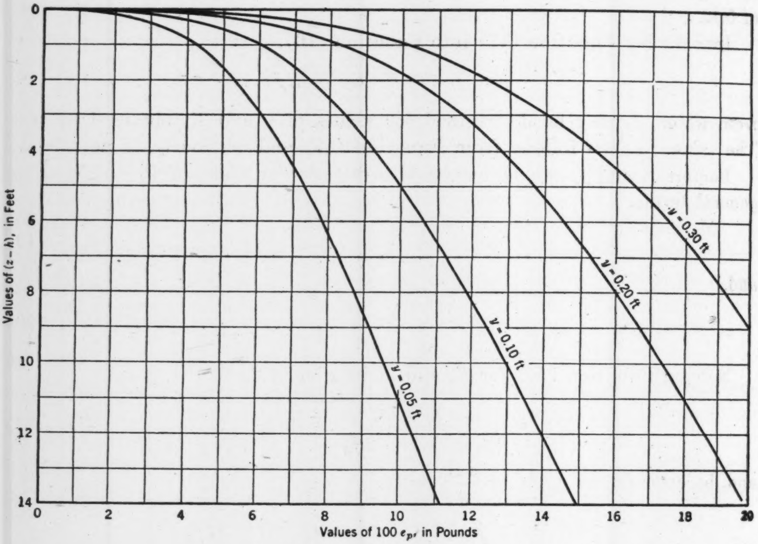

FIG. 11.—DISTRIBUTION OF SPECIFIC PASSIVE RESISTANCE, e_p.

The evaluation of Equation (24) is shown in Fig. 11. The first term in Equation (24) represents principally the influence of active pressure, and a variation of y only affects it through the root in the denominator. For $y = 0$, the term in the bracket becomes 2; then, $e_p = e_a$, and is due to active pressure only.

With sufficient accuracy, Equation (24) may be written in a simpler form, as follows:

$$e_p = \left(\gamma\, \xi_0 - 23 \sqrt[10]{y}\right)(z - h) + \frac{n y}{(z - h) R} \quad \ldots\ldots\ldots\ldots(25)$$

Remembering that $n - m = 2$, or $n = m + 2$, the last term may be written as follows:

$$\frac{n \sqrt{y}}{2 \sqrt{b}} \left\{ (z - h)^{0.5m} \left[1 + \frac{a^2}{4\, by} (z - h)^{2-m} \right]^{-\frac{1}{2}} \right\}$$

It now remains to determine whether the term, $\left[1 + \frac{a^2}{4\,by}(z - h)^{2-m}\right]^{-\frac{1}{2}}$, is convergent for such values of y as are of practical importance, thus:

$$\left[1 + \frac{a^2}{4\,by}(z-h)^{2-m}\right]^{-\frac{1}{2}} = 1 - \frac{a^2}{2 \times 4\,b\,y}(z-h)^{2-m} + \frac{3}{8}\left(\frac{a^2}{4\,b\,y}\right)^2 (z-h)^{4-2m}$$

$$- \frac{15}{48}\left(\frac{a^2}{4\,b\,y}\right)^3 (z-h)^{6-3m} + \ldots$$

Introducing values for a and b, $\frac{a^2}{4\,b} = 0.0000525$, and:

$$\left[1 + \frac{a^2}{4\,by}(z-h)^{2-m}\right]^{-\frac{1}{2}} = 1 - \frac{0.0000525}{2\,y}(z-h)^{2-m}$$

$$+ \frac{3}{8}\left(\frac{0.0000525}{y}\right)^2 (z-h)^{4-2m} \quad \ldots\ldots\ldots\ldots\ldots\ldots(26)$$

Movements of y much less than 0.01 ft are not believed to be of practical interest as they are likely to be partly plastic; their effect is small and difficult to observe. For $y = 0.01$, the right-hand side of Equation (26) becomes:

$$1 - 0.002625\ (z-h)^{2-m} + 0.000002582\ (z-h)^{4-2m} - \ldots$$

Multiplying by $(z - h)^{0.5m}$:

$$(z-h)^{0.5m} - 0.002625\ (z-h)^{v} + 0.000002582\ (z-h)^{2v} \ldots$$

in which $v = 2 - 0.5\,m$. For $(z - h) = 1$, the decrement due to the second and third terms is roughly ¼% of the first and for $(z - h) = 20$, it is about 14% of the first; which means that, with close approximation.

$$e_p = (\gamma\,\xi_0 - 23\,\sqrt[10]{y}\,)(z-h) + \frac{n\,\sqrt{y}\,(z-h)^{0.5m}}{2\,\sqrt{b}} \quad \ldots\ldots\ldots(27)$$

Equation (27) represents the general form. It may be further simplified in the case of driven sheet-pile bulkheads in quasi-level ground since, for $y = 0$, the active pressure is balanced, and the first term may be neglected. The specific passive resistance then becomes,

$$e_p = \frac{n\,\sqrt{y}\ (z-h)^{0.5m}}{2\,\sqrt{b}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(28)$$

The slope then becomes,

$$\frac{de_p}{dz} = \frac{nm\,\sqrt{y}}{4\,\sqrt{b}}\,(z-h)^{0.5\,m-1} \quad \ldots\ldots\ldots\ldots\ldots\ldots(29)$$

and the curvature,

$$\frac{d^2e_p}{dz^2} = \frac{(m-2)\,nm\,\sqrt{y}}{8\,\sqrt{b}}\,(z-h)^{0.5\,m-2} \quad \ldots\ldots\ldots\ldots(30)$$

The vertical, specific pressure due to the weight of the material alone at a depth, $(z - h)$, below the surface, is $\gamma\ (z - h)$, and the ratio, $e_p : \gamma\ (z - h)$, is, from Equation (27):

$$\frac{e_p}{\gamma\ (z - h)} = \xi = \xi_0 - \frac{23 \sqrt[10]{y}}{\gamma} + \frac{n \sqrt{y}}{2\, \gamma \sqrt{b}} (z - h)^{0.5\, m - 1} \quad \ldots\ldots (31)$$

which shows that ξ decreases with the depth.

According to the present theory,

$$\xi = \tan^2 \left(45 + \frac{\phi}{2} \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

in which, ϕ is the angle of internal friction offering resistance to sliding along the surface of rupture. Solving for ϕ:

$$\phi = 2 \text{ arc tan } \sqrt{\xi} - \frac{\pi}{2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

The influence of wall friction is neglected. The feature of primary interest is the decrease of ϕ with the depth similar to δ and the increase with y. This checks qualitatively at least the results of experiments on active pressure by Jacob Feld,[10] M. Am. Soc. C. E., and Professor Terzaghi.[11]

If, as stated previously, wall friction is neglected and $\gamma\ (z - h)$ and e_p are assumed to be principal stresses (that is, horizontal and vertical shear are zero); if $(z - h)$ and η are the co-ordinates of a point of the surface of rupture; and, if ϵ is the angle between a differential length of the surface of rupture and the vertical:

$$\frac{d\eta}{dz} = - \tan \epsilon = - \sqrt{\xi} = - \sqrt{\xi_0 - \frac{23 \sqrt[10]{y}}{\gamma} + \frac{n \sqrt{y}}{2\, \gamma \sqrt{b}} (z - h)^{0.5\, m - 1}}$$

$$= - \left(\sqrt{\frac{n \sqrt{y}}{2 \gamma \sqrt{b}}} \right) (z - h)^{0.25\, (m - 2)} \left\{ 1 + \frac{\dfrac{\gamma \xi_0 - 23 \sqrt[10]{y}}{\gamma}}{\dfrac{n \sqrt{y}}{2\, \gamma \sqrt{b}}} (z - h)^{1 - 0.5\, m} \right\}^{\frac{1}{2}}$$

$$= - c_1\, (z - h)^{0.25 (m - 2)} \left\{ 1 + c_2\, (z - h)^{1 - 0.5 m} \right\}^{\frac{1}{2}} \quad \ldots\ldots\ldots (34)$$

The term in the bracket equals $1 + \frac{1}{2}\, c_2\, (z - h)^{1 - 0.5 m} - \frac{1}{8}\, c_2^2\, (z - h)^{2 - m} + \ldots.$ For $y = 0.10$: Equation (34) yields $c_2 = 0.0407$; and $c_2^2 = 0.00165$; and for $y = 0.30$: $c_2 = 0.0216$; and $c_2^2 = 0.000466$. For $y = 0.10$ and $(z - h) = 1$, the term in the bracket yields $1 + 0.02035 - 0.000207 + \ldots.$ For $y = 0.30$ and $(z - h) = 1 : 1 + 0.0108 - 0.000058 + \ldots$; while for $y = 0.10$ and $(z - h) = 10 : 1 + 0.110 - 0.006$; and for $y = 0.30$ and $(z - h) = 10$: $1 + 0.058 - 0.0017 \ldots.$

[11] *Engineering*, June 13, 1930, p. 754 (Fig. 20).

Neglecting the third member:

$$\frac{d\eta}{dz} = -\left\{ c_1 \, (z - h)^{0.25\,(m-2)} + \frac{c_1 \, c_2}{2} \, (z - h)^{0.25\,(2-m)} \right\} \ldots\ldots (35)$$

Integrating, Equation (35) becomes (for $z = H$ and $\eta = 0$):

$$\eta = -\left\{ \frac{4 \, c_1}{m + 2} \, (z - h)^{0.25\,(m+2)} + \frac{2 \, c_1 \, c_2}{6 - m} \, (z - h)^{0.25\,(6-m)} \right\} + C \ldots (36)$$

in which,

$$C = + \frac{4 \, c_1}{m + 2} \, (H - h)^{0.25\,(m+2)} + \frac{2 \, c_1 \, c_2}{6 - m} \, (H - h)^{0.25\,(6-m)} \ldots\ldots (37)$$

and the equation for η is:

$$\eta = \frac{4 \, c_1}{m + 2} \left\{ (H - h)^{0.25\,(m+2)} - (z - h)^{0.25\,(m+2)} \right\}$$

$$+ \frac{2 \, c_1 \, c_2}{6 - m} \left\{ (H - h)^{0.25\,(6-m)} - (z - h)^{0.25\,(6-m)} \right\} \ldots\ldots\ldots\ldots (38)$$

in which,

$$c_1 = \sqrt{\frac{n}{2 \, \gamma \sqrt{\frac{b}{y}}}}, \text{ and } c_2 = 2 \, \frac{(\gamma \, \xi_0 - 23 \sqrt[10]{y}}{n} \sqrt{\frac{b}{y}}$$

The shape of this surface of rupture indicates that the premise on which the derivation of its formula (Equation (38)) is based—that e_p and $\gamma \, (z - h)$, are principal stresses—is erroneous. In other words, for a rough wall, shear is active along horizontal and vertical planes.

For a frictionless wall (which, of course, never occurs in practice), the equation for the plane of rupture should read:

$$\eta = A + B \, (z - h) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

in which, A, from observation, is $\dfrac{H - h}{\tan\left(45 - \dfrac{\phi}{2}\right)}$, and,

$$B = -\frac{A}{H - h} = -\frac{1}{\tan\left(45 - \dfrac{\phi}{2}\right)} \ldots\ldots\ldots\ldots (40)$$

Equation (39) then reads:

$$\eta = \frac{1}{\tan\left(45 - \dfrac{\phi}{2}\right)} \left\{ (H - h) - (z - h) \right\} \ldots\ldots\ldots\ldots (41)$$

Comparing this with Equation (38): $\dfrac{1}{\tan\left(45 - \dfrac{\phi}{2}\right)} = 2\,c_1\left(\dfrac{2}{m+2} + \dfrac{c_2}{6-m}\right)$; $\dfrac{m+2}{4} = 1$; and, $\dfrac{6-m}{4} = 1$. For $m = 2$, $\dfrac{1}{\tan\left(45 - \dfrac{\phi}{2}\right)} = c_1\left(1 + \dfrac{c_2}{2}\right)$.

For $\phi = 30°$, therefore, $\dfrac{1}{\tan\left(45 - \dfrac{\phi}{2}\right)} = 1.735$, and, as before, c_1 and c_2 for corresponding values of y are:

y	c_1	c_2
0.01	1.355	0.1394
0.10	2.405	0.0407
0.20	2.865	0.024
0.30	3.170	0.0216

Plotting these values, $c_1\left(1 + \dfrac{c_2}{2}\right) = 1.735$ for $y = 0.02$ ft (see Fig. 12). On the other hand, for $y = 0.40$ ft, which would correspond to a movement approaching the upper, practical limit, the term, $c_1\left(1 + \dfrac{c_2}{2}\right) = 3.45$, which would indicate an angle of internal friction, $\phi = 59$ degrees.

FIG. 13.

Introducing $m = 2$ in Equation (27),

$$e_p = \left\{ \left(\gamma\, \xi_o - 23 \sqrt[10]{y}\right) + \frac{n_o \sqrt{y}}{2 \sqrt{b_o}} \right\} (z - h) \ldots\ldots\ldots (42)$$

which means that for a constant value of y the distribution of the specific, passive resistance becomes linear. The term in the bracket corresponds to $\lambda_p = \gamma \tan^2 \left(45 + \frac{\phi}{2}\right)$, and ϕ, which is now independent of z, could be determined as soon as n_o and b_o are obtained from tests.

It is evident from the foregoing that the friction between the sand and the wall, which in practice is always present to a greater or less degree, is responsible for most of the complexities in the phenomenon of passive resistance.

POSSIBLE STRESS DISTRIBUTION IN PASSIVE PRISM FOR $\delta \neq 0$ AND EQUATION OF SURFACE OF RUPTURE

Assuming a parallelopipedon (Fig. 13), acted upon by both normal and tangential forces, the conditions of equilibrium may be expressed as follows:

$$\frac{-\partial \sigma_z}{\partial \eta} + \frac{\partial \tau_\eta}{\partial z} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

$$\frac{-\partial \sigma_\eta}{\partial z} + \frac{\partial \tau_z}{\partial \eta} + \gamma = 0 \ldots\ldots\ldots\ldots\ldots\ldots (44)$$

and,

$$\tau_\eta + \tau_z = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

For the shear stress, τ_z,

$$\tau_z\, dz = e_p \tan \delta\, dz \ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

or,

$$\tau_z = e_p \tan \delta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

in which, $\tan \delta = f_1 (z)$. Then, $\frac{\partial \tau_z}{\partial \eta} = 0$; and, because $\sigma_\eta = \gamma (z - h)$:

$$\frac{\partial \sigma_\eta}{\partial z} = \gamma \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

which satisfies Equation (44).

From Equations (43) and (45):

$$\frac{\partial \sigma_z}{\partial \eta} = \frac{\partial \tau_\eta}{\partial z} = -\left\{ \frac{de_p}{dz} \tan \delta + e_p \frac{d(\tan \delta)}{dz} \right\} = -f_2 (z)$$

Integrating: $\sigma_z = -f_2 (z) [\eta]_0^{(\eta o)} + C.$

Factor $\eta = 0$ when $\sigma_z = e_p$; therefore, $C = e_p$ and,

$$\sigma_z = -f_2 (z) [\eta]_0^{(\eta o)} + e_p \ldots\ldots\ldots\ldots\ldots\ldots\ldots (49)$$

The unit stresses then are:

$$\sigma_z = e_p - f_2(z)\,[\eta]_{0}^{(\eta o)} \quad \dots\dots(50)$$

$$\sigma_\eta = \gamma\,(z - h) \quad \dots\dots(51)$$

and,

$$\tau_\eta = -\,\tau_z = e_p \tan\delta = \pm\,\tau \quad \dots\dots(52)$$

The principal normal stresses are:

$$\sigma_{\text{max.}} = \frac{\sigma_\eta + \sigma_z}{2} + \tfrac{1}{2}\sqrt{4\,\tau^2 + (\sigma_\eta - \sigma_z)^2} \quad \dots\dots(53)$$

and,

$$\sigma_{\text{min.}} = \frac{\sigma_\eta + \sigma_z}{2} - \tfrac{1}{2}\sqrt{4\,\tau^2 + (\sigma_\eta - \sigma_z)^2} \quad \dots\dots(54)$$

The direction of these principal stresses follows from,

$$\tan 2\alpha_1 = \frac{2\,e_p \tan\delta}{e_p - f_2(z)\,[\eta]_{0}^{(\eta o)} - \gamma\,(z - h)} \quad \dots\dots(55)$$

The principal shear stresses are.

$$\tau_{\text{max.}} = +\,\tfrac{1}{2}\sqrt{4\,\tau^2 + (\sigma_\eta - \sigma_z)^2}$$

and,

$$\tau_{\text{min.}} = -\,\tfrac{1}{2}\sqrt{4\,\tau^2 + (\sigma_\eta - \sigma_z)^2}$$

and the direction in which they occur follows from:

$$\tan 2\alpha_2 = \frac{\gamma\,(z - h) - e_p + f_2(z)\,[\eta]_{0}^{(\eta o)}}{2\,e_p \tan\delta} \quad \dots\dots(56)$$

From the condition that the slope of the surface of rupture and the direction of maximum shear must coincide:

$$\tan 2\alpha_2 = \tan 2\,(90 - \epsilon) - \frac{2\,\dfrac{dz}{d\eta}}{1 - \left(\dfrac{dz}{d\eta}\right)^2} \quad \dots\dots(57)$$

and a differential equation of the surface of rupture is obtained as follows:

$$+\left[\left(\frac{d\eta}{dz}\right)^2 - 1\right]\left[\,\gamma\,(z - h) - e_p + f_2(z)\,\eta\,\right] - \frac{4\,d\eta}{dz}\,e_p \tan\delta = 0 \quad ..(58)$$

The writer is not aware of a general solution of Equation (58). Using $\tan\delta$ = constant as a first approximation, Equation (56) gives plausible values of α_2 except near the ground surface.

The surface of rupture could be expressed satisfactorily by an hyperbolic spiral with its polar axis inclined under an angle of $45 - \dfrac{\phi}{2}$ to the horizontal and its pole in front of and above the bottom of the wall. The normal distance of the polar axis from the foot of the wall would then be a function of the wall friction and, for a frictionless wall ($\tan \delta = 0$), this distance would be zero.

Dr. Alfred Streck derives[12] an equation for E_p which is based on the curved shape of a surface of rupture in its lower part and on friction between the sand and the wall. The upper part of the surface of rupture, based on observation, is assumed to be straight, and the dividing point between the straight and the curved part is found by drawing a straight line at an angle of $45 - \frac{\phi}{2}$ to the horizontal, through the top of the wall. The tangent to the surface of rupture at the bottom of the wall is determined by means of Winkler's stress ellipse; that is, by the relation,

$$\sin (2\beta + \delta) = \frac{\sin \delta}{\sin \phi} \quad \ldots\ldots\ldots\ldots (59)$$

in which, β = the angle between the wall and the major axis of the ellipse; δ, the angle of friction between the sand and the wall; and ϕ, the angle of internal friction of sand.

Dr. Streck shows the result of his research work in a diagram from which may be obtained the effectiveness factor, μ, if ϕ and δ are known. He also shows values of μ for $\phi = 35°$ and δ = variable, based on the assumption of a plane surface of rupture to the effect that such an assumption is not on the side of safety, particularly for $\delta > 15$ degrees.

Up to $\delta = 15°$ the maximum error is about 12%; that is, $\mu = 5.50$ for a curved surface and 6.20 for a plane surface. The passive resistance for a wall of a height, h, then is: $E_p = \frac{1}{2}\,\gamma\,\mu\,h^2$.

THE DESIGN OF BULKHEADS, A STATICALLY INDETERMINATE PROBLEM

Despite the refinements suggested by Brennecke-Lohmeyer, as previously described, the present theory of bulkhead design is defective in assuming passive resistance to be static. In other words, it is based on the assumption that soil with a certain characteristic offers a fixed passive resistance, irrespective of the movement of the wall.

The fallacy of this premise becomes quite evident if two sheet-pile walls are compared, having equal lengths and widths above and below ground, the section moduli of which are considerably different and are driven in exactly the same soil.

According to the present method of design, the elastic lines of the two walls will differ due to the different section moduli only, and the passive resistance will remain constant. The only adjustment required to satisfy this condition is in changing the polar distance of the D-polygon by the ratio of the two section moduli. However, from the foregoing, it is evident that passive resistance is a function of both horizontal movement and depth and that it varies much more with the former than with the latter.

---

[12] "Beitrag zur Frage des Erdwiderstandes," von Alfred Streck, *Der Bauingenieur*, 1926, Hefte 1 und 2.

The differential equation of the elastic line below the original ground surface for a triangular active load is:

$$EI\,\frac{d^4y}{dz^4} = \lambda_a\,(z-h) - \frac{n\sqrt{y}}{2\sqrt{b}}\,(z-h)^{0.5m} = a - p \;\ldots\ldots(60)$$

the solution of which is very involved indeed. The only boundary conditions known are $y = 0$ and $\frac{dy}{dz} = 0$ for $z = \infty$. The elastic line thus is comparable with a wave which is gradually diminishing as the depth below the ground increases.

Statically, a sheet-pile bulkhead is a beam, simply supported at or near the upper end and on an infinite number of elastic supports below the ground surface.

If y_0 denotes the yield of the soil at a depth, $z - h$, due to a unit load, then the yield due to a load, p, is $y_0 p$, and if the lengthening of the tie-rod due to a unit force is C_0, then the lengthening due to a force, A_0, is $C_0\,A_0$. The yield, y_0, follows from $e_p = 1$; namely, from Equation (28),

$$y_0 = \frac{4\,b}{n^2\,(z-h)^m} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(61)$$

and,

$$C_0 = \frac{L}{EA} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(62)$$

in which, L = the length of the tie-rod; and, A, the cross-sectional area of the rod. As these forces grow from zero to their full value during deformation, the general equation of the total work of deformation, or the stored-up energy per linear width of wall is:

$$A = \tfrac{1}{2}\,C_0\,A^2_0 + \tfrac{1}{2}\int_h^\infty \tfrac{1}{3}\,y_0\,p^3\,dz + \int_0^\infty \tfrac{1}{2}\,\frac{M^2}{EI}\,dz \;\ldots\ldots\ldots(63)$$

in which,

$$M = A_0\,z - \int_{x=0}^{x=h} a\,(z-x)\,dx + \int_{x=h}^{x=z} p\,(z-x)\,dx \;\ldots\ldots(64)$$

and a = the active pressure. As the amplitude of the wave, representing the elastic line, diminishes rapidly below the ground surface, the boundary conditions, $y = 0$ and $\frac{dy}{dz} = 0$, will be satisfied closely enough for practical purposes at a depth, $z = H$, and Equation (63) becomes finite.

For equilibrium:

$$A_0 - \int_0^h a\,dz + \int_h^H p\,dz = 0 \;\ldots\ldots\ldots\ldots\ldots\ldots(65)$$

and,

$$-\int_0^h a\,z\,dz + \int_h^H p\,z\,dz = 0 \ldots\ldots\ldots\ldots\ldots\ldots(66)$$

FIG. 14.

The problem must be divided into the part above and the part below the ground. If p is positive, it denotes passive resistance on the passive side, and if it is negative it denotes passive resistance on the active side. Factor a is a given function of z.

Introducing Equations (64) and (65) into Equation (63), differentiating by p, and making $\frac{dA}{dp} = 0$, satisfies the condition that the statically indeterminate forces must make the work of deformation a minimum. The solution then consists in assuming p as a function of z and in varying it until all conditions are satisfied, which is a tedious task indeed.

An exact analytical solution is impossible if the active loading is not a steady function of z, which is often the case due: (*a*) To the influence of hydrostatic pressure; (*b*) to the influence of non-uniform material; or, (*c*) to the influence of fill above a relieving platform (see Fig. 7).

On the other hand, a graphical solution hereafter presented is always possible regardless of the load distribution. In this graphical method of analysis,

$$e_p = \frac{n\sqrt{y}}{2\sqrt{b}} (z - h)^{0.5m} \qquad \text{.....................(67)}$$

is used instead of $e_p = \lambda_p (z - h)$. It is best explained by means of an example, as shown in Fig. 14, in which it is applied to the test bulkhead. The active loading is the same as before and so is the method of determining the moment line due to active loads above the ground surface. To base the analysis as closely as possible on the actual conditions, the top 6 in. of the resisting ground was not included, due to the fact that during the test the corresponding material had to be removed for the purpose of reading deflections of the bottom indicator rods. Full active pressure then extends to 6 in. below the ground surface.

A line of closure is then assumed, which fixes the distance, x_0, below the ground surface. In this connection it may be said that due to the true distribution of passive resistance (Fig. 11), the distance, x_0, for the ground with an angle of internal friction of 30°, or more, is smaller than would follow if it was based on $e_p = \lambda_p (z - h)$, and, in the case of a wall fixed at the bottom, $x_0 \leqq 0.05\,h$.

Next, the elastic line is drawn for the simple beam with the span, $h + x_0$, in the same manner as previously described. The horizontal distances between this line and Line *A–B* are the horizontal deflections of the simple beam.

The ground is then divided in horizontal strips, for convenience, 1 ft in height, and the distance, *B–C*, is assumed, which determines the yield of the ground and with it the passive resistance between this point and the surface.

The corresponding force assumed to apply at the center of the first 1-ft strip is found from a diagram (Fig. 15), showing a relation of e_p as a function of z and y and by plotting the differential force, $\lambda_a - e_p$, in the force polygon, a new ray is obtained for the extension of the moment line. In turn, the increment of D thereby determined is plotted in the D-polygon, and the corresponding ray serves to extend the elastic line to the center of the next strip below. This procedure is repeated until the moment diagram is closed.

Two or three trials may be required; that is, two or three assumptions of x_0 and the distance, B–C, may have to be made, to close the moment diagram. However, an erroneous assumption will promptly be detected without the necessity of carrying the moment or the elastic line down very far.

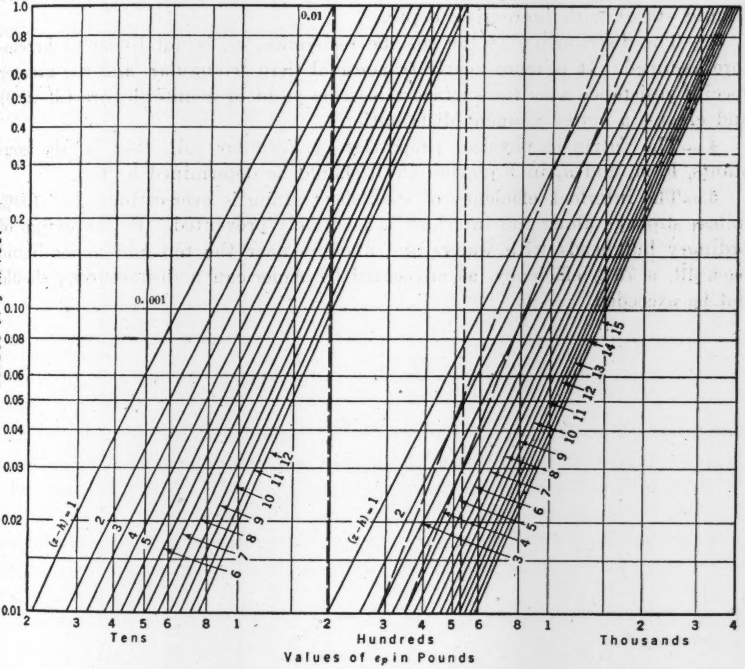

FIG. 15.—RELATION BETWEEN e_p AND y FOR CORRESPONDING VALUES OF $z - h$

As to the example (Fig. 13), it was necessary to apply a factor of 2.50 to the values of e_p to establish equilibrium. If the writer was correct in interpreting the test results of Professor Franzius as being due to a width of wall of 6.6 ft (2 m) rather than of unit width, this would mean that the passive resistance, e_p, of the hydraulic fill in the Outer Harbor at Long Beach, which was about one year old, was as much as 400% of the fill as used in the laboratory tests; but should the test results refer to a unit width, the hydraulic fill would then be about twice as effective as the laboratory fill, and the latter would compare closely with the former without wall friction.

It is interesting to note that the top reaction, A_0, as determined by this new method of analysis, checks the one obtained from extensometer readings on the tie-rods within 1 per cent.

CONCLUSIONS

From the foregoing studies, the following conclusions can be drawn:

1.—The angle of internal friction, ϕ, of granular soil resisting the pressure of a rough wall, and the angle of friction, δ, between the wall and the soil decrease with the depth and increase with the path of the wall.

2.—The angle, ϕ, approaches 90° at the surface (solid state) and zero (liquid state) with increasing depth.

3.—The distribution of the specific resistance, e_p, is not linear as heretofore assumed. It is more nearly trapezoidal than triangular, and the greater specific resistance near the surface raises the point of counterflexure ($M = 0$) and creates a better moment distribution.

4.—The intrinsic physical properties of granular soil, that is, the constants, b, m, and n, in Equation (27), should be determined by test.

5.—The interlock efficiency of steel sheet-piling is over-estimated at 100% unless slippage along the interlock is positively prevented. In the design of ordinary bulkheads with walers and anchors near the top and a non-liquid back-fill, a 75% efficiency, as advocated by American manufacturers, should not be exceeded.

DISCUSSION

JACOB FELD,[13] M. AM. SOC. C. E. (by letter).—Because of the omission of a list of symbols and definitions, this paper is difficult to read and, therefore, much of its value will never be brought to the attention of many engineers who would profit by a careful study of Mr. Baumann's methods of analysis. Furthermore, it would be easier to follow the author's mathematics if the source of the equations were given.

The object of the paper is threefold—and the writer's opinion of each section, in summary, is as follows:

1.—The description of tests made to determine effective passive resistance of sand and of interlock efficiency of sheet-piling is so detailed, for a clear description, that even a re-reading leaves one without a picture of what was intended or what was determined. The results obtained are open to serious criticism, as described more fully hereafter.

2.—The suggestion of a possible stress distribution in the passive prism (or soil-volume resisting pressure) in as far as it applies to the particular problem of the failure of certain sheet-piling at Long Beach, Calif., is based on the results of the tests, and is so full of additional assumptions, that it is not convincing. In so far as it deals with the general problem, keeping in mind the assumptions made, it is a real contribution to the study of soil mechanics.

3.—The new theory of the stability of bulkheads is an ingenious mathematical analysis.

A test is described in which deformations of seven interlocked sheet-piles, embedded 12 ft in sand and acted upon by a hydrostratic pressure of 15 ft of water, were measured. The set of sheets is described as free to deflect without restraint from the side walls of the bin holding the water. The walls of the bin also consisted of sheet-piles driven to the same depth as the test sheets. The purpose of the test was to simulate the condition of a sheet-pile bulkhead which had failed.

There can be no question as to the total value of the acting pressure, on all the sheets. However, the proximity of the rear of the bin to the tested face (about 5 ft), seriously affected the capacity of the soil to resist pressure. This was most serious near the side walls, where these walls, also acted upon by the water pressure, caused resisting stresses in the soil which was supposed to sustain the test piles. As a result, the end piles were forced to throw part of their load toward the center piles which, in addition, were not provided with a full passive prism. An inspection of Fig. 6 showing permanent deformation in the test sheets certainly bears out the foregoing statements. The loads taken by the various sheets were not equal. The analyst makes the assumption that each sheet sustained the same acting pressure. When a permanent deformation of about 2.5 in. remains after a measured maximum deformation of 4.16 in., one wonders what right the author has to use the elastic stress relation to convert strains into stress.

---

[13] Cons. Engr., New York, N. Y.

Some data for the evaluation of the parameters, unit weight, and internal friction required for the interpretation, are listed. However, the following assumptions are made in converting the measured deflections of the sheet-piling to a diagram showing the amount and sign of the pressures acting on the sheet-pile for its full height (Fig. 5):

(*a*) The angle of internal friction equals the angle of natural slope. Some difficulty was found in measuring even the angle of natural slope in the immersed or saturated state, and no attempt was made to determine the coefficient of internal friction.

(*b*) The weight of the average sand was 85 lb per cu ft with 15 to 20% moisture by weight. The great range of values in Table 1 shows a non-homogeneous fill.

(*c*) The angle of internal friction was assumed to be 30° under water.

(*d*) The active pressure of the soil inside the sheet-pile enclosure was assumed to vary parabolically; the active pressure is assumed to act at the same time as passive resistance (see Fig. 5). If the soil was saturated throughout the test, there is no question as to the amount or variation of active pressure, except as the bin action of the enclosure affects the pressure of the sand; the water pressure is definite. Active pressure and passive resistance may act on the same sheet on opposite sides, but not on the same side. The latter is equivalent to assuming motion of the sheet in two opposite directions at the same time.

(*e*) No attempt was made to evaluate the effect of water seeping from the bottom of the test bin.

(*f*) Deflections were computed for several values of a multiplier inserted into the Coulomb formula for passive resistance, and the curves were plotted. A value of 1.68 for the multiplier is arrived at, because that deflection curve, plotted for the full depth of the sheet-pile (27 ft), is considered nearest the deflection curve plotted from the observed deflections. Since the measured deflections were for the top 15 ft only, and the amount of deflections measured is about twice that computed, the real reason for this choice of factor is far from self-evident.

(*g*) Following a discussion of different assumptions as to the maximum value of passive resistance in front of, and in back of, the test wall, and the effect of wall friction and wall deformation on these values, there appears the statement (see, "Method of Graphic Analysis"): "As to the test under consideration, the passive resistance behind the wall was assumed to be 70% or less of the passive resistance in front, because the surcharge was water." Since there was no surcharge in front, why the reduction? A reduction was required for the effect of the rear wall, not for lack of earth surcharge.

The results of the test analysis are next applied to a proof that the sheet-piling bulkhead which failed should have failed. In addition to the foregoing assumptions, it should be pointed out that the bulkhead had a concrete relieving platform resting on timber piles (assumed by the author to take one-third the active earth pressure); and that the "effectiveness ratio" or multiplier of the Coulomb formula equals 2. A method of trial wedges is used to determine the wedge of minimum resistance, assuming such wedge to start at the bottom of the sheet-piling (Fig. 7). If this assumption is true, there cannot be a balancing force at the heel of the pile, and equilibrium cannot exist. The writer cannot see any justification for applying the results of the test to the analysis of the bulkhead; nor is the computed maximum deflection of 4.13 in. convincing. With a yield point of 45 782 lb per sq in., and a maximum stress of 30 000 lb per sq in., there should not be a large amount of permanent set; and, yet, the author states that the shape of the sheets pulled at the bulkhead that had failed agreed with that of the test sheets (Fig. 6) and these had a permanent set of 2.5 in. after a maximum deflection of 4.16 in.

The "Analytical Determination of Interlock Efficiency" is based on approximating a curve the equation of which is known, to the plotted shape of the test piles. The results are subject to the same criticism as that which applies to the test. In addition, the method used is only applicable to deformations within elastic limits, and the measured deformations certainly exceeded that limit.

The suggested theory of stability is a good form of attack on the problem. However, the author fails to point out that it only applies within very small limits, practically within elastic deformations of the soil structure. In stating that: "In the foregoing, * * * earth was treated like a fluid of smaller or greater unit weight than earth for active and passive resistance, respectively," the author falls into an improper use of the word "fluid." A fundamental law of fluids can be re-worded into the requirement that at all depths active pressure is equal and opposite to the passive resistance to pressure.

Before accepting the author's formulas quantitatively, the assumptions must be further checked by experiment. Equation (16) involves the assumption that the passive resistance to pressure varies inversely with an indefinite power of the depth and with the square root of the deflection. Equation (18) shows a relation from which the unknowns may be determined if the lateral resistance at various movements can be measured. However, the value at zero movement must first be measured, this being called the active pressure. The writer is convinced that at zero movement there is no method for measuring the pressure, either active or passive.

Before using the results obtained by Franzius, it should be carefully noted that the wall used in his tests was moved laterally against the soil, that the maximum pressure did not occur at the beginning of movement, but only after the body of the fill was crushed. Such complete lateral movement does not occur in the case of sheet-piling. When the wall is pushed into the fill, the total resistance measured is the sum of (*a*) the passive resistance of the earth to pressure; (*b*) the resistance to the crushing of adjacent grains; and (*c*) the resistance caused by physical displacement.

If no friction exists along the wall (a hypothetical case) the last item disappears, because the soil mass merely adjusts itself by moving upward, just as a liquid would. If friction does exist, a resistance greater than the Coulomb formula would indicate, is measured. Incidentally, the Coulomb formula does not involve the assumption that the amount of movement is large enough to induce any resistance except the passive resistance of the weight of that mass in back of the wall which will give the minimum resistance.

For the benefit of those who do not have ready access to the original papers by Franzius, a summary of results obtained have been made available[14] by the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E. The conclusions listed in Mr. Freeman's book do not agree with some of the assumptions made in this paper.

The writer cannot see how Equation (25) is derived. For deformations within elastic bounds, a term containing the tenth root of the deformation certainly cannot be very considerable in magnitude.

Following Equation (33) the author states that his analysis shows a decrease in the coefficients of internal friction and of friction between sand and wall, with an increase in depth and an increase in wall movement, and also refers to the writer's experiments,[15] for qualitative agreement. Before completing this discussion, the writer tried to find such agreement in his own report and found just the opposite. In his experimental work he found no appreciable variation in either coefficient with either depth or amount of wall movement. Experimental work on the variation of the coefficient of internal friction with applied load has consistently shown no relationship.

The writer agrees that the friction along the wall is responsible for most of the complexities in the phenomenon of passive resistance (see text following Equation (42)). A clearer picture can perhaps be drawn by considering the resistance prism as being acted upon by a drag equal to the friction along the wall. This drag is dissipated through the fill, and causes a curvature in the surface of the rupture.

In view of the foregoing remarks, the writer cannot agree with the conclusions of the paper.

R. L. VAUGHN,[16] M. AM. SOC. C. E. (by letter).—The treatment given in Fig. 7 represents an advanced method of analyzing a bulkhead, which takes into account the restraining action of the ground and the relieving action of the piles back of the bulkhead. It recognizes, as well, the fact that the passive resistance of the soil will be some value greater than that given by the unmodified Coulomb formula. The author himself states that the theory upon which this investigation is based is defective, and devotes much of the remainder of the paper to a demonstration of how hopelessly involved the discussion becomes when an effort is made to develop a better theory.

This is an excellent paper, giving the results of painstaking research and investigation; it presents much information not heretofore generally available in the English language. The writer has found some parts of the mathematical treatment confusing and difficult to follow, and ventures to suggest that the addition of a table of notation would be an improvement.

[14] "Hydraulic Laboratory Practice," by John R. Freeman, pp. 599–603.

[15] *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1448.

[16] San Francisco, Calif.

Perhaps a discussion of a theory of design should not be extended to include a scrutiny of the assumptions as to facts, but most engineers will agree that in any design such assumptions should conform to reasonable expectations. The author presents Fig. 7 as an analysis of the bulkhead at Long Beach, Calif. It becomes in order, therefore, to comment on the asserted physical conditions there shown, as well as to review the admitted defects in theory.

While it is generally referred to as the Coulomb formula, it is understood that the expression, $p = w \tan^2 (45° - \frac{1}{2} \phi)$, is not the exact form originally developed by Coulomb. For many years, however, this formula has been the basis for most discussions concerning earth pressures. The symbol, ϕ, was originally used to designate the angle of repose of a cohesionless granular material, and it has been so utilized in many standard texts. Numerous tables of angles of repose of various materials have been published. However, when materials are not cohesionless the term, "angle of repose," becomes meaningless, since the surfaces they will assume, will not be planes and will vary with the height of bank being observed. It has long been recognized that ϕ should be regarded as the angle of internal resistance rather than as the angle of repose. When the internal unit resistance or shear was considered to be the sum of the true friction plus a constant due to cohesion, it was possible to form a conception of ϕ by considering that it was that angle the tangent of which was the shear divided by the normal pressure. At present, it is recognized: (1) That the friction in a given material may not be constant for different depths; (2) that the cohesion varies with the moisture content and probably with the pressure; (3) that the surface of rupture is not a plane, but is dependent on the values of cohesion and friction; and (4) that, in addition to being dependent upon other things, the horizontal pressure against a wall is also some function of the motion of the wall. Recent mathematical discussions have attempted to take all these factors into account and still retain ϕ. Under these circumstances it is difficult to form any conception of ϕ, and certainly it is far from being the angle of repose. The best definition for this angle at present would be that angle which, when used in the Coulomb formula, will give the correct answer. It is suggested that confusion would be avoided if ϕ was reserved for its original meaning and if some other symbol was used in modern formulas.

The method followed by the author to determine the value of ϕ is open to two objections. It has never been proved that the surface angle of repose has any direct relation to the internal pressure, and there is no reason to think that surfaces of repose of samples 6 in. or 1 ft high will be the same as the angle of repose for a bank 20 ft high.

Permanent deformations exhibited by the piling from the test wall indicate that there must have been a considerable degree of restraint at the corners of the tank. This restraint could not be attributed to the copper seals, which appear to have sufficient flexibility, and must have been due to an arching action against the unloaded ground each side of that against which pressure was directly exerted. Any such restraint would cause the wall to appear stiffer than was actually the case and would result in a correspondingly high computed value of the interlock efficiency. This circumstance, together with the fact that the curve assumed by the piling below the surface of the ground must be estimated, would tend to cast some doubt on the experimental determination of the interlock efficiency and also on that of the passive resistance. A further uncertainty is introduced through the arbitrary assumption of the relation between the passive resistance back of the wall and the same resistance in front of the wall.

After having derived a value for the passive resistance in the test case by a process involving assumptions as to the passive resistance back of the wall, assumptions as to the water pressure in the ground, both in front of and back of the wall, and a derived value of the stiffness of the sheet-piling, the author then derives from the passive resistance thus obtained an "effectiveness factor" to be applied to the Coulomb formula. Aside from the question as to whether or not the passive resistance in the test case has been correctly determined, and aside from the question of using for ϕ values obtained from observations on the surfaces of small samples, the writer knows of no warrant that the same or any other effectiveness factor would be proper for the conditions shown in Fig. 7. If the observations have been made with any approach to accuracy, there must be something wrong about a theory that culminates in a formula the answer to which must be multiplied by a factor of 1.68 or by 2 in order to get the correct result.

Leading authorities now agree that one fault with the Coulomb formula lies in its neglect to include the effect of friction against the face of the bulkhead. This friction only becomes effective apparently when there is an appreciable movement of the wall outward. Equations (16) to (58), inclusive, are presented to show the effect of such friction and, in them, the rather new theory is introduced that ϕ is a function of the displacement of the wall.

That the Coulomb formula, with the addition of an "effectiveness factor" may give questionable results, is evident from the author's actual application of it in Fig. 7. From tests on an experimental box, as described in the paper, it was determined that the effectiveness factor should be 1.68 for this material when it had been deposited in a fill, and for the (assumedly) undisturbed material in the toe slopes it was estimated that a factor of 2 would be suitable. Using that factor, a passive resistance of 20 400 lb per lin ft of wall is obtained for the toe slope at Berth 3. Where the "net passive resistance" of 13 400 lb (referred to in the summary of findings preceding Equation (2)) came from, is not clear, but the former value is the one given in Fig. 7. A rough check on the credibility of this quantity may be obtained by considering resistance against sliding along a plane joining the bottom of the sheet-piles to the nearest point in the bottom of the channel.

The elevation of the bottom of the channel is at − 36.0 (at least, it was agreed on this work to pay for excavation to that depth). The elevation of the bottom of the sheet-piles is at − 38.75; the difference in elevation between the two points is, therefore, 2.75 ft. The horizontal distance between points is 32.5 ft, and the slope is, therefore, 2.75 ÷ 32.5 = 0.0847. Using the author's value of 52 lb per cu ft for the weight of the material, submerged, a simple calculation shows that the submerged weight of 1 lin ft of the ideal toe slope at this point is 14 600 lb. Since the prism must be shoved up an adverse grade, the actual weight should be multiplied by the factor, 1.0847, giving an effective weight against sliding of 15 835 lb. Now, if the author's value for the passive resistance of this prism is correct, the coefficient of this material against sliding on itself must be 20 400 ÷ 15 835 = 1.29. In the construction of hydraulic-fill dams a coefficient of 0.35 is considered safe, although observations have shown that, at times, the coefficient may reach a value of as much as 0.75. Any conclusion to the effect that a fine sand saturated with water can oppose a resistance to sliding equal to one and one-quarter times its own weight seems neither conservative nor reliable.

The author states that American manufacturers advocate the use of 75% of the interlocked section modulus for steel sheet-piles. As far as the writer has been able to learn no such recommendation has been made by American manufacturers except with the qualification that, if such a modulus is to be used, some positive means to prevent slipping along the interlock must be adopted before any load is applied against the piling.

To sum up the objections to the theory upon which the analysis given in Fig. 7 is based: It is assumed that ϕ is a constant and equal to the observed angle of a small sample, whereas there is reason to believe that neither assumption is true. It is assumed that the surface of rupture is a plane, whereas it is generally admitted that such will not be the case. The method takes no cognizance of the effects of friction on the piling. The manner in which the passive resistance is obtained gives a result which, for this class of material, is almost impossibly high. The use of an interlocked section modulus is questionable in the absence of definite and positive means for preventing slippage along the interlock. The author points out many of these objections in his paper.

Turning now to the assumptions of fact. These are two in number: (1) The assumption that the toe slopes would be undisturbed and should retain their theoretical dimensions; and (2) the assumption that the elevation of the water back of the wall would be + 3.5, which is practically mean sea level.

The author states that the toe slopes had been undercut and that in view of the importance of the slopes this was a dangerous procedure. The dredging was conducted in the only practicable manner by which the required channel could be excavated with a cutter type of pipe-line dredge. On the other hand, the design was seriously defective in that the bulkhead had been placed within 32.5 ft of a channel 36.0 ft deep, and that the maximum penetration of the piling was only 2.75 ft below the contract depth in the channel. Especially in view of the unstable and easily erodible character of the material at Long Beach it is not too much to state that any method of excavation would have been dangerous under the circumstances.

The manner in which an hydraulic dredge excavates is not widely known outside of dredging circles and some description is necessary. The entire machine is rotated bodily about a fixed point at the stern, while on successive swings the cutter is lowered to suitable depths, thus removing the material in horizontal layers. There is no method of control by which the depth can be varied with any degree of accuracy as the dredger swings from side to side; that is, the cutter cannot be slid down or up a slope. A floating machine, more than 200 ft long, weighing several thousand tons, controlled by wires, and often operating in rough water, cannot be manipulated with extreme precision; but it is unquestionable that, by a proper adjustment of the width of swing to the depth of cutter, the latter could be placed within a very few feet of the theoretical side-slope line on each swing. At first sight, it would be reasonable to believe that in this manner a practically perfect side slope could be excavated.

However, while the dredge can be swung to any desired width sidewise, it cannot be moved ahead, and as the cutter is lowered on successive swings a nearly vertical bank, circular in plan, is left ahead of the machine. If the material would stand in such a vertical bank until the dredge could be advanced to a position for the next series of swings, there would be no difficulty. Almost invariably, however, the bank will cave down suddenly in a large mass when the cutter has reached some point near the bottom of the cut. Much of this material will fall into a position back of the path of the cutter and cannot be reached. Likewise, some of the material will fall on to the side slopes which have just been formed, will tear loose more or less of the material which has been left there and, with that addition, will also slide down into the cut and come to rest at some point where it cannot be reached. For this reason it is usually found that if an attempt is made to dig the side slopes exactly to line, the result will be a large and unexpected amount of apparent over-dredging there. If the width of swing is narrowed in an attempt to let the material take its own slope, temporarily the slopes will stand at an unnaturally steep angle, only to cave down later and shoal up the channel after the dredge has passed.

One method of overcoming the effect of caving would be to traverse the entire length of channel repeatedly, removing one layer of material at each trip. The ordinary pipe-line dredge is not adapted to such an operation and if it were attempted the output would be greatly reduced and the cost of dredging would be correspondingly increased. No owner would be willing to meet the increased cost and no contractor who contemplated this procedure would ever get any work.

On the other hand, if an attempt is made to finish the channel on the first trip an excessive amount of over-dredging on both sides and bottom is required, as, otherwise, shoaling will occur, which will necessitate a clean-up operation. Consequently, a compromise is reached.

At least one clean-up trip cannot be avoided (except where the cuts are very light) and, therefore, it is just as well to leave enough material to be worth while on the second trip. On the first passage the dredge is swung out over the side slopes and most of the material above the slope line is removed. This operation is necessarily in a series of steps which will be partly above and partly below the slope line. An effort is made to proportion the steps so that the material which remains above the slope line, plus whatever is expected to cave from the bank ahead, will just about fill the holes below the slope line. No effort is made to bring the bottom down to grade; about 4 or 5 ft of material is left for the clean-up.

On the clean-up trip no further dredging is done on the side slopes except at the toe; in fact, the cutter is never raised more than a foot or two above the bottom at any time on this trip. Dredging along the edges of the channel will again disturb the material in the slopes and, at some delayed time, at least some additional material will slide down. If the clean-up is restricted to the specified channel any material that slides down will fall into it, shoaling it along the edges and making another clean-up necessary. It is the custom, therefore, to swing the cutter a short distance over the line in order to provide a space into which such additional materials may come to rest without encroaching into the required channel. The slopes, when of certain materials, may not reach a condition of final equilibrium for weeks or even months after the clean-up has been made. It is not possible, therefore, to determine with any degree of exactitude, by means of soundings, just how much extra width must be dug; it is necessary to guess at it. If the clean-up is carried too wide there will be much excess excavation for which no payment is received. If the swings are kept too close to the line another clean-up will be necessary. At Long Beach the records showed that, following progress surveys, it was found necessary to return and clean up various portions of the edges of the channel as often as three or four times, in order to obtain the required depth along the lines. Such operations cannot be conducted without some additional disturbance of the material in the slopes.

This stepping of the slopes and slight overcutting at the toe is the undercutting process to which the author refers. There is nothing precise about it, but it is the best that can be done. During an experience extending over a period of twenty-one years the writer has never known a job where this process, or some variation of it, was not used. In that time, he has not seen even one job on which some surplus material had not been removed from the slopes.

In view of the uncertain behavior of all earth, and in view of the unavoidable limitations of the hydraulic dredging process, it is the writer's opinion that it would be most unwise for a designer to rely upon obtaining an undisturbed side slope of specified dimensions along any channel.

Where the purpose of a bulkhead is to retain the fill back of an apron wharf, the temptation is great to place the bulkhead close to the channel line, thereby reducing the width and cost of the wharf. Observation and experience indicate that in most materials it is dangerous to depend upon the embankment above the level of the bottom of the channel for much support unless the horizontal distance between the bulkhead and the channel is at least one and one-half times the vertical distance from top of fill to bottom of channel. Even with such proportions, the field engineer should be prepared to reinforce the embankment with rock at the first sign of weakness.

The second assumption of fact has to do with the water pressure to which the wall was subjected. The method used to determine the water level would have been satisfactory if this had been merely an investigation to determine the stability of the bulkhead at the time the observations were taken, but such was not the case. This analysis was undertaken to determine whether or not the original design had been adequate. The actual water load which the bulkhead would be unavoidably called upon to resist during the construction period is far in excess of that corresponding to the assumed water level. This is the most serious error in the analysis. Even had all assumptions as to section modulus, active pressures, and passive resistances, been fully realized, the bulkhead would have failed if the fill had been placed by the hydraulic method, which is the one specified in the contract. Since, undoubtedly, unsuspected water pressures have been at the bottom of many bulkhead troubles, and since the pressures that may arise in an hydraulic fill have been but little discussed and are not widely understood, it follows that this topic is worthy of some consideration.

During the progress of the trial to which the author refers an effort was made to justify the assumed water level on the grounds that a preliminary embankment should have been placed behind the bulkhead and that this, together with the relieving platform, would have prevented any higher level against the wall. In fact, even if suitable material for the purpose had been available, the preliminary embankment would have been of only limited value in this case, while the relieving platform made things much worse instead of better.

There is a tradition in the dredging business that the best thing to do with a weak bulkhead is to pump an embankment behind it before impounding any head of water. The writer has not encountered a completely satisfactory explanation of the manner in which this procedure relieves the pressure against the bulkhead; and it appears that it may not always do so.
